Temperature	Loading	Sag below Upper Support	Sag below Lower Support	Tension
0° F. (−17.8° C.)	½ in. ice 12 lb. wind (1.27 cm. 58.5 kg/sq. m.)	318.3′ (Res.) (97. m.)	171.5′ (Res.) (52.3 m.)	33,500 lb. (15000 kg.)
32° F. 0°(C.)	½in. ice no wind (1.27 cm.)	328.3 ft. (100. m.)	142.8 ft. (45.1 m.)	27,370 lb. (12400 kg.)
−20° F. (−28.9°C.)	no ice, no wind	312.8′ (95.1 m.)	127.3′ (38.8 m.)	18,770 lb. (8500 kg.)
32° F. (0° C.)	no ice, no wind	317.5′ (96.7 m.)	132.′ 40.3 m.)	18,380 lb. (8320 kg.)
60° F. (15.6° C.)	no ice, no wind	320.′ (97.5 m.)	134.5′ 41.0 m.)	18,160 lb. (8250 kg.)
120° F. (48.9° C.)	no ice, no wind	325.′ (99.1 m.)	139.5′ (42.6 m.)	17,710 lb. (8050 kg.)

complete calculations of sags and tensions from which the values in the tabulation were derived.

5. Insulated Supports

The requirements to be met by the insulated supports for the conductors have been suggested above in the discussion with respect to the conductors. For the purpose of selecting the insulator linkages the maximum tension of the conductor was taken as 35,000 lb. (15,900 kg.) and a mechanical factor of safety of two was selected on the total linkage to be employed. The insulators

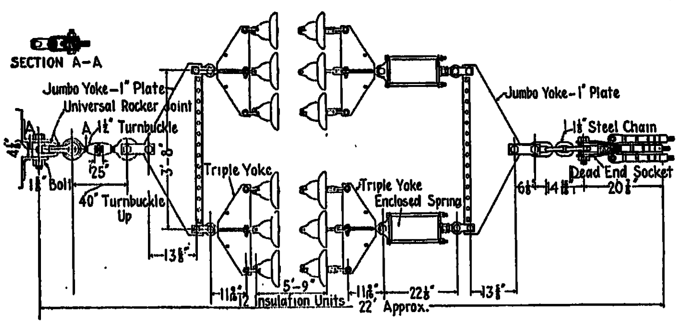

Fig. 8—Assembly of Conductor Insulating Supports for Anchor Tower

are each to be proof-tested at 12,000 lb. (5450 kg.) and to have a maximum ultimate strength of 18,000 lb. (8200 kg.) each.

a. Supports at Anchor Towers. To meet the above conditions six strings of insulator disks of this description are required per conductor at each anchor tower, these to be arranged in two groups of three strings each. The three strings of 12 disks are to be assembled with triple yokes top and bottom and two sets of triple yokes to be combined by one jumbo yoke at top and bottom. Details of this assembly are shown in Fig. 8 from which it will be noted that the over-all distance from the cross-arm to the conductors is approximately 22 ft. (6.7 m.)

The following features of interest are pointed out with respect to this arrangement. The attachment at the crossarm consists in effect of a universal joint made of two steel forgings. Motion in a vertical plane is obtained about the 1⅝-inch (4.13 cm.) diameter steel pin mounted in the crossarm clips and motion in a horizontal plane is obtained by rocker shaped surfaces on the two forgings. A turn-buckle is next provided which provides two feet of take-up. The jumbo yoke is long enough to permit proper equilization of tensions on the six strings of insulators. The holes shown in the triple yokes are for the purpose of attaching outriggers for pulling up the strings of insulators to permit of replacements. Next to the outer triple yoke is a double car spring which will be calibrated so as to show the tension on the insulator strings at any time. It is believed that these springs will also act as shock absorbers in the case of sudden movement of the conductors due to ice falling from them, etc. Next to the outer jumbo yoke are shackles and four links of heavy dredge chain. The entire structure has been designed for a maximum of flexibility and equalization of stresses over the individual insulator strings. With the exception of the steel casting covers of the car springs all metal parts even the insulator caps are made of steel forgings or plates.

The specification calls for a test of the completed assembly of three strings of insulators of 35,000 lb. (15,900 kg.) and of the completed assembly of six strings of insulators at 70,000 lb. (31,800 kg.)

The form of clamp employed at the end of the linkage for attaching to the conductors and the method of handling the conductors are also of special interest. This clamp consists of an aluminum body clamp which is compressed about the exterior of the complete steel reinforced aluminum cable by means of three compressions. The aluminum conductors are then cut off and the steel core continued into a steel Roebling bridge socket into which they are sweated with zinc. The aluminum body clamp and the steel core socket clamp are both carried by a common steel bolt 1⅝ inch (4.13 cm.) in diameter.

The details of this dead-end socket clamp are shown in Fig. 9. The aluminum body clamp contains three projections, the purposes of which are as follows. To one projection will be bolted two small aluminum body clamps attached by compression joints to two lengths of 300,000-cir. mil A. C. S. R. conductors of the type employed in the land transmission line. These two cables arranged in parallel horizontally will then be carried as the loop connection under the crossarm from

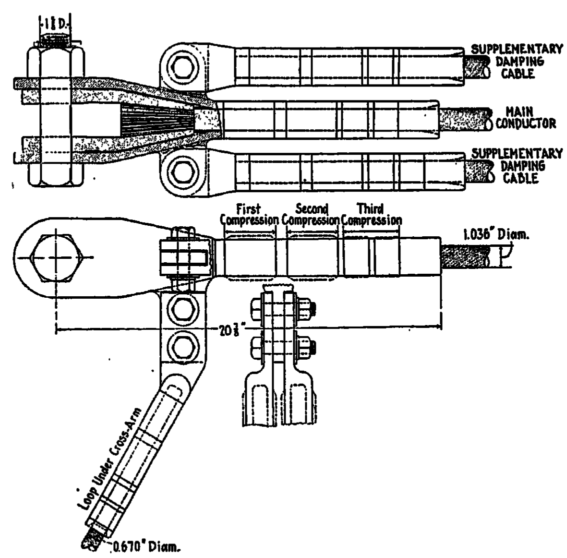

Fig. 9—Detail of Conductor Cable Socket Clamp for Anchor Towers

the river span dead end to the land span dead end. They will be clamped at five-foot intervals with three-bolt, parallel-groove aluminum clamps. The purpose of this latter arrangement is to stiffen the loop and hold to a minimum its swinging with the wind toward the tower. This precaution is of importance on account of the extreme length of these loops which will be about 45 feet (13.75 m.).

As shown in Figs. 8 and 9, there will be bolted to each of the other two projections on the main aluminum body clamp another aluminum body clamp which will be attached by compression joints to a length of supplementary 318,000-cir. mil A. C. S. R. cable which will parallel the main cable for a distance of 20 ft. at the dead end in one case and 15 ft. in the other, and be clamped to it by means of parallel-groove aluminum clamps.

As is well known, long transmission line spans involving high wire tensions are peculiarly susceptible to vibration, the laws of which are not so well known. The vibration, however, has a definite nodal point at the junction with the cable clamp resulting in a tendency for the strands of the cable to break at the point of attachment. The result of study by others of vibration in existing spans indicates that the probability of damage will be materially reduced by spreading the vibration over a number of clamps arranged in parallel, and increasing in mass as above described.

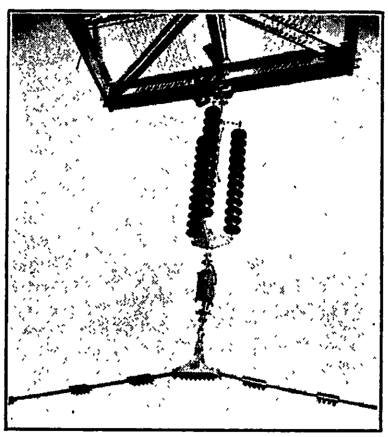

Fig. 9—(a) Conductors in Suspension Position to Intermediate Tower

b. Supports at the Intermediate Tower. As indicated in the description of the intermediate tower itself, the conductors are to be supported by insulators arranged in suspension. This arrangement is in conformity with that followed throughout the rest of the line where every effort has been made to reduce to an absolute

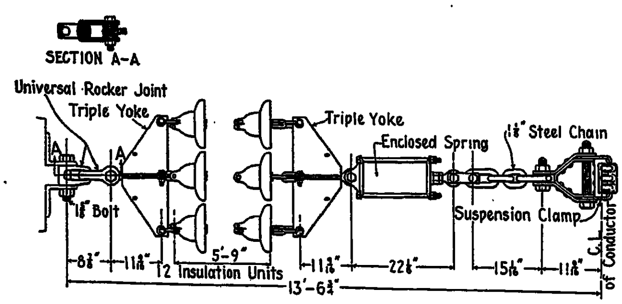

Fig. 10—Assembly of Conductor Insulating Supports for Intermediate Tower

minimum the number of dead-end insulator assemblies. In the river crossing the dead-ending of the conductors on the two terminal towers was a physical necessity. The dead-ending of these conductors was not necessary on the intermediate tower, and accordingly is not employed. In case of breakage of either span the linkage at the intermediate tower is strong enough under its normal strength characteristics to hold the remaining span without slippage. The reasoning behind this arrangement was as follows:

All records indicate that this crossing is in a region of heavy sleet loading. It was considered possible that the span between the intermediate tower and the Missouri anchor tower might be coated with ice while the east span from the intermediate tower to the Illinois anchor tower might not be so coated. This is not an unusual condition in transmission line work and follows usually from the sleet having melted and fallen from one conductor span before doing so in the adjacent span. Under such condition it was considered that if the conductors were carried on rollers or sheave wheels on the intermediate tower, the unbalanced loading of ice on the river span would cause an excessive sag in this span. To prevent just such occurrence or the reverse occurrence of the pulling down of the long land span between the intermediate tower and the Illinois terminal tower it was considered that the conductor should be definitely clamped to the insulator string at the intermediate tower.

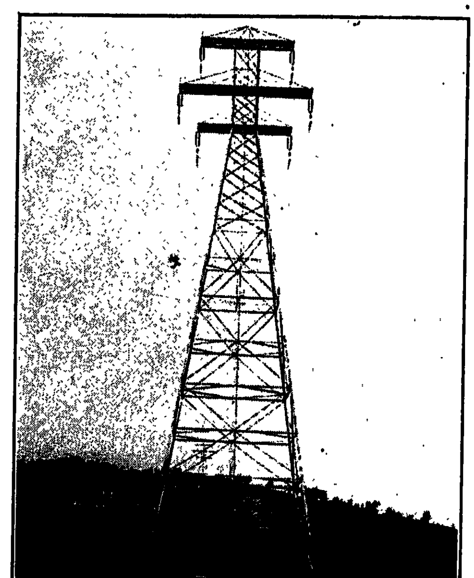

Fig. 10—(a) Intermediate Tower in Foreground; Missouri Tower in Background

Figs. 10 and 11 show the insulator and conductor clamp assembly selected. The order of assembly of the insulator strings, hardware, conductor clamp, etc., are similar to those employed on the dead-end towers, except that a single group of three strings of insulators in parallel is employed. The insulators and hardware exclusive of conductor clamp are the same as those used on the anchor towers and need no further description. The following specific features of the conductor clamp are of interest:

The conductor clamp consists of two aluminum castings bolted together about the conductor and supported

from the insulator assembly in a substantial steel saddle. The cable grooves in the aluminum clamp approximate the position the wire will take due to its normal sag. Paralleling the main conductor will be two supplementary lengths of cable of the same character as the main cable and bolted to it by means of parallel-groove clamps for distances of approximately 20 ft. and 15 ft. respectively on each side of the main supporting clamp. The use of the supplementary cables and clamps constitutes the treatment of the vibration problem in a manner similar to that used on the dead ends on the anchor towers.

For the reasons outlined above it is also considered necessary that this clamp shall prevent excessive slippage of the conductor during any unbalanced loading due either to ice or a break in the adjacent span. This is of particular importance from the standpoint of river navigation as well as of operation of the circuit. The specification requires that this clamp shall hold the cable against slippage at 35,000 lb. (15,900 kg.) tension in the event of breakage of one of the spans.

The foregoing description applies to the design of the river crossing only.

Land Transmission Line

The fundamental design factors included in the specification for the steel tower performance may be summarized as follows:

1. Arrangement of conductors for each circuit—vertical configuration with middle conductor off-set

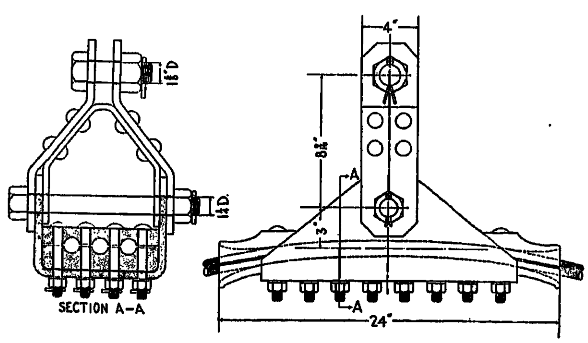

Fig. 11—Detail of Conductor Clamp for Intermediate Tower

from the tower horizontally 3 ft. (.9 m.) with respect to top and bottom conductors.

2. Minimum vertical separation between crossarms 12 ft. (3.7 m.)

3. Minimum clearance conductor to tower steel with conductor swung at angle 60 deg. from the vertical 3 ft. 6 in. (1.06 m.)

4. Number of insulators—10 per string (maximum length 4 ft. 6 5/16 in. (1.37 m.) for suspension tower; strain tower two parallel strings of 10 insulators (maximum length 6 ft. 3¾ in. (1.9 m.); anchor tower two parallel strings of 12 insulators (maximum length 7 ft. 1¼ in. (2.14 m.)

5. Average span 800 ft. (244 m.)

6. Minimum height to lowest crossarm suspension and strain towers 50 ft. (15.3 m.); anchor tower 45 ft. (13.7 m.).

7. Conductor to be employed—300,000-cir. mil A. C. S. R. 30 per cent steel.

8. Maximum tension in conductor for 800 ft. (244 m.) span under conditions 0 deg. fahr. ½ inch (1.27 cm.) ice loading and 8 lb. per sq. ft. (39 kg. per sq. m.) transverse wind pressure—6000 lb. (2725 kg.)

9. Towers to be computed on basis of 13 lb. per sq. ft. (62.5 kg. per sq. m.) wind pressure on 1½ times the exposed area of one side.

10. Maximum unit stresses in tower steel as prescribed by National Electrical Safety Code.

11. Design loading for towers—25 per cent overload over conditions stipulated for each type of tower as given in the following summary, except that crossarms are to be designed for 50 per cent overload and anchors for 50 per cent overload against uplift.

Type of Tower	Loading Conditions to be Met
I—Suspension tower 2 deg. angle	Any one wire broken with 2 deg. angle in line with wire loading as in (8) above.
II—Strain tower 15 deg. angle	Any three wires broken with 15 deg. angle in line with wire loading as in (8) above.
III—Anchor tower 30 deg. angle	Any three wires broken with 30 deg. angle in line with wire loading as in (8) above.
IV—Anchor tower no angle.	All six wires broken on one side with wire loading as in (8) above.
V—Anchor tower 90 deg. angle	All six wires broken with 90 deg. angle in line with wire loading as in (8) above.

The above requirements have resulted in four types of towers. Type *A* suspension tower will meet requirements I; type *B* strain tower will meet requirements II; type *C* anchor tower to meet requirements III and IV; Type *D* 90 deg. anchor tower to meet conditions V. The following tabulation gives a summary

TABLE III

Type	Length Top & Bottom Crossarms	Length Middle Crossarm	Height of Lowest Crossarm	Vertical Separation between Crossarms	Cross Section of Anchor	Depth Anchor Setting	Wt. of Tower Including Anchors	Spacing of Anchors
A	21 ft.	28 ft.	51 ft. 5½ in.	12 ft.	3 ft. 2 in. by 3 ft. 3⅜ in.	8 ft.	8900	16 ft.
B	26 ft. 6 in.	33 ft. 6 in.	51 ft.	13 ft. middle to top 12 ft. middle to bottom	4 ft. 1 in. by 4 ft 8 in.	9 ft. 9 in.	13475	18 ft.
C	20 ft. 6 in.	27 ft. 6 in.	45 ft.	12 ft.	5 ft. by 5 ft. 7⅛ in.	9 ft. 9 in.	13460	18 ft.
D	20 ft. 6 in.	27 ft. 6 in.	45 ft.	12 ft.	5 ft. 2 in. by 5 ft. 9 in.	11 ft. 6 in.	18610	18 ft.

of the physical dimensions and weights of these towers:

To supplement the four types of towers described, 8-, 16- and 32-foot extensions were employed to be used in some cases where obstructions required towers higher than the standard towers to obtain clearance or where the ground conditions required spans longer than the average span.

Type *A* suspension towers were used for all tangent

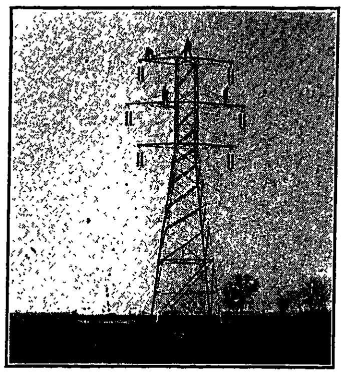

FIG. 12—PHOTOGRAPH OF STANDARD STRAIN TOWER

towers and angles not exceeding 2 deg. Type *B* strain towers were in general employed for every eighth tower position in a straight run and also as corner towers for angles up to 15 deg. Type *C* towers were used at the two terminal towers on the land line and also as corner towers for angles between 15 and 30 deg. For two 90 deg. angles in the line, type *D* towers were employed.

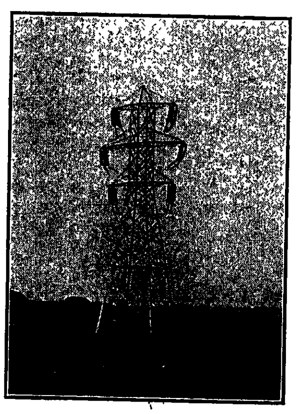

FIG. 13—PHOTOGRAPH OF STANDARD ANCHOR TOWER

Fig. 12 shows the arrangement of a standard strain tower, type *B*, as given in preceding tabulation. From the illustration it will be observed that two parallel strings of 10 insulators, each with equalizing yoke top and bottom, are used in suspension position. These two strings of insulators, together with the conductor clamp, are capable of holding the conductor in case of break in the adjacent span under a tension of 6000 lb.

Fig. 13 shows a standard anchor tower, type *C*. The foundations employed for the transmission line are the so-called earth anchors made of galvanized steel. These anchors consist of a pyramid-shaped frame work of angle iron with their bases completely closed by means of substantial angle iron. The closure was considered desirable on account of the fact that the towers were to be located on sand and silt river bottom land. The use of this type of anchor eliminates the need of transporting concrete materials and plant over the right-of-way. Bolted steel templets were designed for each type of tower and extension to facilitate the leveling of the anchors.

Fig. 14 shows, (1) A group of anchor holes where quicksand was encountered, and (2) the general nature of the anchors themselves as described above.

Fig. 15 shows a close-up view of one of these excavations. The method of handling these wet holes con-

FIG. 14—EXCAVATIONS FOR STANDARD TOWER ANCHORS SHOWING TYPE OF ANCHORS

sisted in shoring the sides of the hole with an open bottom wooden box. The hole was then pumped out by means of a portable gasoline driven pump, the boxing being driven down as the excavation progressed. The bottom was then filled with crushed rock tamped sufficiently to permit of leveling the anchors.

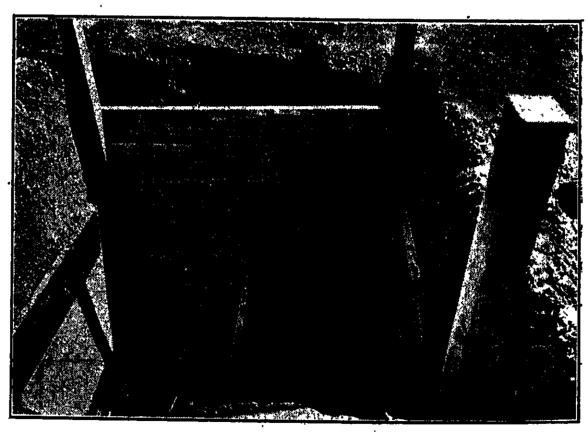

FIG. 15—EXCAVATION PROCEDURE FOR WET ANCHOR HOLES

Fig. 16 shows one of the earth anchors in place. Most of the transmission line as shown in the foregoing illustrations passes through flat bottom land. Fig. 17, however, suggests some difficult clearing work through densely wooded swamp land.

Grateful appreciation is here expressed for the suggestions and assistance received from Messrs. A. O.

Appendix

The calculation of the performance of flexible cables and wires in equilibrium for supports at equal elevations and for short spans may be approximated to the extent of employing the parabolic form of equations or any one of a number of sets of prepared tables or charts. The ordinary tranmission line range of span seldom exceeds 1200 ft. and for such spans the values calculated by such methods serve all practical purposes.

However, when the specific problem arises of a long span and the supports are so arranged as to be at unequal elevations, and when it is important that certain clearances over navigable waters must be maintained and a certain stress is not to be exceeded, the economy of design and assurance of performance require some more rigorous calculation.

The calculation of long spans with supports at unequal elevations arises infrequently, and but little has

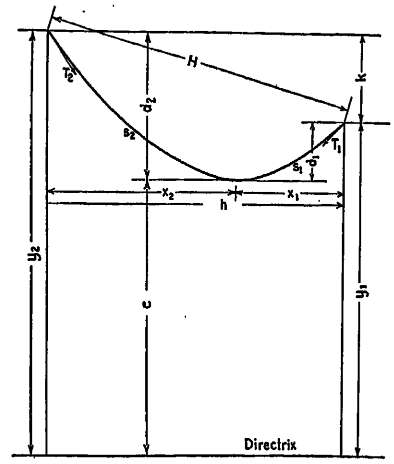

Fig. 18—Graph for Appendix

SYMBOLS

h = horizontal distance between supports.
x_1 = horizontal distance from lower support to the vertex of the catenary
x_2 = horizontal distance from the upper support to the vertex of the catenary
H = air line distance between the upper and lower supports
y_1 = the height of the lower support above the "directrix" or reference line of the catenary
y_2 = height of the upper support above the "directrix" or reference line of the catenary
c = height of the vertex of the catenary above the "directrix"

α = coefficient of linear expansion fahr. of the material carrying the stress

been published to indicate the method of solving the performance of such spans.

Calculation of Sag and Tension Performance for Long Spans with Supports at Unequal Elevations

The mathematical curve in which a stretched flexible cable or wire hangs in equilibrium is the well-known catenary of the form,

$$y = c \cosh \frac{x}{c}$$

$$s = c \sinh \frac{x}{c}$$

$$T = w\,y$$
$$y^2 = s^2 + c^2$$
$$d = y - c$$

It can readily be demonstrated that the curve has the same general form whether the supports are at equal elevations or at unequal elevations.

When the supports are at unequal elevations, y_1 and y_2, these formulas may be written as

$$y_1 = c \cosh \frac{x_1}{c}, \qquad y_2 = c \cosh \frac{x_2}{c}$$

$$s_1 = c \sinh \frac{x_1}{c}, \qquad s_2 = c \sinh \frac{x_2}{c}$$

$$T_1 = w\,y_1, \qquad T_2 = w\,y_2$$
$$y_1^2 = s_1^2 + c^2, \qquad y_2^2 = s_2^2 + c^2$$
$$d_1 = y_1 - c, \qquad d_2 = y_2 - c$$
$$h = x_1 + x_2$$
$$l = s_1 + s_2$$
$$k = y_2 - y_1$$

From these equations we may then by properly combining derive the following formulas:

$$\sqrt{l^2 - k^2} = 2\,c \sinh \frac{h}{c} \qquad (1)$$

which determines the length of cable between supports, and when

T_2, w, h and k are known

$$y_2 = \frac{T_2}{w}, \quad y_1 = y_2 - k$$

$$c^2 \cosh \frac{h}{c} - y_1\,y_2 - \sqrt{(y_1^2 - c^2)\,(y_2^2 - c^2)} = 0 \qquad (2)$$

h = horizontal length of span, or its equivalent
k = difference in elevation of supports, or its equivalent

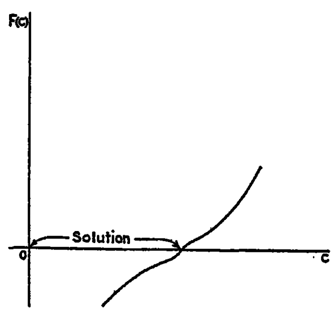

FIG. 19—GRAPH FOR APPENDIX

Then from equation (2) c may be determined by the graphical or trial method, plotting the equation (2) as $F(c)$ as ordinate versus c as abscissa.

It is readily seen from the conditions of the problem that $o < c < y_1$, and in general it is found that $0.9\,y_1 < c < y_1$. After the first two trials of c the actual value of c for the accuracy desired can be quickly arrived at by exterpolation or interpolation and the range of c materially narrowed.

I—INITIAL DETERMINATION OF CHARACTERISTICS OF THE CATENARY UNDER ICE AND WIND LOAD

The first assumption in calculating any span performance is usually the one regarding maximum tension in the cable when certain ice and wind loads prevail at a certain temperature. In the particular case considered it was assumed that the maximum tension shall not exceed 33,000 pounds at 0 deg. fahr., ½ inch ice and a 12-lb. per square foot wind on the ice-covered cable. Under this condition the catenary is hanging in a plane whose angle, θ, from the vertical is determined by the ratio of wind load to weight of bare cable plus ice. The values of h and k for the catenary in this plane are no longer the same as the physical values of h and k in the vertical plane as determined by survey. The one physical dimension, however, which does remain constant is H, the air line distance between the upper and lower supports,

where

$$H^2 = h^2 + k^2$$

The new value of k is the projection of the vertical value of k on the inclined plane established by wind pressure. The new value of k is

$$k_0 = k \cos \theta$$

$$\theta = \tan^{-1}\left(\frac{p}{w_c + w_i}\right)$$

the change in k, $\delta\,k$, may then be expressed as

$$k + \delta\,k = k_0$$
$$\delta\,k = k \cos \theta - k = k\,(\cos \theta - 1) \qquad (3)$$

From

$$H^2 = h^2 + k^2$$

$$\delta\,h = -\frac{2\,k\,\delta\,k + (\delta\,k)^2}{2\,h} \qquad (4)$$

The new value of h then becomes

$$h_0 = h + \delta\,h = h - \frac{2\,k\,\delta\,k + (\delta\,k)^2}{2\,h}$$

These values h_0 and k_0 must then be employed in making the initial determination of c when the maximum tension for a given temperature and ice and wind loading are assumed. The equation for the initial determination of c then becomes,

$$c^2 \cosh \frac{h_0}{c} - y_1\,y_2 - \sqrt{(y_1^2 - c^2)\,(y_2^2 - c^2)} = 0$$

where

T_2, w, h_0 and k_0 are known and

$$y_2 = \frac{T_2}{w}$$

$$y_1 = y_2 - k_0$$

With the value of c thus determined by trial the complete characteristics of the suspended cable at 0 deg. fahr., ½ inch ice and 12 lb. wind are readily tabulated. See example.

II—Determination of Characteristics of the Catenary Without Wind Load

Using as the basis for the determination of the characteristics of the catenary when hanging in a vertical plane (without wind load) the characteristics of the catenary in the inclined plane (with wind load), the following differential equations may be set up.

It is obvious from the previous determination that the change in k_0 and h_0 must be of the same magnitude, but with opposite algebraic sign in order to re-establish the plane of the catenary in the vertical when the wind pressure is removed.

Therefore, $\delta\, k_0$ and $\delta\, h_0$ are known from (3) and (4). From

$$y_2 = y_1 + k_0$$
$$\delta\, y_2 = \delta\, y_1 + \delta\, k_0 \qquad (5)$$

and from

$$y_2^2 = s_2^2 + c^2 \text{ and } y_1^2 = s_1^2 + c^2$$

$$\delta\, y_2 = \frac{\delta\, l + \left(\dfrac{y_1}{s_1}\right)\delta\, k_0 + \left\{\dfrac{c}{s_1} + \dfrac{c}{s_2}\right\}\delta\, c}{\dfrac{y_1}{s_1} + \dfrac{y_2}{s_2}} \qquad (6)$$

and from

$$\sqrt{l^2 - k_0^2} = 2\, c \sinh \frac{h_0}{2\, c}$$

$$\delta\, l = \frac{k_0\, \delta\, k_0}{l} + \sqrt{\frac{l^2 - k_0^2}{l}}\Bigg[\left(2\sqrt{\frac{y_1\, y_2 + s_1\, s_2 - c^2}{2\, c^2}} - \frac{h_0}{c}\sqrt{\frac{y_1\, y_2 + s_1\, s_2 + c^2}{2\, c^2}}\right)\delta\, c + \sqrt{\frac{y_1 y_2 + s_1\, s_2 + c^2}{2\, c^2}}\,\delta\, h_0\Bigg] \qquad (7)$$

This equation (7) is $\delta\, l$ expressed as a function of $\delta\, c$ where $\delta\, k_0$ and $\delta\, h_0$ are known, and equation (6), in which $\delta\, y_2$ is expressed as a function of $\delta\, l$ and $\delta\, c$, may now be expressed as a function of $\delta\, c$.

It now remains to express $\delta\, c$ in some known quantities so that a solution for the change in y_2, l, etc., may be had.

In changing from the condition of ice and wind load to the condition of ice load alone a change in w, the unit weight takes place. This change may be expressed as $\delta\, w$.

$$\delta\, w = (w_c + w_i) - \sqrt{(w_c + w_i)^2 + p^2} \qquad (8)$$

From

$$T_2 = w\, y_2$$
$$\delta\, T_2 = (w + \delta\, w)\, \delta\, y_2 + y_2\, \delta\, w \qquad (9)$$

The equation of the modulus of elasticity of the material carrying the stress may be expressed as

$$E = \frac{\delta\, T_2 \,.\, l}{A \,.\, \delta\, l} \qquad (10)$$

Combining equation (9) and (10)

$$\delta\, l = \frac{l}{E\, A}\left[(w + \delta\, w)\, \delta\, y_2 + y_2\, \delta\, w\right] \qquad (11)$$

Equation (11), expressed in terms of functions of $\delta\, l$ and $\delta\, y_2$, which in turn are functions of $\delta\, c$, is an equation which will give a solution of $\delta\, c$, $\delta\, w$ being known.

Having arrived at a numerical value of $\delta\, c$ the numerical values of $\delta\, y_2$, $\delta\, y_1$, δ 1 and $\delta\, T_2$ may now be established. The new values y_2', y_1' l', c', and T_2' for a given temperature, ice load, but without wind may now be tabulated. See example and detailed mathematical development.

III—Determination of Characteristics of the Catenary for Change of Temperature—Ice Load on the Cable to 32 Deg. Fahr.

Having resolved the catenary into the vertical plane, the values of h and k will be constant for any variations of the catenary in the vertical plane. The calculation of the characteristics of the catenary for change of temperature is introduced at this point in order to be able to determine the characteristics of the catenary at 32 deg. fahr. with ice, which may be found as the condition of maximum sag. This condition of sag, occurring as it does during cold months may however not be of interest as controlling the clearance over water, since during such months ice in the river itself usually is cause for abandoning navigation.

The first equation which may be established for change of temperature is the one expressing the physical phenomenon of change of length, $\delta\, l'$, due to change of temperature, $\delta\, t$,

$$\delta\, l' = l' \,.\, \alpha \,.\, \delta\, t \qquad (12)$$

$\delta\, t$ is predetermined by the condition which is to be investigated and the known condition used as the basis, therefore is a known quantity. (In going from 0 deg. fahr. to 32 deg. fahr. $\delta\, t = 32$). Therefore, we have $\delta\, l$ as a known quantity.

From equation (1)

$$\delta\, c' = \frac{\dfrac{l'}{\sqrt{(l')^2 - (k')^2}}}{2\sqrt{\dfrac{y_1' y_2' + s_1' s_2' - (c')^2}{2\, c^2}} - \dfrac{h'}{c'}\sqrt{\dfrac{y_1' y_2' + s_1' s_2' + (c')^2}{2\, (c')^2}}}\,\delta\, l' \qquad (13)$$

From

$$(y_1')^2 = (s_1')^2 + (c')^2 \text{ and } (y_2')^2 = (s_2')^2 + (c')^2$$

$$\delta\, s_2' = \frac{y_2'}{s_2'} \,.\, \delta\, y_2' + \frac{c'}{s_2'} \,.\, \delta\, c' \qquad (14)$$

$$\delta\, s_1' = \delta\, l' - \delta\, s_2' \qquad (15)$$

$$\delta y_2' = \frac{\delta l' + \left(\frac{c'}{s_1'} + \frac{c'}{s_2'}\right)\delta c'}{\frac{y_1'}{s_1'} + \frac{y_2'}{s_2'}} \tag{16}$$

$$\delta y_1' = \delta y_2' \tag{17}$$

From

$$T_2' = w' y_2'$$
$$\delta T_2' = w' \delta y_2' \tag{18}$$

The characteristics for the catenary at the new temperature may now be tabulated. See example and detailed mathematical development.

IV—Determination of Characteristics of the Catenary for the Bare Cable, Ice Load Removed

At any given temperature when ice prevails the characteristics of the catenary without ice load may be determined by applying the equations which follows:

The plane of the catenary under this condition is in the vertical so that h and k are constants.

The removal of the ice load is a change in weight, $\delta w'$; so that we have as known

$$\delta w'' = w_c - (w_c + w_i) = -w_i \tag{19}$$

Equation (16) is repeated, holding true under the conditions in this section, as

$$\delta y_2'' = \frac{\delta l'' + \left(\frac{c''}{s_1''} + \frac{c''}{s_2''}\right)\delta c''}{\frac{y_1''}{s_1''} + \frac{y_2''}{s_2''}} \tag{20}$$

Equation (9) is repeated holding true under the conditions in this section

$$\delta T_2'' \doteq (w'' + \delta w'') \delta y_2'' + y_2'' \delta w'' \tag{21}$$

and Equation (11) may be repeated

$$\delta l'' = \frac{l''}{E A}\left[(w'' + \delta w'') \delta y_2'' + y_2'' \delta w''\right] \tag{22}$$

Similarly equations (14), (15) and (17) may be employed in this section by properly noting the change from the use of the prime values to the use of the second values.

The characteristics of the catenary at the temperature considered for the bare cable may now be tabulated. See example and detailed mathematical development.

V—Calculation of the Characteristics of the Catenary for the Bare Cable at Various Temperatures

Having determined in Section IV the characteristics of the catenary for the bare cable at a particular temperature, it now remains to determine the characteristics of the catenary at various conditions of temperature in order to have the complete performance of the catenary so that the stringing sag may be governed during installation in order that the clearance at maximum temperature, which will occur during navigation season may be maintained and maximum tension not be exceeded when the ice and wind load come on the cable.

These characteristics may be determined using the characteristics of the catenary for the particular temperature as determined under section IV, and applying to them for various values of δt the equation indicated in section III. See example and detailed mathematical development.

Remarks. It is to be noted in the development as indicated in detail that in most cases differentials of higher than the first order have been neglected. In two instances differentials of the second order have been included where their values were appreciable. The first and most important point at which the differential of the second order must be preserved is in the cases of changing load.

From

$$T_2 = w y_2$$
$$T_2 + \delta T_2 = (w + \delta w)(y_2 + \delta y_2)$$
$$T_2 + \delta T_2 = w y_2 + w \delta y_2 + y_2 \delta w + \delta w \,.\, \delta y_2$$

By subtraction

$$\delta T_2 = w \delta y_2 + \delta w \delta y_2 + y_2 \delta w$$
$$= (w + \delta w) \delta y_2 + y_2 \delta w$$

$\delta w \,.\, \delta y_2$ is of the second order and is not negligible, for although δy_2 is relatively of small value compared to y_2, δw we know to be relatively large in comparison with w. When changing from ice and wind load (3.322 lb. per ft.) to ice load (2.623) δw is -0.699 lb. per ft. and represents approximately 21 per cent of w. Similarly when removing the ice load δw is -0.939 lb. per ft. and represents approximately 35 per cent of w.

In determining h_0 and k_0 for the catenary in the inclined plane $(\delta k)^2$ was preserved while $(\delta h)^2$ was dropped. In this case δk is approximately 21 per cent of k so that $(\delta k)^2$ has appreciable value.

It is to be noted that after the initial solution by trial for c that the formulas have been resolved into forms which do not contain hyperbolic functions. Although tables of hyperbolic functions are available it has been found that where eight place accuracy is required the use of hyperbolic functions from tables is about as cumbersome, due to interpolation, as arriving at the functions by means of the necessary number of terms from the series expressing the desired function. Eight place accuracy is required in order to preserve reasonable accuracy at certain points where differences are taken. Where hyperbolic functions have been replaced by an algebraic expression in these formulas the expression is exact for the conditions which exist.

At any point in the calculations the following check may be applied, which may be taken as a check on the accuracy of the method developed.

$$T_2'' = \delta T_2' + T_2' = w'' y_2''$$

This check applied in the example given shows that the error is less than 0.001 of 1 per cent for the tension.

It is to be noted that in the calculated example that

the change of temperature to 32 deg. fahr. with ice and wind was performed before the wind load was removed. This was done as a matter of convenience in order to find the condition of maximum sag early in the arithmetical calculations. The order of applying the various sections in determining span performance may be arranged to suit the convenience of the calculator in order that any particular point of interest may be arrived at quickly.

Experience indicates that the calculation of the span performance by this method involves little or no more work than by more approximate methods.

Complete Mathematical Treatment

General. Formulas for the symmetrical catenary (supports at equal elevations).

$$y = c \cosh \frac{x}{c}$$

$$s = c \sinh \frac{x}{c}$$

$$T = w\,c \cosh \frac{x}{c} = w\,y$$

$$y^2 = c^2 \cosh^2 \frac{x}{c}$$

$$s^2 = c^2 \sinh^2 \frac{x}{c}$$

$$y^2 - s^2 = c^2 \left(\cosh^2 \frac{x}{c} - \sinh^2 \frac{x}{c} \right) = c^2$$

$$y^2 = s^2 + c^2$$
$$d = y - c$$

The formulas for the unsymmetrical catenary (supports at unequal elevations) may be written as follows,

$$y_1 = c \cosh \frac{x_1}{c}, \qquad y_2 = c \cosh \frac{x_2}{c} \qquad (1)$$

$$s_1 = c \sinh \frac{x_1}{c}, \qquad s_2 = c \sinh \frac{x_2}{c} \qquad (2)$$

$$T_1 = w\,y_1 \quad , \qquad T_2 = w\,y_2 \qquad (3)$$
$$y_1^2 = s_1^2 + c^2 \quad , \qquad y_2^2 = s_2^2 + c^2 \qquad (4)$$
$$d_1 = y_1 - c \quad , \qquad d_2 = y_2 - c \qquad (5)$$
$$h = x_1 + x_2 \qquad (6)$$
$$l = s_1 + s_2 \qquad (7)$$
$$y_2 = y_1 + k \qquad (8)$$
$$d_2 = d_1 + k \qquad (9)$$

$$l^2 = s_1^2 + s_2^2 + 2\,s_1\,s_2$$

$$= y_1^2 - c^2 + y_2^2 - c^2 + 2\,c^2 \,.\, \sinh \frac{x_1}{c} \,.\, \sinh \frac{x_2}{c} \qquad (10)$$

$$\cosh \frac{h}{c} = \cosh \frac{x_1 + x_2}{c}$$

$$= \cosh \frac{x_1}{c} \,.\, \cosh \frac{x_2}{c} + \sinh \frac{x_1}{c} \,.\, \sinh \frac{x_2}{c} \qquad (11)$$

$$\sinh \frac{x_1}{c} \,.\, \sinh \frac{x_2}{c} = \cosh \frac{h}{c} - \cosh \frac{x_1}{c} \,.\, \cosh \frac{x_2}{c} \qquad (12)$$

$$l^2 = y_2^2 + y_1^2 - 2\,c^2 + 2\,c^2 \,.\, \cosh \frac{h}{c}$$

$$- 2\,c \,.\, \cosh \frac{x_1}{c} \,.\, c \,.\, \cosh \frac{x_2}{c}$$

$$= y_2^2 - 2\,y_1\,y_2 + y_1^2 + 2\,c^2 \left(\cosh \frac{h}{c} - 1 \right)$$

$$= (y_2 - y_1)^2 + 2\,c^2 \left(\cosh \frac{h}{c} - 1 \right)$$

$$= k^2 + 2\,c^2 \left(\cosh \frac{h}{c} - 1 \right)$$

$$l^2 - k^2 = 2\,c^2 \left(\cosh \frac{h}{c} - 1 \right) \qquad (13)$$

$$\cosh \frac{h}{c} = \cosh 2 \left(\frac{h}{2\,c} \right) = 1 + 2 \sinh^2 \frac{h}{2\,c} \qquad (14)$$

$$l^2 - k^2 = 2\,c^2 \left(1 + 2 \sinh^2 \frac{h}{2\,c} - 1 \right)$$

$$= 4\,c^2 \,.\, \sinh^2 \frac{h}{2\,c}$$

$$\sqrt{l^2 - k^2} = 2\,c \,.\, \sinh \frac{h}{2\,c} \qquad (15)$$

I. Determination of Characteristics of the Catenary Under Maximum Ice and Wind Load

T_2, w, h and k are known.

$$\theta = \tan^{-1} \left(\frac{p}{w_o + w_i} \right)$$

$$k_0 = k \,.\, \cos \theta$$
$$k + \delta\,k = k_0$$
$$\delta\,k = k\,(\cos \theta - 1) \qquad (16)$$
$$H^2 = h^2 + k^2$$

$$\delta\,(H^2) = 0 = 2\,h \,.\, \delta\,h + 2\,k\,\delta\,k + (\delta\,h)^2 + (\delta\,k)^2$$

$(\delta\,h)^2$ is negligible

$$\delta\,h = - \frac{2\,k\,\delta\,k + (\delta\,k)^2}{2\,h} \qquad (17)$$

$$h_0 = h + \delta\,h$$

$$y_2 = \frac{T_2}{w}, \qquad y_1 = y_2 - k_0$$

From (11)

$$c^2 . \cosh \frac{h_0}{c}$$

$$= c . \cosh \frac{x_1}{c} . c . \cosh \frac{x_2}{c} + c . \sinh \frac{x_1}{c} . c . \sinh \frac{x_2}{c}$$

$$c^2 . \cosh \frac{h_0}{c} = y_1 y_2 + s_1 s_2$$

$$= y_1 y_2 + \sqrt{(y_1^2 - c^2)(y_2^2 - c^2)}$$

$$c^2 \cosh \frac{h_0}{c} - \sqrt{(y_1 - c)(y_1 + c)(y_2 - c)(y_2 + c)} - y^1 y^2 = 0 \qquad (18)$$

Solve by trial for c

Obviously

$$0 < c < y_1$$

In general

$$.9\, y_1 < c < y_1$$

At maximum ice and wind load (Maximum Tension)

$$d_2 = y_2 - c$$
$$d_1 = d_2 - k_0$$
$$s_1 = \sqrt{(y_1 - c)(y_1 + c)}$$
$$s_2 = \sqrt{(y_2 - c)(y_2 + c)}$$
$$l = s_1 + s_2$$

II. Determination of Characteristics of the Catenary with Ice Load, Wind Load Removed

$$\delta k_0 = - \delta k$$
$$\delta h_0 = - \delta h$$

From (8)

$$\delta y_2 = \delta y_1 + \delta k_0 \qquad (19)$$

From (4)

$$\begin{cases} 2\, y_2 \delta y_2 = 2 s_2 \delta s_2 + 2 c \delta c \\ 2\, y_1 \delta y_1 = 2 s_1 \delta s_1 + 2 c \delta c \end{cases}$$

$$y_2 \delta y_2 = s_2 \delta s_2 + c \delta c \qquad (20)$$

$$y_1 \delta y_1 = s_1 \delta s_1 + c \delta c \qquad (21)$$

Substituting (19) in (21)

$$y_1 (\delta y_2 - \delta k_0) = s_1 \delta s_1 + c \delta c$$

$$y_1 \delta y_2 = s_1 \delta s_1 + c \delta c + y_1 \delta k_0 \qquad (22)$$

From (20)

$$\frac{y_2}{s_2} \delta y_2 = \delta s_2 + \frac{c}{s_2} \delta c \qquad (23)$$

From (22)

$$\frac{y_1}{s_1} \delta y_2 = \delta s_1 + \frac{c}{s_1} \delta c + \frac{y_1}{s_1} \delta k_0 \qquad (24)$$

Adding (23) and (24)

$$\left(\frac{y_1}{s_1} + \frac{y_2}{s_2} \right) \delta y_2$$

$$= \delta s_1 + \delta s_2 + \left(\frac{c}{s_1} + \frac{c}{s_2} \right) \delta c + \frac{y_1}{s_1} \delta k_0$$

From (7)

$$\delta l = \delta s_1 + \delta s_2$$

$$\delta y_2 = \frac{\delta l + \frac{y_1}{s_1} \delta k_0 + \left(\frac{c}{s_1} + \frac{c}{s_2} \right) \delta c}{\frac{y_1}{s_1} + \frac{y_2}{s_2}} \qquad (25)$$

From (15)

$$\frac{l \delta l - k_0 \delta k_0}{\sqrt{l^2 - k_0^2}}$$

$$= \left(2 \sinh \frac{h_0}{2c} - \frac{h_0}{c} \cosh \frac{h_0}{2c} \right) \delta c + \cosh \frac{h_0}{2c} \delta h_0$$

$$\delta l = \frac{k_0 \delta k_0}{l} + \frac{\sqrt{l^2 - k_0^2}}{l}$$

$$\left[\left(2 \sinh \frac{h_0}{2c} - \frac{h_0}{c} \cosh \frac{h_0}{2c} \right) \delta c + \cosh \frac{h_0}{2c} \delta h_0 \right]$$

$$\sinh \frac{h_0}{2c} = \sinh \frac{1}{2} \left(\frac{x_1 + x_2}{c} \right) = \sqrt{\frac{1}{2} \left(\cosh \frac{x_1 + x_2}{c} - 1 \right)}$$

$$= \sqrt{\frac{1}{2} \left(\cosh \frac{x_1}{c} . \cosh \frac{x_2}{c} + \sinh \frac{x_1}{c} . \sinh \frac{x_2}{c} - 1 \right)}$$

$$= \sqrt{\frac{1}{2c^2} \left(c . \cosh \frac{x_1}{c} . c . \cosh \frac{x_2}{c} + c . \sinh \frac{x_1}{c} . c . \sinh \frac{x_2}{c} - c^2 \right)}$$

$$\sinh \frac{h_0}{2c} = \sqrt{\frac{y_1 y_2 + s_1 s_2 - c^2}{2c^2}}$$

By similar expansion

$$\cosh \frac{h_0}{2c} = \sqrt{\frac{y_1 y_2 + s_1 s_2 + c^2}{2c^2}}$$

$$\delta l = \frac{k_0 \delta k_0}{l} + \frac{\sqrt{l^2 - k_0^2}}{l}$$

$$\left[\left(2 \sqrt{\frac{y_1 y_2 + s_1 s_2 - c^2}{2c^2}} - \frac{h_0}{c} \sqrt{\frac{y_1 y_2 + s_1 s_2 + c^2}{2c^2}} \right) \delta c + \sqrt{\frac{y_1 y_2 + s_1 s_2 + c^2}{2c^2}} \delta h_0 \right] \qquad (26)$$

$$E = \frac{\delta T_2 l}{A \delta l} \qquad (27)$$

From (3)

$$\delta T_2 = w \delta y_2 + y_2 \delta w + \delta w \delta y_2$$

$$= (w + \delta w) \delta y_2 + y_2 \delta w \qquad (28)$$

$$w = \sqrt{(w_c + w_i)^2 + p^2}$$

$$w + \delta w = w_c + w_i$$

$$\delta w = w_c + w_i - \sqrt{(w_c + w_i)^2 + p^2} \qquad (29)$$

(25) may be expressed as

$$\delta y_2 = a + b\,\delta c \qquad (30)$$

and (26) may be expressed as

$$\delta l = e + f\,\delta c \qquad (31)$$

Substituting (28), (30) and (31) in (27)

$$E = \frac{l\,[(w + \delta w)\,(a + b\,\delta c) + y_2\,\delta w]}{A\,(e + f\,\delta c)} \qquad (32)$$

$$E\,A\,(e + f\,\delta c)$$
$$= l\,a\,w + l\,b\,w\,\delta c + l\,a\,\delta w + l\,b\,\delta w\,\delta c + l\,y_2\,\delta w$$
$$(E\,A\,f - l\,b\,w - l\,b\,\delta w)\,\delta c$$
$$= l\,a\,w + l\,a\,\delta w + l\,y_2\,\delta w - E\,A\,e$$

$$\delta c = \frac{l\,a\,(w + \delta w) + l\,y_2\,\delta w - E\,A\,e}{E\,A\,f - l\,b\,(w + \delta w)} \qquad (33)$$

The value of δc derived from (33) when substituted in (23), (25), (26) and (28) will give the values of δs_2, δy_2, δl and δT_2.

The new values of y_2, y_1, c, l, s_2, s_1, T_2, h and k may now be tabulated.

$$\begin{aligned}
y_2' &= y_2 + \delta y_2 \\
k' &= k_0 + \delta k_0 \\
y_1' &= y_2' - k' \\
l' &= l + \delta l \\
s_2' &= s_2 + \delta s_2 \\
s_1' &= l' - s_2' \\
c' &= c + \delta c \\
T_2' &= T_2 + \delta T_2 \\
h' &= h_0 + \delta h_0 \\
d_2' &= y_2' - c' \\
d_1' &= y_1' - c' \\
w' &= w + \delta w = w_c + w_i
\end{aligned}$$

III. Determination of Characteristics of the Catenary for Change of Temperature. Ice Load on the Cable to 32 Deg. Fahr.

w', h', and k' are constant in this section.

$\therefore\ \delta h' = 0$ and $\delta k' = 0$ and $\delta w' = 0$

$$\delta l' = l'\,\alpha\,\delta t \qquad (34)$$

From (26)

$$\delta l' = \frac{\sqrt{(l')^2 - (k')^2}}{l'}\left(2\sqrt{\frac{y_1'\,y_2' + s_1'\,s_2' - (c')^2}{2\,(c')^2}} - \frac{h'}{c'}\sqrt{\frac{y_1'\,y_2' + s_1'\,s_2' + (c')^2}{2\,(c')^2}}\right)\delta c' \qquad (35)$$

$$\delta c' = \frac{\dfrac{l'}{\sqrt{(l')^2 - (k')^2}}}{2\sqrt{\dfrac{y_1'\,y_2' + s_1'\,s_2' - (c')^2}{2\,(c')^2}} - \dfrac{h'}{\ '}\sqrt{\dfrac{y_1'\,y_2' + s_1'\,s_2' + (c')^2}{2\,(c')^2}}}\,\delta l' \qquad (36)$$

From (25)

$$\delta y_2' = \frac{\delta l' + \left(\dfrac{c'}{s_1'} + \dfrac{c'}{s_2'}\right)\delta c'}{\dfrac{y_1'}{s_1'} + \dfrac{y_2'}{s_2'}} \qquad (37)$$

From (3)

$$\delta T_2' = w'\,\delta y_2' \qquad (38)$$

From (23)

$$\delta s_2' = \frac{y_2'}{s_2'}\,\delta y_2' - \frac{c'}{s_2'}\,\delta c' \qquad (39)$$

By the successive operations indicated in (34), (35), (36), (37), (38) and (39) the values of $\delta l'$, $\delta c'$, $\delta y_2'$, $\delta T_2'$ and $\delta s_2'$ are established.

The new values of y_2, y_1, c, l, s_2, s_1 and T_2 may now be tabulated.

$$\begin{aligned}
y_2'' &= y_2' + \delta y_2' \\
y_1'' &= y_2'' - k' \\
l'' &= l' + \delta l' \\
s_2'' &= s_2' + \delta s_2' \\
s_1'' &= l'' - s_2'' \\
c'' &= c' + \delta c' \\
T_2'' &= T_2' + \delta T_2' \\
d_2'' &= y_2'' - c'' \\
d_1'' &= y_1'' - c'' \\
h'' &= h' \\
k'' &= k' \\
w'' &= w' = w_c + w_i
\end{aligned}$$

IV. Determination of Characteristics of the Catenary for the Bare Cable, Ice Load Removed

h'' and k'' are constant in this section.

$$\therefore\ \delta h'' = 0, \qquad \delta k'' = 0$$

$$\begin{aligned}
w'' + \delta w'' &= w_c \\
\delta w'' &= w_c - w_c - w_i = -\,w_i
\end{aligned}$$

From (25)

$$\delta y_2'' = \frac{\delta l'' + \left(\dfrac{c''}{s_1''} + \dfrac{c''}{s_2''}\right)\delta c''}{\dfrac{y_1''}{s_1''} + \dfrac{y_2''}{s_2''}} \qquad (40)$$

From (26)

$$\delta l'' = \frac{\sqrt{(l'')^2 - (k')^2}\left(2\sqrt{\dfrac{y_1''\,y_2'' + s_1''\,s_2'' - (c'')^2}{2\,(c'')^2}} - \dfrac{h'}{c''}\sqrt{\dfrac{y_1''\,y_2'' + s_1''\,s_2'' + (c'')^2}{2\,(c'')}}\right)}{l''}\,\delta c'' \qquad (41)$$

$$\delta c'' = \frac{\dfrac{l''}{\sqrt{(l'')^2 - (k')^2}}}{2\sqrt{\dfrac{y_1'' y_2'' + s_1'' s_2'' - (c'')^2}{2\,(c'')^2}} - \dfrac{h'}{c''}\sqrt{\dfrac{y_1'' y_2'' + s_1'' s_2'' + (c'')^2}{2\,(c'')^2}}}\,\delta l'' \qquad (42)$$

From (28)

$$\delta T_2'' = (w'' + \delta w'')\,\delta y_2'' + y_2''\,\delta w'' \qquad (43)$$

From (33)

$$\delta c'' = \frac{l''\, y_2''\,\delta w''}{E\,A\,f'' - l''\,b''\,(w'' + \delta w'')} \qquad (44)$$

From (23)

$$\delta s_2'' = \frac{y_2''}{s_2''}\,\delta y_2'' - \frac{c''}{s_2''}\,\delta c'' \qquad (45)$$

The value of $\delta c''$ derived from (44) when substituted in (40), (41), (43) and (45) will give the values of $\delta y_2''$, $\delta l_1''$, $\delta T_2''$ and $\delta s_2''$. The new values of y_2, y_1, c, l, s_2, s_1, and T_2 may now be tabulated.

$$\begin{aligned}
y_2''' &= y_2'' + \delta y_2'' \\
y_1''' &= y_2''' - k' \\
l''' &= l'' + \delta l'' \\
s_2''' &= s_2'' + \delta s_2'' \\
s_1''' &= l''' - s_2''' \\
c''' &= c'' + \delta c''' \\
T_2''' &= T_2''' + \delta T_2'' \\
d_2''' &= y_2''' - c''' \\
d_1''' &= y_1''' - c''' \\
h''' &= h' \\
k''' &= k' \\
w''' &= w'' + \delta w'' = w_c
\end{aligned}$$

V. Determination of Characteristics of the Catenary for the Bare Cable at Various Temperatures

This section is the same as section III, except that the weight of the bare cable is employed, the ice load having been removed in the preceding section. The following formulas are given for the sake of completeness.

w''', h''', and k''' are constant in this section.

$$\because \delta w''' = 0, \quad \delta h''' = 0, \text{ and } \delta k''' = 0$$

From (34)

$$\delta l''' = l'''\,\alpha\,\delta t \qquad (46)$$

From (36)

$$\delta c''' = \frac{\dfrac{l'''}{\sqrt{(l''')^2 - (k')^2}}}{2\sqrt{\dfrac{y_1''' y_2''' + s_1''' s_2''' - (c''')^2}{2\,(c''')^2}} - \dfrac{h'}{c'''}\sqrt{\dfrac{y_1''' y_2''' + s_1''' s_2''' + (c''')^2}{2\,(c''')^2}}}\,\delta l''' \qquad (47)$$

$$\delta y_2''' = \frac{\delta l''' + \left(\dfrac{c'''}{s_1'''} + \dfrac{c'''}{s_2'''}\right)\delta c'''}{\dfrac{y_1'''}{s_1'''} + \dfrac{y_2'''}{s_2'''}} \qquad (48)$$

From (38)

$$\delta T_2''' = w'''\,\delta y_2''' \qquad (49)$$

From (39)

$$\delta s_2''' = \frac{y_2'''}{s_2'''}\,\delta y_2''' - \frac{c'''}{s_2'''}\,\delta_c''' \qquad (50)$$

By the successive operations indicated in (46), (47), (48), (49), and (50) the values of $\delta l'''$, $\delta c'''$, $\delta y_2'''$, $\delta T_2'''$ and $\delta s_2'''$ are established.

The new values of y_2, y_1, c, l, s_2, s_1 and T_2 may now be tabulated.

$$\begin{aligned}
y_2'''' &= y_2''' + \delta y_2''' \\
y_1'''' &= y_2'''' - k' \\
l'''' &= l''' + \delta l''' \\
s_2'''' &= s_2''' + \delta s_2''' \\
s_1'''' &= l'''' - s_2'''' \\
c'''' &= c''' + \delta c''' \\
T_2'''' &= T_2''' + \delta T_2''' \\
d_2'''' &= y_2'''' - c'''' \\
d_1'''' &= y_1'''' - c'''' \\
h'''' &= h' \\
k'''' &= k' \\
w'''' &= w''' = w_c
\end{aligned}$$

Calculation of River Crossing

Span 4279 Ft. Maximum Tension 33,000 Lb. at 0 Deg. Fahr. ½ In. Ice and 12 Lb. per Sq. Ft. Wind

Cable Data

Discussion

J. S. Martin (communicated after adjournment): I have been especially interested in the authors' methods of calculation of the sags required in the wire, as this is a subject of which I have made considerable study. In the proceedings of the Engineering Society of Western Pennsylvania for November 1922, I published a tabular method of calculating sag including a set of tables giving the functions of the catenary in the same manner that the ordinary trigonometrical tables give the functions of the circle. By means of these tables the sag required for any span and any wire can be quickly and accurately determined when the span is level. For the calculation of spans on the slope, the writer has resorted to an approximate method which gives results as close as the work of sagging can be done in the field and in nearly all cases the slight error is on the safe side.

The accurate calculation of the sag of wire in a span where

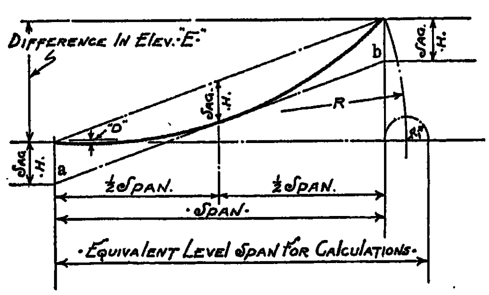

FIG. 1

the supports are not on the same level is a long and tedious process for an expert mathematician even when assisted by these tables, so that for general use in transmission-line work the accurate method is impractical. The computations presented by Messrs. Eales and Ettlinger have afforded the writer an opportunity to compare results with his method.

The method used by the writer for general calculation of sag in sloping spans is to take the difference between the level measurement of span between the points of support, and the actual measurement between these points of support. This difference equals R_1 in the accompanying diagram. Then add this difference to the actual distance between points of support, and use this value as an equivalent level span.

A marking point is then placed on each tower at a distance from the point of support equal to the sag H, of the equivalent level span. See a and b in the diagram. A line of sight $a - b$ is taken between these two marking points, this line of sight being parallel to a line joining the points of support. The wire is then sagged till it strikes this line of sight.

If the wire would hang in a parabola, a similar method could be used, using the level measurement between the points of support as the length of span and the results would be accurate, but since we assume that the wire is hanging in a catenary, there must be a correction, and the method mentioned above is the one used by the writer to obtain this correction. No mathematical demonstration can be given by the writer for this method, except that it is the result of a long series of test problems.

The calculations for the sag of the wire in the span under consideration can be obtained by the tabular method in an hour or less of work and the computation can be entrusted to an apprentice or office boy. With the method presented by the authors of the paper under consideration, the calculations will take a long time and must be made by an expert mathematician.

The writer has compared the results obtained by the two methods and it was found that they differ in giving the elevation of the low point of the wire by about 2.2 ft. In order to check the accuracy of these results the writer calculated the exact location of the low point of the wire at zero temperature. It was found that while for zero temperature there is a difference of 2.19 ft. between the results obtained by the two methods, the exact method gives a result between the two, giving an elevation of 0.73 ft. above the elevation given by the method presented in the paper and 1.46 ft. below the elevation given by the writer's method. This would show that the error of the writer's method is about 0.45 per cent while that of the method given in the paper is 0.30 per cent. This percentage is based on the maximum tension in the wire as strung according to the two methods. This happens to be one of the few cases where the writer's approximate method for sloping spans would give a stress slightly in excess of the theoretical stress desired, but the results are well within the limits of the probable errors in field work and in the assumptions with regard to the quality and characteristics of the wire used, so that this error is negligible.

Where it is necessary to know the elevation of the low point of the wire for determining clearances, the writer has found the following parabolic formula sufficiently accurate for practical purposes.

Let, H = sag as determined for the equivalent level span as previously explained
E = difference in elevation of the points of support
D = deflection of low point of wire below lower support

Then,

$$D = (1/H)\,(H - E/4)^2$$

In our office, a large part of our routine calculations for sags in wires are entrusted to an office boy to do in his spare moments.

The tabular method is so well adapted for the use of a calculating machine, such as the Marchant or Monroe, that it is no trouble at all for any person who is ordinarily careful to determine quickly the proper sag in the wire even for important spans.

E. Ettlinger: The solution of the specific engineering problem of this river crossing, due to the nature of the profile, produced two adjacent long spans. The desire to avoid dead-end construction, influenced the use of insulating supports in suspension on the intermediate tower. Initially, consideration was given to a roller-cradle type of support which would allow the cable to roll from one side to the other with changes of temperature and loading. Numerous objections were found to this type of support, the most serious of which was the danger incident to the dropping off of ice in one span while the ice remained on the adjacent span, resulting in the decision to clamp the cable definitely.

The clamping of the cable at the intermediate tower and supporting it by suspension assembly of insulators introduced the problem of the stress in this support due to temperature and loading variations. Calculations indicated that the suspension assembly would not vary from the vertical by more than approximately 5 deg. Although the suspension assemblies were designed for one-half the ultimate strength of the dead-end assemblies, the actual component of force in them would not reach an excessive value.

The authors are aware of the fact that there are numerous noteworthy tabular and chart methods of calculating spans with supports at equal elevation. Also that various approximate methods are in use by which spans with supports at unequal elevations may be calculated.

The importance of the problem involved in crossing the largest and most important navigable river in this country, it is believed, warranted the development of a direct method of calculations for spans with supports at unequal elevations. The expense and time required to make these calculations are really insignificant when it is realized that the design and construction of a crossing of the Mississippi River with the rigid requirements of clearance as specified by the War Department involves considerable responsibility.

Problems of this magnitude arise but infrequently and are hardly to be classified as a matter of routine calculation. The method was developed for the specific purpose of assurance of span performance and as a check on less accurate and empirical methods. The method of calculation illustrated in the paper should not consume more than three or four hours to complete after one is familiar with the procedure.

Automatic Control for Substation Apparatus

BY WALTER H. MILLAN[1]

Member, A. I. E. E.

Synopsis.—The use of automatically operated stations has become quite general over the country, but as the development has been very rapid, and the engineers involved so busy with their individual problems, very little has been accomplished toward the pooling of ideas and experiences.

This paper outlines some of the more important problems being encountered in automatic development such as the need for automatic fire protection in the stations, the necessary future development of thermal protective devices, voltage regulating devices, etc. Particular stress is laid on the fact that, while we have some problems which we presume have been worked out, some of the solutions are far from perfect.

This paper is prepared in a manner which, it is hoped, will bring out many valuable ideas in its discussion.

THE engineering profession has been presented with many papers and reports covering the field of automatic operation, but in almost every case an attempt has been made to describe some particular installation and, as is most natural, the author, whether manufacturer or operator, brings out all of the clever and agreeable points that he can find. This is very creditable but it is felt that the development has reached a stage where the injection of some pessimism would seem to inspire faster progress. The highest developed is the railway class, being the first to be attempted. This class rapidly came to its present high state of development, principally because of its simplicity. In railway operation, very low load factors are encountered thus avoiding, at least to some extent, temperature troubles with their attending ventilating problems. Also, voltage regulation is more or less rough and distribution system resistance high, lowering the precision required in regulating devices and making parallel operation of machines and stations fairly easy.

1. Union Electric Light & Power Co., St. Louis, Mo.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925.

The next highest developed is the alternating-current transforming and distributing substation. Again we have simplicity, in that there are comparatively few functions, the operation of which actually had to be automatized; the balance being only a matter of finding sufficient courage to close and lock the doors on equipment which had previously been operated with an attendant to watch it. We have had the automatic induction regulator for a good many years but always with someone close by, and while there is no reason why it should not be trusted to operate without a guardian, the author confesses that he had some very anxious hours during the first few weeks of such operation of equipment for which he was responsible. There are only three other automatic operations of a major nature in the average station of this class: First, the automatic switching of supply circuits, not hard to accomplish unless automatic synchronizing is required: Second, the automatic reclosing of distribution circuits on trouble, which detail varies in complexity with the class of service. At the outside, the problem requires the application of only four or five relays or devices per three-phase feeder over and above the standard

apparatus which would be present if the station had an attendant. The third is water control and is present only where transformers and similar equipment is operated "water cooled" over peak-load periods. This is a simple function and is usually given a passing glance only notwithstanding the fact that it is of the highest importance.

The third and least developed class is that of supply stations to heavy Edison system networks where extremely low system resistance is encountered, close precision is called for in voltage regulation and an interruption to service is an unpardonable offense. The author will not attempt to discuss weak points in the automatic railway station field as he is not qualified to do so from the standpoint of experience. Therefore, the following discussion will cover the other two classes only.

Class 2—Automatic A-C. Distribution and Transformer Stations

There are a great many of these stations in successful operation and almost every one of them has some specific points, good as well as unique. Usually these points are emphasized almost to the exclusion of others of equal importance; for example, we may find a station in which a great deal of effort and money has been concentrated on the automatic operation of its supply circuits to prevent the possible loss of supply power due to failure of supply circuit. This is accomplished by automatic transfer devices to keep power on the station bus as long as one of its supply circuits is alive. In the same station we may find only a single transformer unit supplying several important distribution feeders, no provision having been made to save the day if, by any chance, the transformer should fail. Frequently this transformer depends on cooling water to carry it over the peak and we find that there is but one source of water supply; or, if there are two, they are not automatically "changed" in event of failure. The conventional way to protect such a transformer against sustained overload is by means of the well-known thermal relay which is supposed to possess the same relative heating and radiating characteristics as the transformer, and so adjusted that full load amperes will permit the unit to stay on continuously but approximately 25 per cent in excess of this amount tripping the transformer off the line in thirty minutes. The exact principle of the operation of this device is usually only partially understood by the man who actually locates it in the station and upon this point depends its real utility. To be consistent, this thermal relay must undergo exactly the same abuse and benefits regarding ventilation that the transformer suffers and it can be seen that, should the thermal relay be so located that its heat is dissipated by a draught of cold air from a ventilator or by conduction to a wall on which it may be mounted, it may fail to protect the transformer. The manufacturers have recognized this liability and generally provide a thermostat submerged in the transformer oil, which trips off and locks out the transformer if the oil exceeds about 85 deg. cent. This would probably save the transformer (but not the service) if the overload was approached slowly so that too great a drop in temperature between the "hot spot" and the oil was not in evidence, but, if a sudden overload appears after many hours of very light load, when the oil has cooled to a very low temperature, the oil with which the "hot oil" thermostat is in contact may be 50 deg. cooler than the "hot spot" and the thermostat quite useless should the thermal relay fail to function. The above would indicate that we should attempt to develop a means of direct relaying from the actual, measured, hot spot temperature rather than try, by means of a proportional auxiliary circuit, to imitate the performance of the transformer. Much may be said about thermostats. The average operating engineer notes in the specifications that a thermostat will stand guard over his transformer and he accepts this face value. He may, in fact, for years possess many of these devices embedded in his apparatus without ever having actually seen one of them. Without injustice to the electrical manufacturers, it may be said that we should not expect them to know as much about building these devices as do the manufacturers of heating and ventilating apparatus. The author has found that these latter manufacturers possess equipment of this nature directly applicable to our needs which has been developed and in successful operation for years. When applied to transformers, thermostats are usually mounted on some projection on the head block or core, and this means that the transformer must be taken out of service and the oil lowered to get at them for test purposes. With "conservator" or "inertaire" types of transformers, where the case lid is tightly sealed, this becomes an expensive matter and as a result the thermostats once installed are not tested. We attacked this problem some months ago and, as a result, we are installing in many St. Louis station transformers, thermostats made by a well-known manufacturer of heating apparatus who knew nothing of the possible applications to this field. These thermostats are no closer to the "hot spot" than their predecessors—(that being another problem)—but they may be removed and tested without even taking the transformer off the line. This applies to the "sealed" types of transformers as well as others.

The control of cooling water, so far as the thermostat is concerned, is also partly solved by the above, but, automatically operated water valves have not been given sufficient attention. The author has had experience with two types of valves which are furnished by the electrical manufacturers,—the motor operated type and the type which is operated by the expansion and contraction of a gas or fluid in a capillary tube. In his opinion, the latter type is dangerous, as a leak in the pressure system renders the device inoperative without visible indication of trouble until it fails to operate—

and perhaps the load lost. The motor-operated valve, of course, depends upon the continuity of the wiring and the 100 per cent behavior of the motor, which is usually small and operates through a reduction gear, the friction of which is a large percentage of the total power required. The author's experiences with both of the above types have been unhappy, in that both types have failed to function on many occasions, resulting (fortunately in one case only) in the loss of 5000 kw. of distribution load for about one hour. A water valve has been made up of standard materials; this by means of current flowing through a solenoid, holds the water off. The opening of the circuit to the solenoid by the thermostat allows the law of gravity to turn the water on. This device is in effect a closed circuit one and accidents (electrical or mechanical), can result only in wasted water. Some of these devices have been in operation in St. Louis for two years without a failure and almost all station transformers, under the writer's jurisdiction, either have been or are being equipped with this type of valve.

No attempt has been made to protect against failure of induction regulators for distribution circuits, other than to depend on the overload relays to clear them from the line when failure actually occurs. The induction regulator is admittedly a weak piece of apparatus because of its very nature; and it would seem advisable to take steps to give them at least temperature protection. There is a tendency on the part of the operating companies to allow their distribution feeders to become overloaded and, with regulators designed for a 55-deg. rise, this abuses the regulator. The failure of an induction regulator in a manual station may not be serious when an operator who can operate a fire extinguisher is present, but here, again, in the automatic station, we have in most cases failed to provide any protection against fire except faith. Automatic equipment possesses only the intelligence which is incorporated in its design and this falls short of human intelligence in that we have not as yet been able to give it all five of the human senses. It can only *feel* but does not possess the senses of smell, taste, hearing or sight. In manual stations many serious accidents have been forestalled by the operator's ability to "smell something getting hot," *hear* the growl of an arc or *see* smoke issuing from a piece of apparatus the protective devices for which have not *felt* the necessity of removing it from the line; that necessity not being felt until the trouble has developed into a short-circuit, which usually means fire. In general, while this class of station may be said to be satisfactory, it is obvious that there is still a very extensive field in which to progress.

Class 3—Automatic D-C. Substations Feeding Heavy Edison Networks

This class has been developed mostly along the lines of single-unit stations consisting of a motor-generator set or synchronous converter located here and there throughout systems, the major portion of the system being manually operated. This means that the automatic stations are merely followers supplying power to parts of the net-work which grew out of the original manual capacity. In systems of over 30,000 or 40,000 kw. cases where automatic stations are the predominating factors are extremely rare; if, in fact, there are any at all. Where the system is so heavy, it is usually of high density and this in turn means not only a large number of stations but stations of such capacity that several large units per station are necessary. With these large stations close together, parallel operation begins to present a problem. To begin with, the demand upon the operating attendants in the manual stations of such a system is that they hold the "standard feeder-end pressure" to within one volt (0.5 volt per side). There is a reason for this other than the required candle power of customer's lamps, and it is a fact that by lowering or raising the voltage in a station one volt from standard, upwards of 1000 kw. of the load will be shifted to and from adjacent stations. The writer has been unable to find on the market an automatic regulating device which could be applied to this class of service and which might be adjusted to give closer than 1.5 volts, plus or minus (a zone of three volts) on the 240-volt basis. It is obvious then that the stations would not only not give sufficiently close regulation but would be continually "stealing" load from each other. It might be possible, of course, by means of costly pilot circuits to prevent the load from shifting, but we would still lack the precision in voltage regulation at the customer's lamp. On voltage regulators it would seem that some intensive development is necessary. The voltage regulator being the keynote to this situation, too much stress cannot be placed on this point. The question of parallel operation of any number of machines in the same station is being worked upon and there seems to be no doubt that all obstacles will ultimately be overcome; not however, without doing some things that have never been done before. It is always possible to make each machine literally an isolated station by feeding directly into the system over its own feeders, but it means that all copper is not working on light loads unless some extra money is invested in heavy bus tie breakers and, after all, it is dodging the main problem. While the apparent "intelligence" of some of the d-c. automatics now in service, is remarkable, we are still relying too much upon pilot wires and periodical inspection to approach the intelligence of an operating attendant. We must remember that automatic equipment will do just the things we build it to do and, incidentally, keep on doing them even if dangerous to life or property. In other words, it cannot use judgment, change its mind nor respond to the dictates of fear. This means that the equipment comprising an automatic station must be rugged in every detail. For example, it would not be desirable to protect all d-c. circuit-breakers with temperature devices and they

should therefore be selected so as to allow ample margin. Based on actual experience, the author feels that no d-c. circuit-breaker in this class of service should be operated at a contact brush density of more than 350 amperes per sq. in. If heavier duty is imposed it is possible for a breaker to heat up so quickly that its bridges will be annealed before this is discovered. The author advocates the use of "maximum" thermometers, the fluid columns of which remain at the highest point reached unless shaken down intentionally. One of these thermometers on the contact block of each breaker will divulge, to the inspector, the value of the highest temperature reached during his absence and an oxidized contact can be caught before the critical point (annealing) is reached. This same idea may be applied to bearings, as the only protection they now have is through the medium of a gas type thermostat by which the machine is locked out when a dangerous temperature is reached on any of the bearings. Ventilating equipment is another factor that should be fortified with ample margin and ruggedness, as in most cases the station cannot operate unless its ventilating equipment is delivering. Again the "maximum" thermometer is useful, as it can be applied to the machine and outside temperatures in conjunction with recording load-indicating devices to determine if the equipment has been properly cooled in the absence of the inspector and a brewing case of trouble arrested. The method of tripping oil and air circuit-breakers and contactors is one that should have close attention. There is a tendency to employ, so far as possible, standard breakers which almost always are held in by a mechanical latch or toggle. This must be struck sharply by the tripping solenoid to actually open the main device. Breakers furnished for standard manual application have been known to fail to trip on the first impulse of the tripping solenoid and as there is no attendant in an automatic station to follow up and trip it manually, this breaker remains closed. The author feels that a holding-in type of latch should be used in these applications, as it does not depend on the continuity of an electrical circuit for its operation. In some cases this is not possible, as in the case of automatizing an existing station already equipped. We have partly solved this problem by the application of two relays in the tripping circuit, so connected that if the main device does not open at the first impulse, it is followed up by a succession of hammer blows which will either open the toggle or break it, in which latter case the main device, although broken, would be opened. Too much stress cannot be brought to bear on the matter of auxiliary switches on the mechanisms of all types of breakers. Originally these switches were for the sole purpose of operating indicating lamps and an occasional interlock. In an automatic station there is hardly an operating circuit that does not interlock through the auxiliary switch of some breaker or contactor and it follows that the failure of almost any of these auxiliary switches will cripple the station. The author has had some bad experiences with this equipment, both where existing devices were automatized and where the equipment was furnished specifically for automatic operation.

General

While the author feels that progress is being made, there is still too much of a tendency to be satisfied with some questionable equipment as its exists. It is necessary that we look further into the future and in solving the problems which we encounter as we go along, bear in mind the importance to always leave sufficient margin so that that particular thing will be forever placed behind us.

Discussion

E. C. Stone: I want to second vigorously Mr. Millan's conclusion that the auxiliary equipment, relays, etc., which are used in automatic substations must be designed with a very great degree of reliability.

Automatic equipment adds cost to the station but we often forget that it saves operators' salaries. In any event the automatic equipment is only a small percentage of the cost of the stations and we should not hesitate to spend even 50 per cent more on it if, by doing so, we could be assured of obtaining perfect operation.

Chester Lichtenberg: One point which might be emphasized is the rapid development of automatic-station control equipment during the past three years. A survey of the situation indicates that during this period a great deal more attention has been paid to the details of design not only of the complete equipments but also of the individual devices so as to make them of maximum reliability with minimum maintenance.

For feeder-voltage regulators Mr. Millan suggests two types of protection.

1. Grounding protective relay.
2. Temperature protective relay.

Both of these devices are available and have been in automatic station service for several years. The grounding protective relay (device function No. 64) is quite well known in certain parts of the country where it has proven exceptionally valuable in giving the impulse for disconnecting apparatus from service when such apparatus developed faults to ground. The same device slightly modified last year has been successfully applied to feeder-voltage regulators and other similar devices. It will operate on any fault to ground in excess of 30 amperes and in combination with suitable oil circuit breakers affords protection against extensive damage.

Temperature protective relays (device function No. 49) for feeder-voltage regulators are available. They have not been sold in general, however, because the purchasers of the feeder-voltage regulators do not care to pay the small additional expense which these devices would add.

Most of the a-c. automatic stations which have been installed to date are of the relatively simple type described by Mr. Millan. There are outstanding examples, however, of very complete a-c. automatic stations which are very much more extensive and which have been in successful operation for three or more years. For example, the Kansas City Power & Light Company has had in operation since 1921 two a-c. automatic substations. They each have two or more incoming lines with two or more banks of transformers and a dozen or more outgoing feeders. The stations are designed so as to have only sufficient transformers connected in service to supply power to the load. Consequently, in times

of light load a minimum transformer capacity is excited. The stations are also arranged so that in case of trouble to any transformer bank or incoming line the bank or line is automatically switched out of service and replaced by an emergency bank or line.

The successful operation of these automatic stations emphasizes another point. It is the requirement that relaying devices for automatic substations be considered on quite a different basis from those for manual substations. In the manual station there is an attendant. It is his ordinary duty to watch the instruments provided for him so that he may check the operation of the various relays, etc. In case of trouble he is expected to substitute himself for the relay devices should they fail. In an automatic station there is no attendant. If a relay is called upon to perform its function it must not only be ready to perform that function but must perform it successfully. If there is dust on the contacts the contacts must be so designed that when operating the dust must either be wiped off or contact be made notwithstanding the dust. If the operation is to occur at 180 volts then it must occur at 180 volts and not wait until the pressure is at some other value. This has meant a new and very rigid standard with regard to the performance of relaying devices for automatic stations and the successful operation of several thousand of these during the past ten years evidences what can be done.

In connection with automatic stations there have been developed a number of supervisory systems. Some of these use automatic telephone relays. Such relays are suited for automatic telephone-central service but are not suited for automatic power-substation service. For example, the usual automatic telephone exchange has reasonably clean rooms kept at a relatively constant temperature. Besides, the relays are usually inspected and tested about once a day or at the most once a week. In automatic station service, however, supervisory system relays are frequently called upon to operate without inspection or test excepting at intervals of one month or more. The ones in the outlaying stations are subjected to temperatures varying from 40 deg. cent. below zero to 80 deg. cent. or more above zero. The conditions, therefore, are quite different and it is easy to see why a totally different class of relaying device is required for a supervisory system in automatic power-substation service than for automatic telephone-exchange work. This analysis has been proven correct by actual experience. So much so that one of the manufacturers furnishing supervisory systems has discarded all automatic telephone relays and uses relays developed exclusively for railway train-dispatching service where inspections are made not oftener than once a year. These relays represent almost the last word in relay development because experience has indicated that when correctly installed they require no maintenance and practically no inspection.

E. K. Huntington: In our system in Rochester, New York, we have recently installed two a-c. and one Edison automatic substations. The reference that various devices, which have been taken from the manual station and applied to the automatic station, should be more reliable is certainly one that needs our attention. Among these might be mentioned bearing temperature of relays and devices which cannot be easily tested after their installation. We have found that most devices are subject to change in calibration after installation and unless tested periodically are unreliable for that reason. In one automatic station in which there is a vertical hydro-generator, we are using a recording bearing-temperature device which not only records the bearing temperature and shows that it is working, but also has contacts on it for tripping the machine in case the temperature reaches the value at which the contacts are set to operate. Such a device seems very desirable where its cost is warranted.

We have found that constant attention is necessary on all devices in automatic stations. At the present time we are making a practise of putting each automatic operation through its complete cycle at least once every month, as a check upon the operation of various devices which may stand for a considerable time without operating in actual service.

In our Edison system, we have about a 20,000-kw. load supplied over an area of about one mile radius. The voltage-regulating devices, which were supplied with our Edison automatic substation equipment hold bus voltage within about two volts either way, or a four-volt swing on the 250-volt system. In our particular case, this has worked out very satisfactorily and no objectionable exchange of load has been noticed. More sensitive voltage-regulating devices are undoubtedly necessary, in supplying the highly concentrated loads of the larger cities but not in the average Edison system.

H. O. Stephens (communicated after adjournment): Mr. Millan points out a number of details in the automatic equipment which may give trouble on account of failure to operate. In particular, he mentions the possibility of trouble developing with thermostats and water-control valves on water-cooled transformers. The remedy is obvious and should not be passed over without mention.

When the type of transformer for automatic sub-stations is being selected, there are usually three choices available:

First: Water-cooled transformers.

Second: Combination self-cooled, water-cooled transformers capable of carrying light loads without water, but with automatic thermostats and valves for turning on the water supply for water cooling during peak loads.

Third: Self-cooled transformers capable of carrying the maximum peak load.

The cost of a self-cooled transformer will range from zero to fifty per cent greater than the cost of a water-cooled transformer, depending upon the size, complications, and voltage; while the cost of a combination self-cooled, water-cooled transformer will be approximately midway between the cost of a water-cooled transformer and a self-cooled transformer.

Transformers of all three types have been used in automatic substations but it is my opinion that while more or less practical control devices are on the market for controlling the water for water-cooled and combination self-cooled water-cooled transformers, they involve altogether too "clever" designing. The simple self-cooled transformer capable of carrying the maximum peak load is the obvious solution as all of the auxiliary thermostats and valves for controlling the water supply are eliminated and the increase in cost of the self-cooled transformer can be justified when it is considered that the efficiency of the self-cooled transformer is also usually higher. The self-cooled transformer has another decided advantage since the oil temperature is a much better indication of the load than it is on a water-cooled transformer; while the oil temperature of combination self-cooled water-cooled transformer fluctuates so widely that it is of little or no value in indicating the load. A reliable thermostat for tripping off the load in case the transformer reaches a dangerous temperature can readily be installed in the top oil of a self-cooled transformer. These facts should be very carefully considered before deciding on the use of anything but self-cooled transformers in an *automatic* substation.

Initial and Sustained Short-Circuits in Synchronous Machines

Analytical and Graphical Treatment of General Cases of Armature Windings Displaced by Arbitrary Angles, with Applications to One-, Two- and Three-Phase Machines

BY VLADIMIR KARAPETOFF[1]

Fellow A. I. E. E.

Synopsis.—A knowledge of the instantaneous values of armature and field currents, when an alternator is short-circuited, is becoming of increasing practical importance. These currents determine the rating of protective apparatus, mechanical stresses in the machine itself, possible damage to other equipment, etc. During the first few cycles, immediately after a short-circuit, the currents are usually much larger than those on sustained short-circuit, and gradually approach the latter values over a number of cycles. It is, therefore, necessary to distinguish between the initial and sustained values of currents, and formulas are deduced in this paper for both. The novel feature of the treatment consists in starting with a generalized unsymmetrical three-phase winding, also containing an external inductance in one of the phases. The Kirchoff equations are written and solved for this general case, and it is then shown how the formulas for the usual one-, two-, and three-phase machines can be directly derived from the general expressions, without considering the magnetic linkages in detail in each case. A graphical interpretation of the equations is also given, in the form of space-vector diagrams, in which the m. m. f s. vary according to the sine law in space but not in time.

Index to Appendices

INTRODUCTION

THE purpose of the paper is to deduce general formulas for the field and armature currents in a synchronous machine on initial and sustained short-circuit. While the subject is by no means new, the present treatment is perhaps more general than those published heretofore (See Appendix XII).

In a companion paper by R. F. Franklin, entitled "Short-Circuit Currents of Synchronous Machines," emphasis is laid upon the important practical cases, and the formulas are illustrated by calculated curves of currents. In the present paper, emphasis is laid upon the general method of derivation, and specific cases are carried out only far enough to show that the results check with Franklin's work.

In accordance with the preference of the Institute readers, the paper, itself, is made short and non-mathematical, while the details of derivation of the formulas are placed in the appendices to which references are made in the text.

THE DIAGRAM OF CONNECTIONS

Figs. 1 and 2 show a three-phase winding of a synchronous machine in which, for the sake of generality, the electrical angles between the phases are assumed to be different from 120 deg. Moreover, each phase winding is assumed to possess a different number of turns and therefore a different inductance (for notation, see Appendix XIII). An external inductance, L, is shown in series with one of the armature windings, and equations are derived with this inductance in the circuit. By putting $L = 0$, an ordinary three-phase short-circuit is obtained; by putting $L = \infty$. the phase C is opened and a single-phase short-circuit is obtained between the phases A and B.

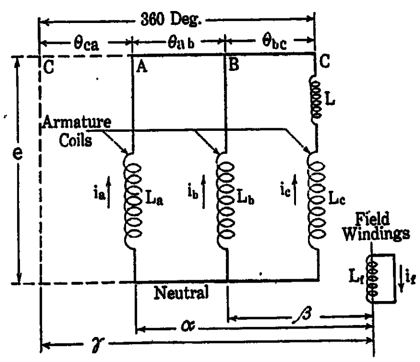

FIG. 1—GENERALIZED UNSYMMETRICAL THREE-PHASE WINDING

The field winding is assumed to be placed on a cylindrical rotor, so that the self and mutual inductances of the armature windings may be considered to remain constant throughout a cycle. Moreover, the mutual

1. Professor of Electrical Engineering, Cornell University, Ithaca, New York.

Presented at the Spring Convention of the A. I. E. E., St. Louis, April 13-17, 1925.

inductances between the field and the armature windings have been assumed to vary harmonically (Appendix I).

The resistances of all the windings are neglected altogether. For this reason, the field winding is shown in Fig. 1 short-circuited upon itself, since the excitation voltage is only necessary for overcoming the resistance of the winding. A certain field current is assumed to exist at the instant of short-circuit, and then to vary only under the influence of the armature currents so as to keep the flux linkages constant; equations (4) and (25).

The assumption of zero resistances is justified during the first half cycle or so after the instant of short-circuit, when the magnetic fluxes essentially determine the currents. With large alternators, this assumption is also justified for the armature windings on sustained short-circuit, the ohmic drop being practically negligible. The resistances of the windings enter as a factor in the gradual adjustment of the currents from the initial values to those on sustained short-circuit. This transitional period is not considered in the paper.

By neglecting the resistances, it becomes possible to integrate directly the Kirchoff equations (1) to (4). With resistance terms, the corresponding simultaneous differential equations become practically unsolvable. A few attempts to solve them even approximately in the simplest cases have led to expressions which are too complicated for practical use. The method of successive approximations, although quite tedious, may possibly be applied with more success.

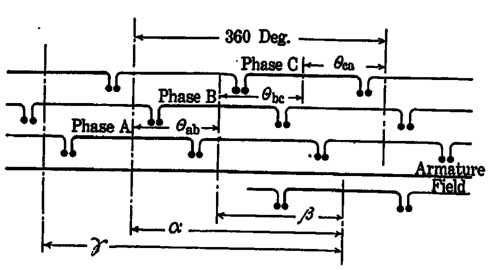

Fig. 2—The Relative Position of the Armature and Field Windings

Having obtained the fundamental equations, (1) to (5), for the general case shown in Fig. 1, and integrated them in the form of equations (22) to (25), various special cases are considered in the subsequent appendices, as indicated below.

Single-Phase Short-Circuit

The most general case of single-phase short-circuit considered in this paper is that through an external inductance (Appendix V). The angle, θ_{ab}, is put equal to zero and the windings in the phases A and B are assumed to coincide, so as to form but one winding. The current flows through this combined winding, through the inductance L, and through the phase winding C. Since the angle, θ_{bc}, is not necessarily equal to 180 deg., this case covers not only a short-circuit of a single-phase machine, but a single-phase short-circuit of a polyphase machine as well.

More specific cases are then considered in detail in Appendix VII, with the assumption $L = 0$. For the single-phase machine $L_c = 0$; for a two-phase machine the inductance L_c is equal to the parallel combination of L_a and L_b, and $\theta_{bc} = 90$ deg.; for a three-phase machine $\theta_{bc} = 120$ deg. The final formulas are shown to check with those in Franklin's paper. Finally, a graphical interpretation of the single-phase short-circuit is given in Appendix XI.

Polyphase Short-Circuit

The general expressions for the armature and field currents, equations (22) to (25), are first interpreted graphically, as shown in Fig. 4 (Appendix III). This figure gives a much clearer idea of the inter-relationship of the currents than the equations themselves. It is then shown in Appendix IV that when $L = 0$ and $L_c > 0$, the voltage e (Fig. 1) between the terminals and the neutral, is always equal to zero. This leads to a simplification of Fig. 4 to Fig. 6, and the corresponding equations are derived in Appendix VI. These equations are then applied to the usual two-phase and three-phase machines in Appendix VIII, and the results are shown to check with Franklin's formulas.

Individual vs. Common Short-Circuit

With two-phase and three-phase short-circuits, several cases have to be considered, as shown in Figs. 7 and 8. In the Appendix IX, it is shown that the cases 7 a and 7 b are electrically equivalent, and that identical currents may be expected in both, at least within the limits of the fundamental assumptions made in the paper. Similarly, the cases 8 a and 8 b are identical, but the case 8 c presents some additional features. The influence of the ohmic resistance and of the character of the mutual inductance between the phases is discussed, and the conclusion is reached that at least in usual alternators the currents in case 8 c may be expected to be approximately equal to those computed for the cases 8 a and 8 b.

Conclusion

The determination of short-circuit currents in synchronous machines is of considerable importance to the designer as well as to the operating engineer. These currents may cause considerable mechanical stresses in the machine, influence the selection of the protective equipment, determine the transient conditions in the connected lines, etc.

The fundamental equations with which this investigation begins (Appendix I), are of quite general application, and it is hoped that the mathematical portions of the paper, especially the general method, may be of service not only in cases in which the equations or their solutions actually apply, but also in other cases, (for example, in an induction machine), in which simi-

lar equations may be established and a similar method of solution used.

Mr. R. E. Doherty, of the General Electric Company, suggested this investigation as a sequel to his own well-known researches in the subject, and the author wishes to acknowledge, gratefully, his encouragement and assistance in the preparation of the paper. Mr. K. C. Mobarry read and corrected the manuscript and made several valuable suggestions, for which the author wishes to express to him his gratitude.

Appendix I

The Fundamental Equations

Referring to Fig. 1, let at an instant (t) the voltage between the neutral points be (e). Then, equating to (e) the total e. m. f. induced in phase (A), we have,

$$L_a\, d\, i_a/d\, t + M_{ab}\, d\, i_b/d\, t + M_{ca}\, d\, i_c/d\, t + d\,(M_{fa}\, i_f)/d\, t = e \qquad (1)$$

For notation, see Appendix XIII. The coefficients of mutual induction, M_{ab} and M_{ca}, do not vary with the time and therefore, are left outside the sign of the derivative. The coefficient of mutual induction, M_{fa}, between the field winding and the armature phase (A), is a function of time and, therefore, a derivative must be taken of the linkages, $M_{fa}\, i_f$.

By analogy, we can write for phases (B) and (C), respectively, with a cyclic substitution of the subscripts (a), (b), (c):

$$L_b\, d\, i_b/d\, t + M_{bc}\, d\, i_c/d\, t + M_{ab}\, d\, i_a/d\, t + d\,(M_{fb}\, i_f)/d\, t = e \qquad (2)$$

$$(L_c + L)\, d\, i_c/d\, t + M_{ca}\, d\, i_a/d\, t + M_{bc}\, d\, i_b/d\, t + d\,(M_{fc}\, i_f)/d\, t = e \qquad (3)$$

In equation (3), $(L_c + L)$ is used instead of (L_c), where (L) is the external inductance. (L) is not interlinked magnetically with any of the phases, and therefore does not enter in the other equations. For the field circuit, we have;

$$L_f\, d\, i_f/d\, t + d\,(M_{fa}\, i_a)/d\, t + d\,(M_{fb}\, i_b)/d\, t + d\,(M_{fc}\, i_c)/d\, t = 0 \qquad (4)$$

The first Kirchoff law, applied to the armature winding, gives,

$$i_a + i_b + i_c = 0 \qquad (5)$$

Equations (1) to (5) contain five unknown functions of time (t); namely, i_a, i_b, i_c, i_f, e; by solving the equations, all these functions can be determined.

The foregoing equations can be somewhat simplified by expressing the inductances through the corresponding equivalent permeances and the numbers of turns[2]. Moreover, with the fluxes and m. m. f's. assumed to be distributed sinusoidally along the air-gap, the various mutual inductances are simple cosine functions of the angles of separation between the two coils.

Let the permeance of the useful (or common) magnetic path through the field and the armature be $(\mathcal{P})$ henries. Let τ be the magnetic leakage coefficient of the field circuit, that is, let,

$$\tau = \Phi_{useful}/\Phi_{total} \qquad (6)$$

when the field alone is excited. Similarly, let (σ) be the magnetic leakage coefficient of the armature winding. Both (σ) and (τ) are less than unity. The four self-inductances can be expressed as follows:

$$L_a = \sigma^{-1}\, \mathcal{P}\, N_a^2;\; L_b = \sigma^{-1}\, \mathcal{P}\, N_b^2;\; L_c = \sigma^{-1}\, \mathcal{P}\, N_c^2 \qquad (7)$$

$$L_f = \tau^{-1}\, \mathcal{P}\, N_f^2 \qquad (8)$$

It is convenient to assume the external inductance coil (L) to have the same number of turns as one of the phase windings, for example phase (A), and to represent its equivalent permeance in the form, $k\, \sigma^{-1}\, \mathcal{P}$, so that,

$$L = k\, \sigma^{-1}\, \mathcal{P}\, N_a^2 \qquad (9)$$

The factor (k) may have any positive value between zero and infinity, so that equation (9) in no way limits the value which may be assigned to (L).

The simplest assumption which can be made in regard to the coefficients of mutual inductance is that they are harmonic functions of the space angles between the coils. This approximately holds true for machines in which the armature m. m. f. is distributed in space in accordance with the sine law. Let the coils in phase (B) be shifted until they completely coincide with the coils in phase (A). Then, the coefficient of mutual inductance between the two is equal to $\mathcal{P}_m\, N_a\, N_b$, where $\mathcal{P}_m$ is the mutual or common permeance of the magnetic circuit embraced by the two groups of coils. When the coils completely coincide, $\mathcal{P}_m = \sigma^{-1}\, \mathcal{P}$. Now, as the coil (B) is moved back to its true position, we may assume that the part of the flux due to (A) and linking with (B) varies as the cosine of the angle of shift. The mutual permeance varies in the same ratio. With these assumptions, we obtain the following expressions for the various M' s;

$$M_{ab} = \sigma^{-1}\, \mathcal{P}\, N_a\, N_b \cos\theta_{ab} \qquad (10a)$$

$$M_{bc} = \sigma^{-1}\, \mathcal{P}\, N_b\, N_c \cos\theta_{bc} \qquad (10b)$$

$$M_{ca} = \sigma^{-1}\mathcal{P}\, N_c\, N_a \cos\theta_{ca} \qquad (10c)$$

$$M_{fa} = \mathcal{P}\, N_a\, N_f \cos\alpha \qquad (11a)$$

$$M_{fb} = \mathcal{P}\, N_b\, N_f \cos\beta \qquad (11b)$$

$$M_{fc} = \mathcal{P}\, N_c\, N_f \cos\gamma \qquad (11c)$$

The coefficient of mutual inductance, M_{fa}, reaches its maximum when $\alpha = 0$. By definition, the coefficient of magnetic coupling, K, is determined from the relationship,

$$K^2 = (\text{max. } M_{fa})^2/(L_f\, L_a) \qquad (12)$$

Substituting the values from equations (7), (8), and (11a), we get, after reduction,

$$K^2 = \sigma\, \tau \qquad (13)$$

The variable angles α, β, γ, differ from each other by constant amounts; namely,

$$\beta = \alpha - \theta_{ab} \qquad (14)$$

$$\gamma = \alpha + \theta_{ca} \qquad (15)$$

2. V. Karapetoff, "The Magnetic Circuit," p. 184.

Instead of t, we shall take α for the independent variable, where

$$\alpha = \omega\, t = 2\,\pi\, f_0\, t \tag{16}$$

We then have,

$$d/d\,t = \omega\,.\,d/d\,\alpha = \omega\,.\,d/d\,\beta = \omega\,.\,d/d\,\gamma \tag{17}$$

It is convenient to represent (e) in equation (1) as a derivative of some function with respect to time, because then the equation can be integrated directly. We, therefore, put,

$$e = \sigma^{-1}\, \mathcal{P}\, N_a^2\, d\,s/d\,t \tag{18}$$

where (s) is a function of time, containing no constant term. However, any desired constant term may be added to (s) without changing the value of e in equation (18). We shall arbitrarily assume that this constant term is zero so that $s = 0$ when $e = 0$. The factors σ, N_a^2, and $\mathcal{P}$ are added in order later to cancel them on both sides of certain equations.

The following assumptions are further made:

(a) The coils (A) and (B) have the same number of turns (N), so that,

$$N_a = N_b = N \tag{19}$$

(b) The number of turns in coil (C) is (c) times that in (A); in other words,

$$N_c = c\,N \tag{20}$$

The factor (c) may have any value between zero and infinity.

(c) The number of turns in a field coil is (f) times that in the coil (A), so that,

$$N_f = f\,N \tag{21}$$

Substituting the foregoing expressions in equations (1) to (4), we obtain, after integration and simplification:

$$i_a + i_b \cos\theta_{ab} + c\, i_c \cos\theta_{ca} + f\,\sigma\, i_f \cos\alpha = s + A \tag{22}$$

$$i_b + c\, i_c \cos\theta_{bc} + i_a \cos\theta_{ab} + f\,\sigma\, i_f \cos\beta = s + B \tag{23}$$

$$(c^2 + k)\, i_c + c\, i_a \cos\theta_{ca} + c\, i_b \cos\theta_{bc} + c\, f\,\sigma\, i_f \cos\gamma = s + c\,C + [k\, I_c] \tag{24}$$

$$i_a \cos\alpha + i_b \cos\beta + c\, i_c \cos\gamma + f\,\tau^{-1}\, i_f = F\, f\, \tau^{-1}\, I_f \tag{25}$$

Here, (A), (B), (C), (F), are constants of integration; for the initial short-circuit conditions, they depend upon the values of the currents and of (s) at the instant of short-circuit. In order to make the initial constant (C) independent of (k), the term $k\,I_c$ is added in equation (24). This term is placed in the brackets to indicate that it is used only for the initial short-circuit. With a sustained or established short-circuit, the currents are independent of the initial values, such as I_c, and the term $k\,I_c$ is simply omitted.

Equations (22) to (25), together with equation (5), contain five unknown functions of the time-angle (α), namely i_a, i_b, i_c, i_f, s, and can be solved for these as simultaneous equations.

Appendix II

Constants of Integration

1.—*Armature Constants for the Initial Short-Circuit.*

For the instant of short-circuit, equations (22) to (24) become

$$U \cos\xi = S + A \tag{26}$$

$$U \cos(\xi - \theta_{ab}) = S + B \tag{27}$$

$$c\, U \cos(\xi + \theta_{ca}) = S + c\,C \tag{28}$$

where

$$U \cos\xi = I_a + I_b \cos\theta_{ab} + c\, I_c \cos\theta_{ca} + f\,\sigma\, I_f \cos\alpha_0 \tag{29}$$

$$U \cos(\xi - \theta_{ab}) = I_b + c\, I_c \cos\theta_{bc} + I_a \cos\theta_{ab} + f\,\sigma\, I_f \cos\beta_0 \tag{30}$$

$$U \cos(\xi + \theta_{ca}) = c\, I_c + I_a \cos\theta_{ca} + I_b \cos\theta_{bc} + f\,\sigma\, I_f \cos\gamma_0 \tag{31}$$

In equation (29), the initial linkages on the right-hand side are arbitrarily denoted by $U \cos\xi$. Granting this notation, the other two equations can be deduced as follows:

Let I_a, I_b, I_c, I_f and U be thought of as vectors (in space, *not* in time.) Then equation (29) may be thought of as the real part of the expression

$$U\,\epsilon^{j\xi} = I_a\,\epsilon^{j0} + I_b\,\epsilon^{j\theta_{ab}} + c\, I_c\,\epsilon^{j\theta_{ca}} + f\,\sigma\, I_f\,\epsilon^{j\alpha_0} \tag{32}$$

Multiplying this equation throughout by $\epsilon^{-j\theta_{ab}}$, and equating the real parts, equation (30) is obtained. Multiplying both sides of equation (32) by $\epsilon^{j\theta_{ca}}$ and equating the real parts, gives equation (31).

To solve equations (29) to (31) for (U) and (ξ), use equation (32), since it gives, directly, the values of $U \cos\xi$ and $U \sin\xi$. Dividing the second value by the first will give $\tan\xi$ and consequently $\cos\xi$. (U) is then found by dividing the expression for $U \cos\xi$ by $\cos\xi$.

In the actual solution of equations (22) to (25), the first step is to eliminate (s) by subtraction. Consequently, it is also convenient to eliminate (S) from equations (26) to (28). We then get[3]

$$B - A = 2\,U \sin 0.5\,\theta_{ab} \sin(\xi - 0.5\,\theta_{ab}) \tag{33}$$

$$A - c\,C = U\, b \sin(\xi + \theta_{ca}') \tag{34}$$

where

$$b \sin\theta_{ca}' = 1 - c\cos\theta_{ca} \tag{35}$$

$$b \cos\theta_{ca}' = c \sin\theta_{ca} \tag{36}$$

Equation (34) is deduced as follows: Subtracting equation (28) from equation (26), we get

$$U\,[\cos\xi - c\cos(\xi + \theta_{ca})] = A - c\,C \tag{37}$$

Expanding the expression in the parentheses and introducing the quantities (b) and θ_{ca}', according to the defining equations (35) and (36), gives:

$$U\,[b\cos\xi \sin\theta_{ca}' + b\sin\xi\cos\theta_{ca}'] = A - c\,C \tag{38}$$

3. The symbol (b) appearing in equations (35) and (36), and later in equations (66) and (67), has nothing to do with phase (B), but is an auxiliary constant defined by these equations.

From this expression, equation (34) follows directly. A geometric interpretation of the auxiliary quantities (b) and θ_{ca}' is shown in Fig. 3. ($A\,C$) represents the phase (A), with the number of turns arbitrarily assumed to be equal to unity. To the same scale, ($A\,B$) represents the winding of the phase (C), with the number of turns (c) times that of phase (A). The space angle between the windings is θ_{ca}. The closing line of the triangle ($A\,B\,C$) represents (b), and the angle which it forms with the normal to ($A\,C$) is equal to θ_{ca}'. Equations (35) and (36) are then satisfied. We also have

$$b^2 = 1 + c^2 - 2\,c\cos\theta_{ca} \qquad \textbf{(38a)}$$

$$\tan\theta_{ca}' = (1 - c\cos\theta_{ca})/(c\sin\theta_{ca}) \qquad \textbf{(39)}$$

When $$I_a = I_b = I_c = 0 \qquad \textbf{(40)}$$

equations (29) to (31) simply become

$$U = f\,\sigma\,I_f; \quad \xi = \alpha_0 \qquad \textbf{(41)}$$

with the corresponding simplification of equations (33) and (34).

Because of the form (41) to which the expression for (U) is reduced in the simplest case, it is convenient for some purposes to put generally:

$$U = u\,f\,\sigma\,I_f \qquad \textbf{(42)}$$

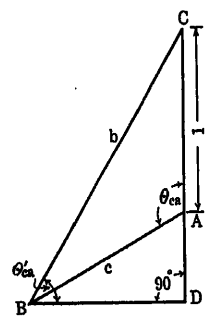

FIG. 3—DEFINITION OF THE AUXILIARY QUANTITIES B AND θ_{ca}

where (u) is a proper factor to make equation (42) agree with equations (29) to (31).

It is shown in Appendix IV that when $k = 0$, (s) is equal to zero at all instants, so that (S) is also equal to zero. Equations (26) to (28) are then simplified accordingly.

2.—Armature constants for the permanent short-circuit.

In this case, omitting the term [$k\,I_c$] in equation (24), we simply have:

$$A = B = U = 0 \qquad \textbf{(43)}$$

and $$C = 0 \qquad \textbf{(44)}$$

for the following reasons: The armature currents i_a, i_b, i_c in equation (22), can have no d-c. component, because the phenomenon now consists in an established operation of the alternator, all transients having died out. Hence, the average value of each current over a cycle is equal to zero; since

$$\text{average } i = (2\,\pi)^{-1}\int_0^{2\pi} i\,d\,\alpha$$

we have, $$\int_0^{2\pi} i\,d\,\alpha = 0 \qquad \textbf{(44a)}$$

The field current, i_f, has a d-c. component and (we may provisionally assume) has some sinusoidal harmonics. However, a sine-wave component of fundamental frequency is absent because it could be induced only by a stationary armature flux or by one moving at twice the synchronous speed. Therefore, expanding the field current into a Fourier series, we have,

$$i_f = i_0 + i_2\sin(2\,\alpha + \mu_2) + i_3\sin(3\,\alpha + \mu_3) + \text{etc.}$$

and consequently

$$i_f\cos\alpha = i_0\cos\alpha + i_2\cos\alpha\sin(2\,\alpha + \mu_2) + i_3\cos\alpha\sin(3\,\alpha + \mu_3) + \ldots + i_n\cos\alpha\sin(n\,\alpha + \mu_n) \qquad \textbf{(44b)}$$

But,

$$\cos\alpha\sin(n\,\alpha + \mu_n) = 0.5\sin[(n+1)\,\alpha + \mu_n] + 0.5\sin[(n-1]\,\alpha + \mu_n].$$

Multiplying by $d\,\alpha$ and integrating over a cycle, we get,

$$\int_0^{2\pi}\cos\alpha\sin(n\,\alpha + \mu_n)\,d\,\alpha = 0$$

Hence, if we multiply equation (44b) by $d\,\alpha$ and integrate over a cycle, each term on the right-hand side is separately equal to zero, and consequently

$$\int_0^{2\pi} i_f\cos\alpha\,d\,\alpha = 0 \qquad \textbf{(44c)}$$

Therefore, from equations (44a) and (44c) we see that if equation (22) is multiplied by $d\,\alpha$ and integrated over a cycle, each term on the left-hand side is separately equal to zero, so that the right-hand side is also equal to zero.

But, by assumption, (s) has no constant term and consists of sinusoidal terms only, so that its integral over a cycle is equal to zero. Consequently $2\,\pi\,A = 0$ or $A = 0$. By a similar reasoning it can be shown from equation (23) that $B = 0$; equation (44) can be proved from equation (24). The result $U = 0$ follows from equations (33) and (34).

3.—Field Constant for the Instant of Short-circuit.

The constant of integration (F), in equation (25), is determined from the condition

$$(F - 1)\,f\,\tau^{-1}\,I_f = I_a\cos\alpha_0 + I_b\cos\beta_0 + c\,I_c\cos\gamma_0 \qquad \textbf{(45)}$$

When the condition (40) is satisfied,

$$F = 1 \qquad \textbf{(46)}$$

4.—Field Constant for Permanent Short-Circuit.

Permanent armature currents can induce in the field winding only alternating voltages, without any d-c. component. Hence, the average value of i_f over a cycle is equal to the actual value I_f of the field current at no-load. In other words

$$\int_0^{2\pi} i_f\,d\,\alpha = 2\,\pi\,I_f \qquad \textbf{(47)}$$

Under the assumed conditions, the field current is a periodic function of α; so that, in general, we may write,

$$i_{fp} = m\, F\, I_f\, \phi\,(\alpha) \tag{47a}$$

where the subscript (p) signifies "permanent," (m) is a known constant, and $\phi\,(\alpha)$ is a certain function of the time-angle α. Therefore, equation (47) becomes:

$$m\, F \int_0^{2\pi} \phi\,(\alpha)\, d\,\alpha = 2\,\pi \tag{47b}$$

Knowing (m) and $\phi\,(\alpha)$, the factor (F) can be determined from this expression.

In this investigation, only two particular forms of $\phi\,(\alpha)$ occur. Each of these forms permits definite integration and, hence, a solution for (F). For a two-phase or three-phase short-circuit, with $k = 0$, $i_{fp} = I_f$ (see equation **134**), so that it is permissible to put $F = m = \phi\,(\alpha) = 1$. With a single-phase short-circuit, equation (**106**), the function ϕ is of the form:

$$\phi\,(\alpha) = [n - 2\,q \sin^2(\alpha - \theta')]^{-1} \tag{48}$$

where n, q, θ', are known constants. Equation (**48**) may also be written as

$$\phi\,(\alpha) = [(n - q) + q \cos 2\,(\alpha - \theta')]^{-1} \tag{48a}$$

Integrating in this latter form, we get[4]

$$\int_0^{2\pi} \phi\,(\alpha)\, d\,\alpha = 2\,\pi / \sqrt{(n - q)^2 - q^2} \tag{49}$$

so that, from equation (**47b**),

$$F_{1p} = m^{-1} \sqrt{(n - q)^2 - q^2} \tag{49a}$$

The subscript (p 1) signifies "permanent single-phase short-circuit."

Appendix III

Graphical Representation of the Linkage Equations (22) to (25) in a Polyphase Short-Circuit[5]

Equations (**22**) to (**25**) are represented in Fig. 4 by means of a polygon of *space vectors*. The currents being non-sinusoidal in time, no ordinary time-vector diagrams can be used. However, the distribution of all the m. m. f's in space being by assumption sinusoidal, these m. m. f's, for a particular instant of time, can be represented by space vectors. For another instant of time, the lengths of the vectors i_a, i_b, i_c, i_f, and the angle (α), are different, but the angles θ_{ab}, θ_{bc}, θ_{ca}, ξ, and the lengths $O\,K$ and $H\,N$ remain constant.

Taking first equation (**22**) and substituting for (A) its value from equation (**26**), we get:

$$\begin{aligned} i_a + i_b \cos \theta_{ab} + c\, i_c \cos \theta_{ca} + f\, \sigma\, i_f \cos \alpha \\ = U \cos \xi + (s - S) \end{aligned} \tag{50}$$

In Fig. 4, $O\,A = i_a$ and $A\,B = i_b$, the space angle (*not* the time angle) between these two m. m. f. vectors being θ_{ab}. Since $i_a + i_b + i_c = 0$, instead of laying off the vector $c\, i_c$ in the direction of i_c, we draw the vector $c\,(i_a + i_b) = B\,C$ in the opposite direction. Let, at the instant shown in Fig. 4, the angle (α) be equal to $A\,O\,P$. In other words, if $O\,A$ represents the axis of an armature coil in phase A, $O\,P$ is the axis of the field coil, revolving clockwise.[6] The vector $C\,G = f\,\sigma\, i_f$ is drawn parallel to $O\,P$ and consequently at an angle α to $O\,A$. The vector $O\,K = U$ makes an angle ξ with $O\,A$. Finally, the vector $K\,A' = s - S$ is drawn parallel to $O\,A$. $K\,A'$ is shown as a chord of a circle drawn on $K\,G$ as a diameter. This is to indicate that $G\,A'$ is perpendicular to $O\,A$. The direction $G\,K$ is extended to L, and a circle is drawn on $K\,L$ as a diameter. The length of this diameter is such that the chord $K\,A'' = S$, where A lies on the same straight line with K and A'. Since $K\,A' = s - S$, we have that $A''\,A' = s$. Thus, by means of the two circles both s and S can be represented separately.

In the polygon $O\,A\,B\,C\,G\,A'\,K$, all the sides, except $A'\,G$, have been expressed through the physical quantities which enter into our problem. If, however, all the sides of the polygon be projected on $O\,A$, the side $A'G$ is eliminated, and we may write that

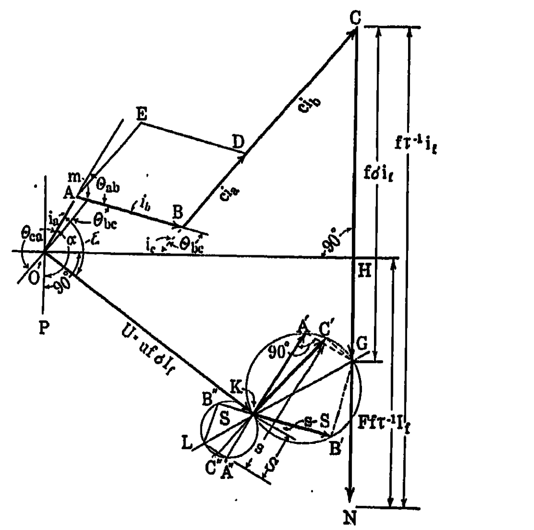

Fig. 4—Space Diagram of the Armature and Field m. m. f's.

$$\begin{aligned} &\text{Sum of projections on } O\,A \text{ of } (O\,A + A\,B + B\,C + C\,G) = \\ &\text{Sum of projections on } O\,A \text{ of } (O\,K + K\,A') \end{aligned} \tag{51}$$

A comparison of this equation with equation (**50**) shows the two to be identical, and we conclude that the above-mentioned polygon represents equation (**22**).

By analogy with equation (**50**), equation (**23**) may be written in the form:

$$\begin{aligned} i_b + c\, i_c \cos \theta_{bc} + i_a \cos \theta_{ab} + f\, \sigma\, i_f \cos \beta \\ = U \cos (\xi - \theta_{ab}) + (s - S) \end{aligned} \tag{52}$$

Thus, to represent equation (**23**), it is only necessary to replace $K\,A'$ by $K\,B'$ parallel to $A\,B$. When projecting the new polygon on the direction $A\,B$, the unknown vector $B'\,G$ is eliminated. Since both $K\,A'$ and $K\,B'$ are equal to $s - S$, the angles $A'\,K\,G$ and $B'\,K\,G$ must in reality be equal.

4. See, for example, Peirce's "Short Table of Integrals," p. 41, Equation (**300**), the last line.

5. For a similar representation in the single-phase case see Appendix XI.

6. The counter-clockwise rotation has been standardized for time vectors only, and there is no objection to using the clockwise rotation for space vectors.

To represent equation (**24**), we first eliminate $c\,C$ by using equation (**28**). The result is:

$$c^2 i_c + c\, i_a \cos \theta_{ca} + c\, i_b \cos \theta_{bc} + c\, f\, \sigma\, i_f \cos \gamma$$
$$= c\, U \cos (\xi + \theta_{ca}) + (s - S) - k\, i_c + [k\, I_c] \quad \textbf{(53)}$$

Here we have to distinguish between the case when $c > 0$ and when $c = 0$. When $c > 0$, both sides of equation (**53**) can be divided by c. The result corresponds to the polygon $O\,A\,B\,C\,G\,C'\,K$, where $K\,C' = (s - S)\, c^{-1} - k\, i_c\, c^{-1} + [k\, I_c/c]$ and is parallel to $B\,C$. When $c = 0$ equation (**53**) is reduced to:

$$s - S = k\, i_c - [k\, I_c] \quad \textbf{(53a)}$$

and permits to eliminate $s - S$ in a simple manner.

The polygon which corresponds to equation (**25**) is $O\,A\,B\,C\,H$, where:

$$C\,H = f\, \tau^{-1} (i_f - F\, I_f) \quad \textbf{(54)}$$

The sum of the projections of $O\,A + A\,B + B\,C + C\,H$ upon $O\,P$ is always equal to zero, for any value of angle α. In other words,

$$C N + \text{Sum of projections of } (O A + A\,B + B\,C) = H N \quad \textbf{(55)}$$

This is identical with equation (**25**).

As angle α varies, the directions $O\,A$, $A\,B$, $B\,C$ remain the same, only the values of the currents, and consequently the positions of the points A, B, C, vary. The vector $O\,K$ remains constant in magnitude and in direction. The vector $C\,N$ turns so as to remain parallel to $O\,P$, and its part $H\,N$ remains of constant length equal to $F\,f\,\tau^{-1}\,I_f$. The diameters $K\,G$ and $K\,L$ vary in magnitude and in direction.

When there is no external reactive coil (that is, when $k = O$), $S = s = O$ at all instants, and the voltage between the neutral points remains equal to zero (see proof below). Consequently, both circles in Fig. 4 shrink to zero and the diagram is considerably simplified; see Appendix VI.

Appendix IV

PROOF THAT $s = O$ WHEN $k = O$ AND $c > O$

Multiply equation (**50**) by $c \sin \theta_{bc}$, equation (**52**) by $c \sin \theta_{ca}$ and equation (**53**) by $\sin \theta_{ab}$, and add them together. In the result, the factor by which $c\, i_a$ is multiplied is

$$\sin \theta_{bc} + \sin \theta_{ca} \cos \theta_{ab} + \sin \theta_{ab} \cos \theta_{ca}$$
$$= \sin \theta_{bc} + \sin (\theta_{ca} + \theta_{ab}) \quad \textbf{(56)}$$

But, according to Figs. 1 and 2,

$$\theta_{ab} + \theta_{bc} + \theta_{ca} = 360 \text{ deg.} \quad \textbf{(57)}$$

so that $\sin (\theta_{ca} + \theta_{ab}) = - \sin (\theta_{bc})$ **(58)**

Therefore, expression (**56**) is identically equal to zero. Similarly, it can be proved that the resulting equation does not contain i_b and i_c.

One of the factors by which $c\, i_f$ is multiplied in the result is:

$$\text{Cos}\, \alpha \sin \theta_{bc} + \cos (\alpha - \theta_{ab}) \sin \theta_{ca} + \cos (\alpha + \theta_{ca}) \sin \theta_{ab}$$
$$= \cos \alpha (\sin \theta_{bc} + \sin \theta_{ca} \cos \theta_{ab} + \sin \theta_{ab} \cos \theta_{ca})$$
$$+ \sin \alpha (\sin \theta_{ab} \sin \theta_{ca} - \sin \theta_{ca} \sin \theta_{ab}) \quad \textbf{(59)}$$

In this expression, the term by which $\sin \alpha$ is multiplied is identically equal to zero, and the term by which $\cos \alpha$ is multiplied is the same as expression (**56**) which we have shown before to be equal to zero. Thus, the resultant equation does not contain i_f. For the same reason the quantity (U) is eliminated. Thus, the result is:

$$(s - S)\,(c \sin \theta_{bc} + c \sin \theta_{ca} + \sin \theta_{ab})$$
$$= k\, i_c \sin \theta_{ab} - [k\, I_c \sin \theta_{ab}] \quad \textbf{(60)}$$

If k is not equal to zero then, since i_c is a function of time, (s) is also a function of time. But when $k = O$, s must be equal to (S), where (S) is a constant; consequently, (s) must also be constant. According to equation (**18**), this means that when $k = O$, (e) is also equal to zero, no matter how unbalanaced the phases may be. But, by assumption, (s) contains no constant term; hence, when $k = O$,

$$s = S = O \quad \textbf{(61)}$$

The foregoing deduction, being based on equations (**56**) and (**59**), presupposes that the coefficients of mutual inductance are harmonic functions of space angles; in other words, that equations (**10a**) to (**11c**) hold true. If the winding is such that these relations are not satisfied, or satisfied only approximately, (s) may depart from zero and be a function of time. When equation (**61**) is satisfied, only two out of the three equations, (**22**), (**23**) and (**24**), are independent of each other. The third one can be obtained by properly combining the other two. The same is true of equations (**50**), (**52**), and (**53**). This may be seen directly from Fig. 4. When $S = s = O$, point K coincides with G (Fig. 6) and the closed polygon $O\,A\,B\,C\,G\,K$ is the same for each of the three aforementioned equations. But the condition that a polygon is closed is expressed by stating that the sum of its projections on any two axes is equal to zero. It is superfluous to equate to zero the sum of its projections on any third axis, because the equations so obtained can be written by properly combining the other two equations. This follows from the fact that if the projections of a vector on two given directions are known, its projection on any third direction is also known.

Thus, in this case we have only four equations instead of five, but we also have only four unknown functions; namely, the armature currents and the field current. This case is considered in detail in Appendix VI.

The foregoing deduction, and the condition (**61**), do not necessarily hold true when one of the angles θ is equal to zero. Let, for example θ_{ab} be equal to zero, so that $\theta_{bc} = 360$ deg. $- \theta_{ca}$. Then equations (**50**) and (**52**) become identical and can no more be considered as independent equations. Moreover, both sides of equation (**53**) cannot be multiplied by $\sin \theta_{ab}$, because $\sin \theta_{ab} = O$. From the physical point of view, when any two of the windings,—say A and B,—coincide in space

they form a single phase, with the winding C as the return phase. We thus have a single-phase circuit, the sum of the currents i_a and i_b being considered as one current. The voltage between the neutral and the terminals (Fig. 1) is then not equal to zero, unless $c = O$, that is, unless the phase C is simply a jumper of negligible impedance. This case is further considered in Appendices V and X.

Appendix V

Single-Phase Short-Circuit Through an Inductance

Let, in Fig. 1 and 2, the angle θ_{ab} be equal to zero, so that the windings of the phases (A) and (B) coincide. Let the angle θ_{bc} now be simply denoted by θ; then, $\theta_{ca} = 360$ deg. $- \theta$. The currents (i_a) and (i_b) do not exist singly, but their sum is equal to $- i_c$. Equation (**50**) becomes,

$$- i_c (1 - c \cos \theta) + f \sigma i_f \cos \alpha = U \cos \xi + (s - S) \qquad (62)$$

Equation (**52**) becomes identical with equation (**62**) and cannot be used. Equation (**53**) becomes,

$$i_c (c^2 - c \cos \theta) + c f \sigma i_f \cos (\alpha - \theta) = c\, U \cos (\xi - \theta) + (s - S) - k\, i_c + [k\, I_c] \qquad (63)$$

Equation (**25**) becomes,

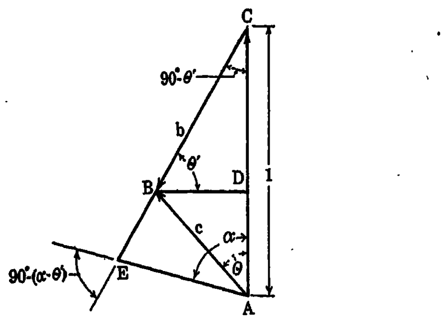

Fig. 5—Definition of the Auxiliary Quantities B and θ^1

$$f \tau^{-1} i_f + i_c [c \cos (\alpha - \theta) - \cos \alpha] = F f \tau^{-1} I_f \qquad (64)$$

To eliminate $(s - S)$, we subtract equation (**62**) from equation (**63**). The result is,

$$i_c [c^2 - 2\, c \cos \theta + 1 + k] + f \sigma i_f [c \cos (\alpha - \theta) - \cos \alpha] = U [c \cos (\xi - \theta) - \cos \xi] + [k\, I_c] \qquad (65)$$

In this equation, the expressions within all the brackets can be simplified by introducing auxiliary quantities (b) and (θ'), shown in Fig. 5. ($A\,C$) is a unity vector; ($A\,B$) is equal to (c) and is drawn at an angle (θ) to ($A\,C$). Then, (b) is the closing side of the triangle and (θ') is the angle between (b) and the perpendicular $B\,D$ to $A\,C$. Let the direction $A\,E$ be drawn at an angle α to $A\,C$. Then, from the geometry of the figure, the angle at E is equal to 90 deg. $+ \theta' - \alpha$, and we have,

$$1 - c \cos \theta = b \sin \theta' \qquad (66)$$

$$c \sin \theta = b \cos \theta' \qquad (67)$$

$$b^2 = c^2 + 1 - 2\, c \cos \theta \qquad (68)$$

Multiply equation (**66**) by ($\cos \alpha$) and equation (**67**) by ($\sin \alpha$); subtracting the first result from the second, gives,

$$c \cos (\alpha - \theta) - \cos \alpha = b \sin (\alpha - \theta') \qquad (69)$$

and by analogy,

$$c \cos (\xi - \theta) - \cos \xi = b \sin (\xi - \theta') \qquad (70)$$

Therefore, equation (**65**) becomes,

$$i_c (b^2 + k) + f \sigma b\, i_f \sin (\alpha - \theta') = U\, b \sin (\xi - \theta') + [k\, I_c] \qquad (71)$$

while equation (**64**) is reduced to,

$$b\, i_c \sin (\alpha - \theta') + f \tau^{-1} i_f = F f \tau^{-1} I_f \qquad (72)$$

Solving equations (**71**) and (**72**) for i_c and i_f, we get,

$$i_{f1} = \frac{F\, I_f [1 + (k/b^2)] - [k\, I_c]\, \tau \sin(\alpha = \theta')/(b f) - (U/f)\, \tau \sin (\xi - \theta') \sin (\alpha - \theta')}{[1 + (k/b^2)] - K^2 \sin^2 (\alpha - \theta')} \qquad (73)$$

$$i_{c1} = \frac{- (F/b)\, I_f f \sigma \sin (\alpha - \theta') + (U/b) \sin (\xi - \theta') + [k\, I_c]/b^2}{[1 + (k/b^2)] - K^2 \sin^2 (\alpha - \theta')} \qquad (74)$$

where K^2 is defined by equations (**12**) and (**13**), and the subscript (1) stands for "single-phase." For the determination of the constants, U, ξ, and F, see Appendix II. In particular, for a permanent short-circuit, $U = O$, $I_c = O$, and comparing equation (**73**) with equations (**47 a**) and (**48**), we find that,

$$m = n = 1 + (k/b^2); \quad q = 0.5\, K^2$$

Hence, equation (**49a**) will give,

$$F_{p1} = [1 + (k/b^2)]^{-1} \cdot \{ [1 + (k/b^2) - 0.5\, K^2]^2 - (0.5\, K^2)^2 \}^{0.5} \qquad (75)$$

For a graphical interpretation of equations (**71**) and (**72**), see Appendix XI.

Appendix VI

Three-Phase Short-Circuit Without External Inductance

It is shown in Appendix IV that $s = O$ when there is no external inductance in the phase C ($k = O$). In this case, Fig. 4 is simplified to Fig. 6, because the diameter $K\,G$ of the circle shrinks to zero.[7] The armature currents are shown in Fig. 6 in a somewhat different order; namely, the vectors $O\,A$ and $B\,D$ ($= A\,E$), both of which are proportional to (i_a), are placed in succession. Similarly, the vectors $A\,B$ ($= E\,D$) and $D\,C$, both proportional to (i_b), are drawn together. While the resultant vector between O and C is not changed thereby, it becomes possible to combine the vectors (i_a) and ($c\, i_a$) into one vector, $O\,E = l\, i_a$, where (l) is a numerical factor; the direction of $O\,E$ is characterized by the angle λ which it forms with $O\,A$. The sum of the vectors $E\,D$ and $D\,C$ is represented by the vector $E\,C = h\, i_b$, where (h) is a constant factor; $E\,C$ is

7. Fig. 6 does not hold true when $\theta_{ab} = 0$, even though (s) may be equal to zero. We then have a single-phase short-circuit, considered graphically in Appendix XI.

characterized by the position angle (η) which it forms with $O\,A$. In this manner, the number of armature current vectors between O and C is reduced from four to two, shown by the heavy lines.

Equations (50), (52), and (53), together with the conditions $s = S = k = O$, represent the sums of the projections of the sides of the closed polygon $O\,A\,B\,C\,G\,O$ (Fig. 6) on three different directions. But, the sum of the projections of this polygon on any axis is equal to zero. Hence, these three equations can be combined into one vectorial equation of the form:

$$i_a\,\epsilon^{j\delta} + i_b\,\epsilon^{j(\theta_{ab}+\delta)} + c\,i_c\,\epsilon^{j(-\theta_{ca}+\delta)} + f\,\sigma\,i_f\,\epsilon^{j(\alpha+\delta)} = U\,\epsilon^{j(\xi+\delta)} \tag{76}$$

In this expression, (δ) is an arbitrary angle; by giving it a suitable value and equating the real and the imaginary parts of equation (76) separately to zero, algebraic equations of projections on any two desired perpendicular directions can be obtained.

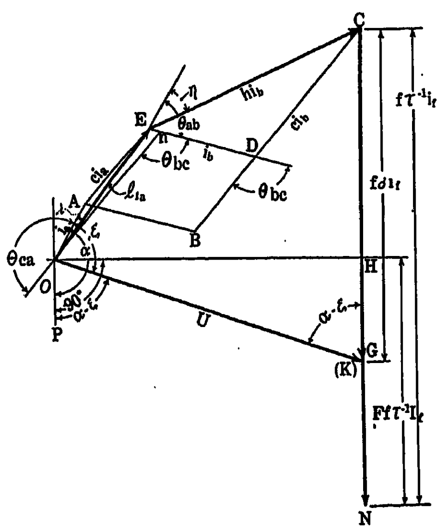

FIG. 6—A PARTICULAR CASE OF FIG. 4, WHEN $E = 0$

Substituting for (i_c) its value from equation (5), equation (76) becomes,

$$i_a\left[\epsilon^{j\delta} - c\,\epsilon^{j(-\theta_{ca}+\delta)}\right] + i_b\left[\epsilon^{j(\theta_{ab}+\delta)} - c\,\epsilon^{j(-\theta_{ca}+\delta)}\right] = U\,\epsilon^{j(\xi+\delta)} - f\,\sigma\,i_f\,\epsilon^{j(\alpha+\delta)} \tag{77}$$

The two vectors in the first brackets represent $O\,A$ and $A\,E$, respectively; the two vectors in the second brackets represent the vectors $E\,D$ and $D\,C$. Using their geometric sums, $O\,E$ and $E\,C$, equation (77) is simplified to:

$$l\,i_a\,\epsilon^{j(\lambda+\delta)} + h\,i_b\,\epsilon^{j(\eta+\delta)} = U\,\epsilon^{j(\xi+\delta)} - f\,\sigma\,i_f\,\epsilon^{j(\alpha+\delta)} \tag{78}$$

To solve this equation for i_a, we put,

$$\eta + \delta = 90 \text{ deg.} \tag{79}$$

Then, the real part of the equation becomes,

$$l\,i_a \cos(\lambda + 90 \text{ deg.} - \eta) = U \cos(\xi + 90 \text{ deg.} - \eta) - f\,\sigma\,i_f \cos(\alpha + 90 \text{ deg.} - \eta) \tag{80}$$

Solving for i_a, we get,

$$i_a = \frac{U \sin(\xi - \eta) - f\,\sigma\,i_f \sin(\alpha - \eta)}{l \sin(\lambda - \eta)} \tag{81}$$

By analogy, putting in equation (78) $\lambda + \delta = 90$ deg., we obtain,

$$i_b = \frac{U \sin(\xi - \lambda) - f\,\sigma\,i_f \sin(\alpha - \lambda)}{h \sin(\eta - \lambda)} \tag{82}$$

The auxiliary quantities (l) and (λ) are found from the equation,

$$l\,\epsilon^{j\lambda} = 1 - c\,\epsilon^{-j\theta_{ca}} \tag{83}$$

Equating separately the real and the imaginary parts, we get,

$$l \cos\lambda = 1 - c\cos\theta_{ca} \tag{84}$$

$$l \sin\lambda = c \sin\theta_{ca} \tag{85}$$

From these equations, (l) and (λ) can be readily computed. Similarly, for (h) and (η) we may write,

$$h\,\epsilon^{j\eta} = \epsilon^{j\theta_{ab}} - c\,\epsilon^{-j\theta_{ca}} \tag{86}$$

from which,

$$h \cos\eta = \cos\theta_{ab} - c\cos\theta_{ca} \tag{87}$$

$$h \sin\eta = \sin\theta_{ab} + c\sin\theta_{ca} \tag{88}$$

The field current (i_f) is determined from the condition,

$$H\,G = U\cos(\alpha - \xi) = H\,N - G\,N \tag{89}$$

Consequently,

$$U\cos(\alpha - \xi) = F\,f\,\tau^{-1}\,I_f - (f\,\tau^{-1}\,i_f - f\,\sigma\,i_f) \tag{90}$$

from which,

$$i_f = \frac{F\,I_f - \tau\,(U/f)\cos(\alpha - \xi)}{1 - K^2} \tag{91}$$

where K^2 is defined by equations (12) and (13). Substituting the value of (i_f) from equation (91) in equations (81) and (82), we get,

$$i_a = [(1 - 0.5\,K^2)\,U\sin(\xi - \eta) - \sigma f F I_f \sin(\alpha - \eta) + 0.5\,K^2\,U\sin(2\,\alpha - \xi - \eta)]/[l\,(1 - K^2)\sin(\lambda - \eta)] \tag{92}$$

$$i_b = [(1 - 0.5\,K^2)\,U\sin(\xi - \lambda) - \sigma f F I_f \sin(\alpha - \lambda) + 0.5\,K^2\,U\sin(2\,\alpha - \xi - \lambda)]/[h\,(1 - K^2)\sin(\eta - \lambda)] \tag{93}$$

In the derivation of these expressions, the following trigonometric transformation was used:

$$\cos(\alpha - \xi)\sin(\alpha - \eta) = 0.5\sin(2\,\alpha - \xi - \eta) + 0.5\sin(\xi - \eta) \tag{94}$$

From equations (92) and (93), using equation (5), we can readily find the value of $i_c = -(i_a + i_b)$.

Equations (91), (92), and (93), are not applicable when one of the space angles, say θ_{ab}, becomes equal to zero. This case is analyzed in Appendix X.

Appendix VII

SPECIAL CASES OF SINGLE-PHASE SHORT-CIRCUIT, EQUATIONS (73) AND (74)

When $k = O$, these equations are simplified as follows:

(a) *For the initial short-circuit,* with equations (40), (41), and (46) satisfied:

$$i_{f1i} = \frac{I_f\,[1 - K^2 \sin(\alpha_0 - \theta') \sin(\alpha - \theta')]}{1 - K^2 \sin^2(\alpha - \theta')} \qquad \text{(94a)}$$

$$i_{c1i} = \frac{(f\,\sigma\,I_f/b)[-\sin(\alpha - \theta') + \sin(\alpha_0 - \theta')]}{1 - K^2 \sin^2(\alpha - \theta')} \qquad \text{(95)}$$

where the subscript (1) stands for "single-phase" and the subscript (i) for "initial." The denominator can also be transformed into a function of 2 α; namely,

$$1 - K^2 \sin^2(\alpha - \theta') = (1 - 0.5\,K^2) + 0.5\,K^2 \cos 2\,(\alpha - \theta') \qquad \text{(96)}$$

If (i_{c1i}) and (i_{f1i}) are to reach their greatest possible values after the short circuit occurs, we must put,

$$\alpha_0 - \theta' = -\,90 \text{ deg.} \qquad \text{(97)}$$

Thus, equations (94) and (95) have their maxima at

$$\alpha - \theta' = 90 \text{ deg.} \qquad \text{(98)}$$

that is, half a cycle after the instant of short-circuit.

(1) *Single-phase machine,* or a polyphase machine with one phase-terminal grounded to the neutral. The winding C then electrically does not exist, so that $c = O$. From equations (66) and (67), $b = 1$ and $\theta' = 90$ deg. Consequently, $\alpha_0 = O$, and,

$$i_{f1i} = I_f\,\frac{1 - K^2 \cos\alpha}{1 - K^2 \cos^2\alpha} \qquad \text{(99)}$$

$$i_{c1i} = -\,f\,\sigma\,I_f\,\frac{1 - \cos\alpha}{1 - K^2 \cos^2\alpha} \qquad \text{(100)}$$

These expressions agree with Franklin's equations (10) and (11), remembering that his (i_a) is the same as our ($-\,i_{c1i}$).

(2) *Two-phase machine,* terminal-to-terminal short-circuit. In this case, $c = 1$ and $\theta = 90$ deg. Equations (66) and (67) are satisfied when $\theta' = 45$ deg. and $b = \sqrt{2}$. Consequently, $\alpha_0 = -\,45$ deg. and

$$i_{f1i} = I_f\,\frac{1 + K^2 \sin(\alpha - 45 \text{ deg.})}{1 - K^2 \sin^2(\alpha - 45 \text{ deg.})} \qquad \text{(101)}$$

$$-i_{c1i} = (f\,\sigma\,I_f/\sqrt{2})\,\frac{1 + \sin(\alpha - 45 \text{ deg.})}{1 - K^2 \sin^2(\alpha - 45 \text{ deg.})} \qquad \text{(102)}$$

These expressions are identical with Franklin's equations (23) and (24), keeping in mind that his current (i_a) in the machine itself is equal and opposite to our current (i_{c1i}) in the external connection.

(3) *Three-phase machine,* terminal-to-terminal short-circuit. In this case, $c = 1$ and $\theta = 120$ deg. Equations (66) and (67) give $\theta' = 60$ deg. and $b = \sqrt{3}$. Hence, $\alpha_0 = -\,30$ deg. and,

$$i_{f1i} = I_f\,\frac{1 + K^2 \sin(\alpha - 60 \text{ deg.})}{1 - K^2 \sin^2(\alpha - 60 \text{ deg.})} \qquad \text{(103)}$$

$$-i_{c1i} = (f\,\sigma\,I_f/\sqrt{3})\,\frac{1 + \sin(\alpha - 60 \text{ deg.})}{1 - K^2 \sin^2(\alpha - 60 \text{ deg.})} \qquad \text{(104)}$$

These expressions agree with Franklin's equations (40) and (41).

(b) *For the permanent short-circuit,* $U = O$. From equation (75), putting $k = 0$, we find

$$F_{p1} = \sqrt{1 - K^2} \qquad \text{(150)}$$

so that equations (73) and (74) become

$$i_{f1p} = I_f\,\frac{\sqrt{1 - K^2}}{1 - K^2 \sin^2(\alpha - \theta')} \qquad \text{(106)}$$

$$-i_{c1p} = [(I_f f \sigma \sqrt{1 - K^2})/b]\,\frac{\sin(\alpha - \theta')}{1 - K^2 \sin^2(\alpha - \theta')} \qquad \text{(107)}$$

In these expressions, the values of (b) and (θ') are the same as those computed above for the initial short-circuit. With these values, equations (106) and (107) will be found to check with Franklin's equations (80) and (81), except for the sign of the armature current, as explained above.

For a graphical representation of the field and armature currents in the single-phase case, see Appendix XI.

Appendix VIII

Some Particular Cases of Polyphase Short-Circuit, Equations (91) to (94)

(a) *Initial Short-Circuit.* Assuming equations (40), (41), and (46) to be satisfied, we get

$$i_{f23i} = I_f\,\frac{1 - K^2 \operatorname{Cos}(\alpha - \alpha_0)}{1 - K^2} \qquad \text{(108)}$$

$$i_{a23i} = f\,\sigma\,I_f\,\frac{(1 - 0.5\,K^2)\operatorname{Sin}(\eta - \alpha_0) + \operatorname{Sin}(\alpha - \eta) - 0.5\,K^2 \operatorname{Sin}(2\,\alpha - \alpha_0 - \eta)}{l\,(1 - K^2)\operatorname{Sin}(\eta - \lambda)} \qquad \text{(109)}$$

$$i_{b23i} = f\,\sigma\,I_f\,\frac{(1 - 0.5\,K^2)\operatorname{Sin}(\alpha_0 - \lambda) - \operatorname{Sin}(\alpha - \lambda) + 0.5\,K^2 \operatorname{Sin}(2\,\alpha - \alpha_0 - \lambda)}{h\,(1 - K^2)\operatorname{Sin}(\eta - \lambda)} \qquad \text{(110)}$$

where the subscript $23i$ stands for "two-phase- or three-phase, initial short-circuit"[8].

The field current reaches a maximum value

$$\max.\, i_{f23i} = I_f\,(1 + K^2)/(1 - K^2) \qquad \text{(111)}$$

at the field position corresponding to

$$\alpha - \alpha_0 = 180 \text{ deg.} \qquad \text{(112)}$$

that is, half a cycle after the instant of short-circuit.

Let it be required to find the values of α_0 and α such that the current i_a reaches its absolute maximum. The numerator of expression (109) becomes a positive maximum when the following three conditions are fulfilled:

$$\sin(\eta - \alpha_0) = 1 \qquad \text{(113)}$$

$$\sin(\alpha - \eta) = 1 \qquad \text{(114)}$$

$$\sin(2\,\alpha - \alpha_0 - \eta) = -\,1 \qquad \text{(115)}$$

These equations are satisfied when

$$\alpha_0 = \eta - 90 \text{ deg.} \qquad \text{(116)}$$

$$\alpha = \eta + 90 \text{ deg.} \qquad \text{(117)}$$

The same result can be obtained by equating to zero the partial derivatives of expression (109) with respect to α and α_0. We see that the armature current in phase

8. The equations deduced in this Appendix do not hold true when $\theta_{ab} = O$. We then have a single-phase short-circuit treated in Appendices V, VII, and XI.

A reaches its maximum half a cycle after the instant of the short-circuit. Substituting the value of α_0 from equation (116) in equations (108), (109), and (110), gives

$$i_{f23i} = I_f \frac{1 - K^2 \sin(\eta - \alpha)}{1 - K^2} \quad (118)$$

$$i_{a23i} = f\,\sigma\,I_f \frac{(1 - 0.5\,K^2) + \sin(\alpha - \eta) - 0.5\,K^2 \cos 2\,(\alpha - \eta)}{l\,(1 - K^2)\sin(\eta - \lambda)} \quad (119)$$

$$i_{b23i} = f\,\sigma\,I_f \frac{-\,(1 - 0.5\,K^2)\cos(\eta - \lambda) - \sin(\alpha - \lambda) + 0.5\,K^2 \cos(2\alpha - \eta - \lambda)}{h\,(1 - K^2)\sin(\eta - \lambda)} \quad (120)$$

(1) *Two-phase machine, two-phase short-circuit.* In this case $c = O$ and $\theta_{ab} = 90$ deg. From equations (84) and (85), $l = 1$ and $\lambda = O$. From equations (87) and (88), $h = 1$, $\eta = 90$ deg. Consequently,

$$\alpha_0 = O \quad (121)$$

$$i_{f2i} = I_f \frac{1 - K^2 \cos\alpha}{1 - K^2} \quad (122)$$

$$i_{a2i} = f\,\sigma\,I_f \frac{(1 - 0.5\,K^2) - \cos\alpha + 0.5\,K^2 \cos 2\,\alpha}{1 - K^2} \quad (123)$$

$$i_{b2i} = f\,\sigma\,I_f \frac{-\sin\alpha + 0.5\,K^2 \sin 2\,\alpha}{1 - K^2} \quad (124)$$

These expressions are identical with Franklin's equations (48) to (50).

(2) *Three-phase machine, two-phase short-circuit.* Here again $c = O$, but $\theta_{ab} = 120$ deg. Consequently $l = 1$; $\lambda = O$; $h = 1$; $\eta = 120$ deg. Therefore,

$$\alpha_0 = 30 \text{ deg.} \quad (125)$$

$$i_{f2(3)i} = I_f \frac{1 - K^2 \cos(\alpha - 30 \text{ deg.})}{1 - K^2} \quad (126)$$

$$i_{a2(3)i} = f\,\sigma\,I_f\,(2/\sqrt{3}) \cdot \frac{(1 - 0.5K^2) - \cos(\alpha - 30\text{deg.}) + 0.5K^2\cos 2\,(\alpha - 30\text{deg.})}{1 - K^2} \quad (127)$$

$$i_{b2(3)i} = f\,\sigma\,I_f\,(2/\sqrt{3}) \cdot \frac{0.5\,(1 - 0.5\,K^2) - \sin\alpha - 0.5\,K^2 \cos 2(\alpha + 30 \text{ deg.})}{1 - K^2} \quad (128)$$

These expressions agree with Franklin's equations (57) to (59).

(3) *Three-phase machine, three-phase short-circuit.* In this case $c = 1$; $\theta_{ab} = \theta_{ca} = 120$ deg. Hence, $l = \sqrt{3}$; $\lambda = 30$ deg.; $h = \sqrt{3}$; $\eta = 90$ deg. We therefore have:

$$\alpha_0 = O \quad (129)$$

$$i_{f3i} = I_f \frac{1 - K^2 \cos\alpha}{1 - K^2} \quad (130)$$

$$i_{a3i} = (2/3)\,f\,\sigma\,I_f \cdot \frac{(1 - 0.5\,K^2) - \cos\alpha + 0.5\,K^2 \cos 2\,\alpha}{1 - K^2} \quad (131)$$

$$i_{b3i} = -\,(2/3)\,f\,\sigma\,I_f \cdot \frac{0.5(1 - 0.5K^2) + \sin(\alpha - 30 \text{ deg.}) + 0.5\,K^2 \cos(2\alpha + 30 \text{ deg.})}{1 - K^2} \quad (132)$$

These equations check with Franklin's formulas (71) to (74).

(b) *Permanent Short-Circuit.* In this case, according to equation (43), $U = O$, so that equation (91) gives

$$i_f = F\,I_f/(1 - K^2) \quad (133)$$

But the armature currents cannot induce a constant e. m. f. in the field circuit, so as to reduce the field current I_f in a constant ratio $F/(1 - K^2)$. Hence,

$$i_f = I_f \quad (134)$$

and

$$F = 1 - K^2 \quad (135)$$

Equations (92) and (93) become

$$i_{a23p} = \frac{\sigma\,f\,I_f \sin(\alpha - \eta)}{l \sin(\eta - \lambda)} \quad (136)$$

$$i_{b23p} = -\,\frac{\sigma\,f\,I_f \sin(\alpha - \lambda)}{h \sin(\eta - \lambda)} \quad (137)$$

In these expressions, the same values of l, λ, h, η, apply as those deduced above for the initial short-circuit. We, therefore, get the following specific results, all of which check with the corresponding expressions deduced by Mr. Franklin.

(1) *Two-phase machine*:

$$i_{a2p} = -\,\sigma\,f\,I_f \cos\alpha \quad (138)$$

$$i_{b2p} = -\,\sigma\,f\,I_f \sin\alpha \quad (139)$$

(2) *Three-phase machine, two-phase short-circuit*:

$$i_{a2(3)p} = -\,(2/\sqrt{3})\,\sigma\,f\,I_f \cos(\alpha - 30 \text{ deg.}) \quad (140)$$

$$i_{b2(3)p} = -\,(2/\sqrt{3})\,\sigma\,f\,I_f \sin\alpha \quad (141)$$

(3) *Three-phase machine, three-phase short-circuit*:

$$i_{a3p} = -\,(2/3)\,\sigma\,f\,I_f \cos\alpha \quad (142)$$

$$i_{b3p} = -\,(2/3)\,\sigma\,f\,I_f \sin(\alpha - 30 \text{ deg.}) \quad (143)$$

Appendix IX

INDIVIDUAL VS. COMMON SHORT-CIRCUIT TO THE NEUTRAL

1. *Two-Phase Short-Circuit.* For a two-phase machine, the general diagram of connections shown in Fig. 1 is reduced to that shown in Fig. 7A, by putting $L = L_c = O$. Therefore, the formulas for two-phase short-circuit currents, deduced in Appendix VIII, apply to Fig. 7A. However, the currents in the case shown in Fig. 7B are identical with those in Fig. 7A, so that the same formulas hold true, no matter whether a common jumper (j) is used for both phases, or individual jumpers, (j_1) and (j_2), for each phase. The connection (j_3) does not affect the values of the currents.

The fact that the diagrams shown in Fig. 7A and

7B are electrically equivalent follows directly from a consideration of the magnetic linkages in both cases. The currents in Fig. 7B at each instant are of such values as to keep the flux in each circuit constant. But in Fig. 7A the points (p) and (q) are at the same potential, because the jumper (j), by assumption, is of zero resistance. Thus, the same two individual circuits exist in Fig. 7A as in 7B, and the first Kirchoff law does not enter in the problem. From a formal mathematical point of view, the same linkage equations can be written for both diagrams; hence, the solutions for the currents are also identical.

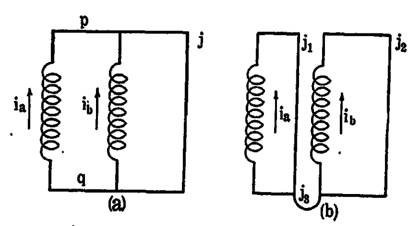

FIG. 7—COMMON AND INDIVIDUAL TWO-PHASE SHORT-CIRCUIT

2. *Three-Phase Short-Circuit.* When in Fig. 1 the external inductance (L) is omitted, the diagram of connections becomes identical with Fig. 8A. Therefore, the formulas deduced in Appendices VI and VIII apply first of all to the short-circuit of the three terminals, as shown in Fig. 8A. However, it may be shown that the same results hold true for the case shown in Fig. 8B, with a jumper connection (j) between the short-circuited terminals and the neutral, and also to the case shown in Fig. 8C where each phase is short-circuited individually.

It is proved in Appendix IV that the difference of potential between the points (p) and (q) in Fig. 8A is zero at all instants. Hence, the addition of the jumper (j), shown in Fig. 8B, does not alter the potential distribution in the phases. Moreover, the sum of the three armature currents in Fig. 8A is equal to zero at all instants, and since the phase currents are the same in Fig. 8B, the return current i_c in the common return conductor (j) theoretically is equal to zero. Of course, in practise, some return current may be expected, partly because the resistances have been neglected, and partly due to higher harmonics, multiple of three. Moreover, (s) has been shown to be equal to zero only when the mutual inductances obey the harmonic law, in accordance with equations (**10a**) to (**11c**); otherwise (s) may be a function of time.

For the case of the individually short-circuited armature phases, Fig. 8C, equations (**1**) to (**4**) apply, with $e = O$. Equation (**5**) does not necessarily hold true. By first transforming equations (**1**), (**2**), and (**3**) into the form (**50**), they can be finally combined into the vectorial equation (**76**). Equation (**4**) can be reduced to the form (**90**) and gives a perfectly definite value of the field current. Equation (**76**) is equivalent to two algebraic equations of projections, for the three unknown quantities i_a, i_b, i_c. Thus, the problem seems to be indefinite and to admit of an infinite number of sets of values of armature currents which satisfy all the equations which apply in this case.

This indefiniteness is due to two simultaneous assumptions made in this investigation; namely, (a) that the resistances of the windings are negligible and (b) that the coefficients of mutual induction are cosine functions of the space angles. If either one of these assumptions be dropped, the problem becomes definite. We shall consider the two cases separately.

(a) *Armature windings possess small resistances.* By assuming the resistances to be small, we can neglect their influence in the foregoing linkage equations, but at the same time add the condition that the heat generated is a minimum[9].

We then have

$$r_a i_a^2 + r_b i_b^2 + r_c i_c^2 = \text{min.} \tag{144}$$

This is a fourth condition which, with the foregoing three, makes it possible to obtain definite values of armature currents. For example, if the three resistances are equal, equation (**144**) may be written in the form

$$(i_{a0} + \Delta i)^2 + (i_{b0} + \Delta i)^2 + (i_{c0} + \Delta i)^2 = \text{min.} \tag{145}$$

where i_{a0}, i_{b0}, i_{c0} are some currents which satisfy Kirchoff's first law, so that

$$i_{a0} + i_{b0} + i_{c0} = O \tag{146}$$

The quantity Δi is the unknown difference between the real currents and the fictitious currents which satisfy equation (**146**). Equation (**145**) may be written in the form

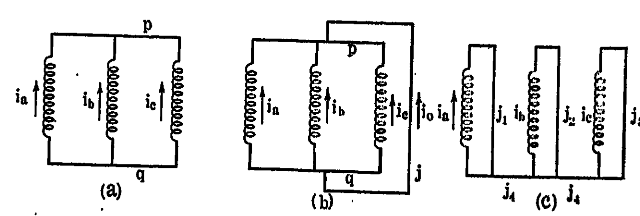

FIG. 8—THREE KINDS OF THREE-PHASE SHORT-CIRCUIT

$$\begin{aligned}(i_{a0}^2 + i_{b0}^2 + i_{c0}^2) + 2\,\Delta i\,(i_{a0} + i_{b0} + i_{c0})\\ + 3\,(\Delta i)^2 = \text{min.}\end{aligned} \tag{147}$$

The second term is equal to zero in view of equation (**146**), and the remainder becomes a minimum when $\Delta i = O$. Thus, the three currents which satisfy Kirchoff's first law produce the least amount of heat loss and are those which would actually flow under the limitations specified above.

In the general case, two of the armature currents, say i_a and i_b, can be expressed through the third, i_c, and

9. J. H. Jeans, The Mathematical Theory of Electricity and Magnetism, Fourth Edition, p. 321. Because of the small magnitude of the resistances and a comparatively low frequency, this law may be assumed to hold true for the variable currents in the case under consideration.

their values substituted in equation (144). Equating to zero the first derivative with respect to i_c, the latter can be determined, and consequently the other two currents evaluated.

(b) *The coefficients of mutual inductance between the armature windings depart from the cosine law.* In this case the equations (1), (2) and (3) still hold true (with $e = O$), but after integration give three independent equations, which cannot be reduced to two equations of projections, as heretofore. These three equations, together with the integrated equation (4), give four conditions which the four currents must satisfy. The problem is then perfectly definite.

As an example, consider three identical windings displaced by 120 electrical degrees, as in an ordinary three-phase alternator. Equations (1), (2), and (3), after integration and evaluation of the constants of integration, become:

$$L\, i_a + M\, i_b + M\, i_c + i_f\, M_f\, \psi\,(\alpha) = I_f\, M_f\, \psi\,(\alpha_0) \qquad (148)$$

$$L\, i_b + M\, i_c + M\, i_a + i_f\, M_f\, \psi\,(\alpha - 120 \text{ deg.}) = I_f\, M_f\, \psi\,(\alpha_0 - 120 \text{ deg.}) \qquad (149)$$

$$L\, i_c + M\, i_a + M\, i_b + i_f\, M_f\, \psi\,(\alpha + 120 \text{ deg.}) = I_f\, M_f\, \psi\,(\alpha_0 + 120 \text{ deg.}) \qquad (150)$$

In these expressions, the subscripts a, b, c, of (L) and (M) have been omitted since these quantities are the same in all the three armature phases, because of the assumed symmetry of the windings. M_f is the maximum value of the mutual inductance between the field winding and one of the armature phases, when the two are in space opposition. The function $\psi\,(\alpha)$ expresses the law according to which the mutual inductance between the field and an armature phase winding varies with the angle α. Adding the three equations term by term, we get:

$$(L + 2\,M)\,(i_a + i_b + i_c) = I_f\, M_f\,[\psi\,(\alpha_0) + \psi\,(\alpha_0 - 120 \text{ deg.}) + \psi\,(\alpha_0 + 120 \text{ deg.})\,] - i_f\, M_f\,[\,\psi\,(\alpha) + \psi\,(\alpha + 120 \text{ deg.}) + \psi\,(\alpha - 120 \text{ deg.})\,] \qquad (151)$$

Everywhere in the text above it is assumed that $\psi\,(\alpha) = \cos \alpha$. With this assumption, both expressions in the brackets on the right-hand side of the foregoing equation are equal to zero. On the left hand side, we then must have

$$\text{either} \qquad L + 2\,M = O \qquad (152)$$

$$\text{or} \qquad i_a + i_b + i_c = O \qquad (153)$$

Assuming equations (7) and (10) to hold true, equation (152) is satisfied, and, therefore, equation (153) does not necessarily have to be satisfied. This leads to the indeterminate case mentioned above. On the other hand, if the mutual inductances of the armature phases do not follow exactly the cosine law, while the mutual inductances between the field and the armature do, equation (152) is not satisfied, and, therefore, equation (153) must hold true. This is equivalent to including equation (5) with equations (1) to (4) and thus making the problem definite.[10]

Summing up the foregoing discussion, it would seem that in the case represented by Fig. 8C, the currents may be expected to satisfy equation (5) at least approximately, and that in machines of the usual types the short-circuit according to Fig. 8C is electrically equivalent and causes nearly the same currents as a short-circuit according to Fig. 8A or 8B.

Delta-connected machine. The conditions as analyzed above for Fig. 8C also apply to a short-circuit of all the three terminals of a delta-connected machine. Here also we have three individual windings, each short-circuited upon itself, with practically no current interchange between the phases. We, therefore, reach the conclusion that the short-circuit currents in the windings themselves have the same values as have been deduced above for Y-connected windings. The instantaneous current in each lead to a terminal is equal to the algebraic difference of the currents in the adjacent phase windings.

Appendix X

THE CRITICAL CASE OF $\theta_{ab} = O$

Let in Fig. 1 and 2, the space angle (θ_{ab}) between the windings in the phases A and B be gradually reduced to zero so that in the limit the axes of both windings coincide in space. With $\theta_{ab} = O$, equations (84) and (85) become identical with equations (87) and (88), so that $\lambda = \eta$. Consequently, from equations (92) and (93),

$$i_a = -\, i_b = \infty \qquad (154)$$

Thus, it would seem that, as the two windings approach a coincidence, a circulating current of ever increasing magnitude takes place between them, while both the current in the third branch and the field current remain of finite magnitude, the latter current being expressed by equation (91). On the other hand, when the phases A and B coincide, they simply form a single-phase winding consisting of two parallel branches (Appendix V), and there is no physical reason for an infinitely large circulating current between the branches. Moreover, equation (91) does not hold true for a single-phase circuit; in Appendix V it is shown that in this case the denominator of the expression for (i_f) is also a function of (α).

We thus have a seeming paradox that the answer to the case $\theta_{ab} = O$ is different, according to whether we gradually reduce this angle to zero and use the formulas for the polyphase circuit, or assume a single-phase circuit beforehand and use the corresponding equations. The following considerations will help to understand the real conditions.

(1) All the equations in Appendix VI are deduced on the supposition that $s = O$ because $k = O$. However, it is shown at the end of Appendix IV that pre-

10. I am indebted to Mr. R. H. Park for having called my attention to the relationship expressed by equation (151) and to the fact that equation (152) must be satisfied when equation (153) does not hold true.

cisely in the case of $\theta_{ab} = O$, this conclusion does not hold true, unless (c) is also equal to zero. Thus, the case under consideration cannot be treated as a particular application of equations (**91**) to (**93**).

(2) Fig. 6 does not hold true when (s) is not equal to zero, and the more general Fig. 4 must be used. Consequently, equation (**90**) does not apply in this case and the field current is not expressed by equation (**91**).

(3) Equations (**81**) and (**82**) are based on equation (**76**). When $\theta_{ab} = O$, equation (**76**) can be solved only for the sum of i_a and i_b, and not for each current separately.

(4) Even when $k = c = s = O$, Fig. 6 does not hold true for $\theta_{ab} = O$. In this case equations (**50**) and (**52**) are identical and both are reduced to the form

$$(i_a + i_b) + f\,\sigma\,i_f \cos\alpha = (I_a + I_b) + f\,\sigma\,I_f \cos\alpha_0 = A \qquad (155)$$

Equation (**53**) becomes $O = O$. The condition (**155**) does not require that the quantities $(i_a + i_b), f\,\sigma\,i_f$, and A, form a closed triangle. The vectorial condition of a closed polygon exists only when equations of projections, such as (**155**), can be written for two directions. But, if Fig. 6 does not apply in this particular case, equation (**90**) cannot be written, and its solution, equation (**91**), does not hold true. A graphical representation of the single-phase short-circuit is given in Appendix XI.

(5) According to equations (**92**) and (**93**), the currents (i_a) and (i_b) increase indefinitely as the angle θ_{ab} approaches zero. On the other hand, equations (**1**) and (**2**) show that the voltage (e) induced in each phase tends to a finite limit. Throughout this investigation, the resistance of the windings has been neglected, because, with finite currents, the ohmic drop is small as compared with the various induced voltages which balance each other magnetically. However, in this particular case, with the currents seemingly tending to infinity, the ohmic drop, if properly considered, would limit the currents to moderate finite values. In other words, the very fact that the armature currents tend to infinite values when θ_{ab} approaches zero, shows the necessity of using, in this particular case, more accurate differential equations, that is, equations of the form (**1**) with the term $(i_a\,r_a)$ added on the left-hand side.

The following three conclusions are therefore reached;

(a) As θ_{ab} becomes smaller, the currents in the phases A and B become larger.

(b) For small values of θ_{ab}, current equations derived without considering the ohmic drop are not reliable and should not be used.

(c) When $\theta_{ab} = O$, the phases A and B become two windings in parallel, and the formulas derived in this investigation for the single-phase short-circuit should be used.

Appendix XI

Graphical Representation of Currents in a Single-Phase Short-Circuit

The relations treated in Appendix VII have a graphical interpretation shown in Fig. 9. We shall limit the analysis to the simplest case of $c = O$. Putting in equation (**22**) $\theta_{ab} = O$, $c = O$, and $s = O$, and using $-\,i_c$ in place of $(i_a + i_b)$, we get,

$$-\,i_c + f\,\sigma\,i_f \cos\alpha = A \qquad (156)$$

where the constant of integration (A) is equal to the value of the expression on the left-hand side of equation (**156**) at the instant of short-circuit; that is,

$$A = -\,I_c + f\,\sigma\,I_f \cos\alpha_0 \qquad (157)$$

Equation (**23**) becomes identical with equation (**156**), and equation (**24**) gives $O = O$. Equation (**25**) becomes,

$$f\,\tau^{-1}\,i_f - i_c \cos\alpha = F\,f\,\tau^{-1}\,I_f \qquad (158)$$

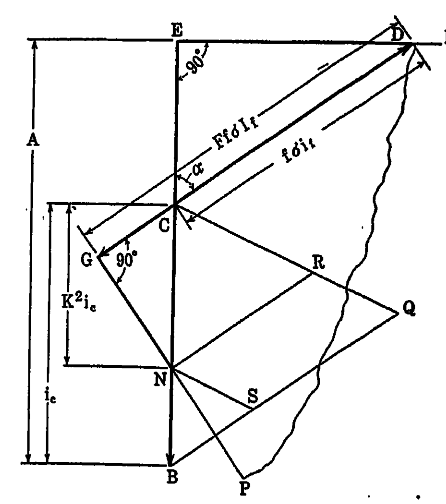

Fig. 9—Graphical Interpretation of Single-Phase Short-Circuit

Multiplying both sides of this expression by K^2, according to equation (**13**), we get,

$$f\,\sigma\,i_f - K^2\,i_c \cos\alpha = F\,f\,\sigma\,I_f \qquad (159)$$

Equations (**156**) and (**159**) are the only ones to be satisfied; they can be combined into a single diagram, as shown in Fig. 9. The current (i_c), at a certain instant corresponding to the angle (α), is represented by the vector $C\,B$.[11] The vector $C\,D = f\,\sigma\,i_f$, represents the field current referred to the armature circuit by means of the factor $f\,\sigma$. The length $B\,E$ represents the constant of integration A. Therefore, equation (**156**) simply becomes,

$$B\,C + C\,E = B\,E \qquad (160)$$

Point N is so chosen that it divides the length $B\,C$ in the ratio of K^2 to $1 - K^2$, and $C\,N = K^2\,i_c$. The length $G\,D$ is constant and equal to $F\,f\,\sigma\,I_f$. Hence, equation (**159**) becomes,

11. Space vectors and not time vectors are, of course, understood. The currents are non-sinusoidal in time and the length of a vector gives only an instantaneous value.

$$C\,D - C\,G = G\,D \tag{161}$$

Here $C\,D$ and $C\,G$ are to be understood as two vectors drawn from point C in the oppos te directions. Their difference, $G\,D$, is represented by a vector connecting their extremities G and D.

To make this diagram represent the conditions at any instant of time, assume $B\,E$ to be constant in direction and magnitude, and draw the direction $E\,E'$ perpendicular to $B\,E$. Out of a sheet of paper or celluloid, cut the figure $D\,G\,P$ in which $D\,G = F\,f\,\sigma\,I_f$, and $G\,P$ is perpendicular to $G\,D$. Imagine a pair of proportional dividers, $B\,C\,Q$, with their points laid along $B\,E$, so that the ratio of $B\,N$ to $N\,C$ always remains the same when the points C and N move along $B\,E$. For a chosen position of C, there is but one possible position of the figure $D\,G\,P$ for which D lies on $E\,E'$, $G\,D$ passes through C, and $G\,P$ passes through N. This determines the angle (α) and the instantaneous value of the field current (i_f) for the chosen value of (i_c). Conversely, by assuming a value of (α), the position of C may be found and hence the instantaneous values of the armature and field currents.

Thus, the periodic variations of i_c and i_f can be visualized, and the instantaneous values actually measured, by assuming $G\,D$ to be rotating in the plane, with the point D always remaining on $E\,E'$ and the sides $G\,D$ and $G\,P$ passing through the points C and N of the proportional dividers. The point C is variable, but the angle $E\,C\,D$ always gives the instant to which the values of the currents refer.

For an initial short-circuit, A is given by equation (**157**). For a sustained short-circuit, $A = O$ (see Appendix II), and the points B and E coincide. The value of F for the initial short-circuit, according to equation (**45**), is determined by the condition,

$$(F - 1)\,f\,\tau^{-1}\,I_f = -\,I_c \cos \alpha_0 \tag{162}$$

When $I_c = O$, $F = 1$. For a permanent short-circuit, F is determined by equation (**105**).

One can thus visualize the change from a transient to a permanent short-circuit by starting in Fig. 9 with the values of A and F corresponding to an initial short-circuit and assuming the lengths $B\,E$ and $G\,D$ to change gradually to their final values, while $G\,D$ is revolving uniformly and the point C is moving periodically up and down.

Notation

(All the quantities are understood to be *per pole*, where such an interpretation is possible.)

A, B, C	Constants of integration referring to the armature currents; equations (**22**) to (**24**).
F	Constant of integration referring to the field current.
I_a, I_b, I_c	The initial values of the armature currents, at the instant of short-circuit.
I_f	Initial or steady value of the field current at the instant of short-circuit.
K	Coefficient of magnetic coupling, equations (**12**) and (**13**).
L	External inductance in phase C, Fig. 1.
L_a, L_b, L_c	Self-inductances of the armature phases.
L_f	Self-inductance of the field current.
M_{ab}, M_{bc}, M_{ca}	Coefficients of mutual induction between the armature phases.
M_{fa}, M_{fb}, M_{fc}	Coefficients of mutual induction between the field winding and the three armature phases, respectively.
N	See equation (**19**)
N_a, N_b, N_c	Numbers of turns in the armature windings.
N_f	Number of turns in the field winding.
$\mathcal{P}$	Permeance of the useful (or common) magnetic path through the field and the armature.
S	Initial value of s at the instant of short-circuit.
U	Constant of integration, defined by equations (**26**) to (**31**).
b	Auxiliary constant, defined by equations (**35**) and (**36**), and by Fig. 3. It is also defined by equations (**66**) and (**67**), and by Fig. 5.
c	Ratio of turns in phases C and A; equation (**20**).
e	Instantaneous voltage between the terminals and the neutral in Fig. 1.
f	Ratio of turns in the field winding and the phase A; equation (**21**).
f_0	Frequency of the armature currents in a steady state.
h	Geometric sum of 1 and c; Fig. 6, triangle $E\,D\,C$; equations (**87**) and (**88**).
i	Subscript signifying "initial short-circuit."
i_a, i_b, i_c	Instantaneous currents in the armature phases, Fig. 1.
i_f	Instantaneous value of field current.
j	$\sqrt{-1}$
k	Numerical factor which characterizes the external inductance L, equation (**9**).
l	Geometric sum of 1 and c; Fig. 6, triangle $O\,A\,E$; equations (**84**) and (**85**).
m	A constant; equation (**47a**).
n	A constant; equation (**48**).
p	Subscript signifying "permanent short-circuit."
q	A constant; equation (**48**).
s	Auxiliary function of time defined by equation (**18**).
t	Time.
u	Coefficient of proportionality, defined by equation (**42**).

1, 2, 3	Used as subscripts, indicate the number of phases.
α, β, γ	Variable electrical angles which determine the instantaneous position of the field winding with respect to the three armature windings; Figs. 1 and 2, and equations (**14**) and (**15**).
$\alpha_0, \beta_0, \gamma_0$	The initial values of α, β, γ, at the instant of short-circuit.
δ	An arbitrary angle; equation (**76**).
ϵ	Base of natural logarithms.
η	Angle at E, Fig. 6; equations (**87**) and (**88**).
θ	The value of the angle θ_{bc} when $\theta_{ab} = 0$; Appendix V.
$\theta_{ab}, \theta_{bc}, \theta_{ca}$	Electrical angles between the armature phases, Figs. 1 and 2; the sum of these angles is equal to 360 deg.
θ'	Auxiliary angle defined by equations (**66**) and (**67**), and in Fig. 5.
θ_{ca}'	Auxiliary constant angle defined by equations (**35**) and (**36**), and in Fig. 3.
λ	Angle at O, Fig. 6; equations (**84**) and (**85**).
ξ	Constant electrical angle defined by equations (**26**) to (**31**).
σ	Magnetic leakage coefficient of the armature circuit, defined in a manner similar to equation (**6**).
τ	Magnetic leakage coefficient of the field circuit, defined by equation (**6**).
ϕ	A function of the time-angle α; equation (**47a**).
ψ	A function of α; equations (**148**) to (**150**).
$\omega = 2\pi f_0$	Electrical angular velocity, or the angular speed of a two-pole machine.

Short-Circuit Currents of Synchronous Machines

BY R. F. FRANKLIN*

Associate, A. I. E. E.

Synopsis.—The importance of short-circuit forces in large alternators has warranted an investigation of them. The first step in this investigation, which is discussed in this paper, is the calculation of the short-circuit currents that produce them. The method of solution used is that of the assumption of zero resistance and constant flux linkages which has proven so useful in the solution of many short-circuit problems. Formulas are calculated in the Appendix for both the initial and permanent short-circuit currents of all circuits involved in the short-circuit. The formulas cover all the common connections of single-phase, two-phase and three-phase alternators. A discussion of some of these formulas, together with a plot of them for assumed alternator constants, is also given.

INTRODUCTION

ONE of the difficult problems encountered in the design of large alternators is that of providing sufficient strength of the different parts to withstand the forces produced during short circuit. The author participated in an investigation of these short-circuit forces which was begun a couple of years ago and recently completed. The results of this investigation will be given in this and future papers before the Institute.

The short-circuit forces depend largely upon the abnormal short-circuit current that flows in the various windings and can be calculated if the character and magnitude of these currents are known. The first step, therefore, in the calculation of these forces is the calculation of the short-circuit currents that produce them.

Since Bucherot's excellent discussion of alternator short-circuit currents in 1911[1], many papers have been published treating of both the phenomena involved and the method of calculation. A method of solution which has proven useful in the investigation of many short-circuit problems is that of the assumption of zero resistance and constant flux linkages. This method was used in 1918 in a paper by Messrs. R. E. Doherty and O. E. Shirley[2], for an explanation of short circuit phenomena in synchronous machines, and again in 1921 in a paper by Messrs. R. E. Doherty and E. T. Williamson[3] for an investigation of the short circuit current of induction motors and generators. In a recent paper[4] Mr. Doherty again emphasized the importance of this method of interpreting short circuit problems and gave a number of applications. In a more recent paper[5] Mr. C. M. Laffoon applied this method to the calculation of several cases of short circuit of an alternator. It is the purpose of this paper to apply this constant-linkage method to the calculation of both the *initial* and *permanent* short-circuit currents of synchronous machines.

METHOD OF SOLUTION

The constant-linkage method is based on the assumption that the electrical resistance of the various circuits is zero. As a result of this assumption the following *constant-linkage theorem* has been proved[6]: "*In a circuit having zero resistance the algebraic sum of the flux linkages of the circuit must remain constant.*" The application of this theorem to the calculation of short-circuit currents is very similar to that of the application of Kirchoff's laws to the solution of networks. First, currents are assumed to flow in the different branches of the circuits. The flux linkages in any branch are those due to the current in that branch and those due to currents in other branches. The flux linkages of each circuit are then summed up and equated to some constant value of flux linkages which is known to exist in the circuit. By solving, simultaneously, these flux-linkage equations expressions for the currents flowing in the different branches of the circuits are obtained.

RESULTS

The various alternator connections and kinds of short-circuit for which formulas are derived are shown by the nine cases in Fig. 1. For each case formulas are derived for both the *initial* and *permanent* short-circuit conditions. A tabulation of the formulas for the various cases of Fig. 1 are given in Table I. These formulas are plotted in Figs. 3 to 14, for assumed alternator constants.

INITIAL SHORT CIRCUIT CURRENT

The initial short-circuit current waves, Figs. 3 to 8, show all peaks of the same height since, resistance being neglected, the transient decay of the current wave actually obtained in practise is not present. The instant of short-circuit in each case is so chosen as to give the maximum possible value of current in phase *a*. The maximum value of current occurs 180 electrical degrees after the instant of short-circuit. During this time the resistance of the circuits, which in the calculations has been neglected, reduces this peak value slightly from that calculated. The formulas thus

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925 and at the Regional Meeting of Dist. No. 1, Swampscott, Mass., May 7-9, 1925.

6. For a proof of this theorem refer to discussion of Mr. R. E. Doherty's paper, Bibliography 5.

give a peak value a little higher than actually obtained in practise. In Table II are given the peak values of the initial short-circuit current for the various cases in terms of the peak value of the current obtained in the three-phase alternator, case 9, in which all three phases are short-circuited simultaneously. It will be observed from Table II that the short-circuit current obtained for a single-phase short-circuit of one phase of a three-phase alternator from one terminal to ground is 150 per cent of the three-phase value. A single-phase short circuit between terminals gives only 86 per cent of the three-phase value, and a two-phase short-circuit between two terminals and ground, 173 per cent of the three-phase value.

PERMANENT SHORT-CIRCUIT CURRENT

In the calculation of the permanent short-circuit current formulas the flux linkage equations of the armature circuits were equated to zero. The reason for this is, that during the transient period of a short circuit, the

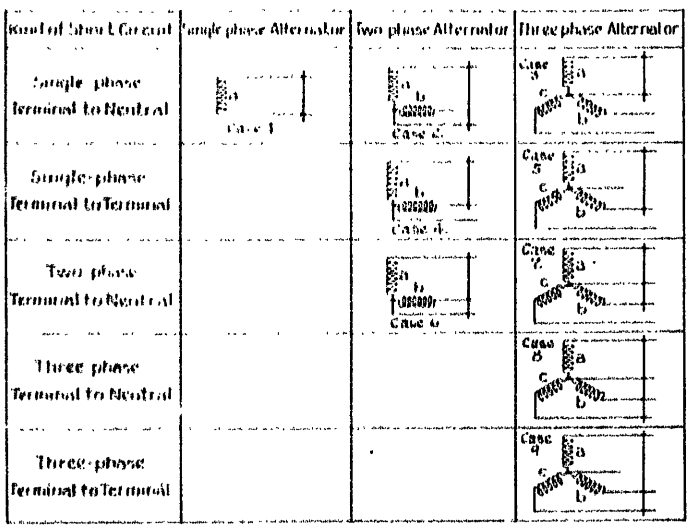

FIG. 1—CASES FOR WHICH INITIAL AND PERMANENT SHORT-CIRCUIT CURRENT FORMULAS ARE DERIVED

flux linkages which are caught by the armature circuits at the instant of short circuit are consumed by the resistance of the circuits. Therefore, when the permanent condition is reached the only flux linkages supplied by the field circuit are those which are being consumed by resistance. If zero resistance is assumed in the permanent condition, then no flux linkages are supplied to the armature circuits by the field circuit and the currents that flow in the armature circuits must be such as to at all times, keep out all field flux linkages. In other words, the flux linkages of each armature circuit must be zero.

The formulas for the permanent condition are plotted in Figs. 9 to 14. The single-phase cases show the characteristic double frequency pulsation in the field current. In Fig. 15 is given an oscillogram of the armature and field current of a three-phase alternator during a permanent single-phase short circuit between terminals in which the shape of the current waves is very similar to those calculated in Fig. 11.

The field current for the three-phase alternator case with two phases short-circuited between terminals and ground, (Case 7, Fig. 13), does not have any alternating component induced in it. This is due to the fact that the coefficient of inductive coupling between the short-circuited phases a and b was assumed in the derivation of the formulas, equal to the cosine of the angle between phases. Thus, for a three-phase alternator, this coupling coefficient was assumed equal to cos 120, or $-$ 0.5. This ideal value of coupling is seldom obtained in practise. The effect of a coupling co-efficient different from $-$ 0.5 on the field current is shown by the oscillogram of Fig. 16. The field current contains an alternating component of double frequency and of about $\pm$ 9 per cent of the d-c. component. This corresponds to a coupling coefficient between phases a and b of about $-$ 0.49. In the study of this phase of the subject formulas were calculated for all cases in which no definite value of coupling coefficient between phases was assumed. These formulas were very complicated compared to the formulas here given. The effect of this coupling coefficient is so slight that it was felt unwarranted to complicate the formulas by making them more general in this respect. For all practical applications the value $-$ 0.5, assumed in the calculation of the formulas, is sufficiently accurate.

ASSUMPTIONS

The following assumptions were made in the calculation of the formulas:

a. Zero resistance in all circuits
b. Magnetic saturation neglected
c. Sine wave distribution of field flux
d. Constant coefficient of self-inductance of armature phases.
e. Variation of mutual inductance between armature phases as the cosine of the angle between them.

The calculation of alternator short-circuit currents becomes very involved if too many refinements are attempted. Therefore in order to obtain as simple a solution as possible, the above assumptions are necessary. While some of these assumptions may not appear reasonable a careful study of them and a comparison with results in practise reveals that for very many practical problems they can be tolerated.

The assumption of zero resistance was made necessary by the method of solution of the problem. The predominence of reactance over resistance during the short-circuit of an alternator makes it possible to neglect the resistance in this kind of a problem. Assumption *b* should involve greater error, but any attempt to take saturation into account makes the problem very complicated. The error due to saturation can be minimized by taking it into consideration in the calculation of the inductance coefficients. Assumption *c* is very close to present practise in the design of alternators. Assumption *d* involves the neglect of the salient pole feature of alternators since the coefficient of self inductance of the armature phases is not constant but will vary somewhat with the position of the field poles. An investigation of the affect of this variation upon the short-circuit currents showed that only a small double frequency current was introduced which did not appreciably effect the results obtained. The effect of *e* has already been discussed. Formulas were calculated for all cases in which the coefficient of coupling between armature phases was not assumed constant. The formulas are greatly complicated by this general assumption. The assumption of -0.5 for this coupling coefficient which was made in the derivation of the formulas of this paper greatly simplify the formulas and does not introduce appreciable error.

In concluding the author wishes to express his appreciation of the assistance of Messrs. R. E. Doherty and R. H. Park and Professor V. Karapetoff in the solution of this problem.

Appendix

Derivation of Short-Circuit Current Formulas Initial Condition

1. *Single-Phase Short Circuit.*

(a) Single-phase or polyphase alternator.

One general formula can be obtained for the single-phase short-circuit current of a single-phase, two-phase, or three-phase alternator when only one armature phase is involved in the short circuit. (Cases 1 to 3, Fig. 1). The instant of short circuit will be taken when the armature phase *a* encloses maximum field flux as this is the condition when maximum short circuit current is obtained. This condition occurs when the angle α in Fig. 2A equals zero[7].

There are only two circuits involved; the field circuit and the armature circuit *a*. The flux linkages of these two circuits at the instant of short circuit, *i. e.*, when α equals zero, are respectively[8].

$$\Omega_f = I_f L_f \tag{1}$$

$$\Omega_a = I_f M_0 \tag{2}$$

The flux linkages of these two circuits at any instant after short circuit are,

$$\Omega_f' = i_f L_f + i_a M_{fa} \tag{3}$$

$$\Omega_a = i_a L_a + i_f M_{af} \tag{4}$$

Applying the constant linkage theorem, the flux linkages at any instant after short circuit, (3) and (4),

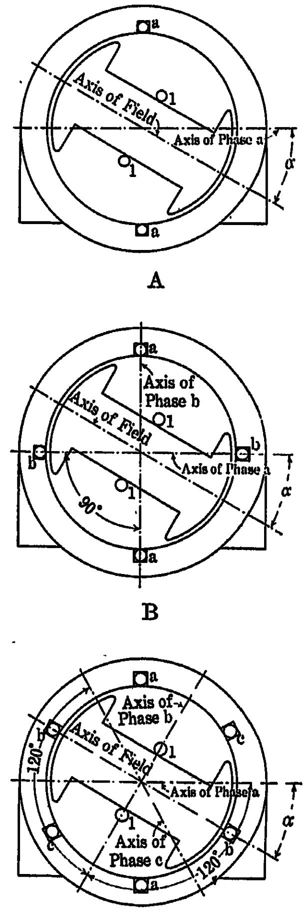

Fig. 2—Schematic Diagrams Showing the Relations of the Various Alternator Circuits

must equal the flux linkages before short circuit, (1) and (2) respectively,

$$i_f L_f + i_a M_{fa} = I_f L_f \tag{5}$$

$$i_a L_a + i_f M_{af} = I_f M_0 \tag{6}$$

7. For simplicity a two pole alternator is shown in which case the electrical angle is equal to the mechanical angle.

8. For definition of symbols see Notation.

Solving these two equations simultaneously for the currents i_f and i_a,

$$i_f = I_f \frac{L_f L_a - M_0 M_{fa}}{L_f L_a - M_{fa}^2} \tag{7}$$

$$i_a = I_f \frac{L_f M_0 - L_f M_{fa}}{L_f L_a - M_{fa}^2} \tag{8}$$

The inductance coefficients L_f and L_a are assumed constant. The coefficients M_{fa} varies with the rotation of the rotor, and may be approximated by a cosine function; thus[9]

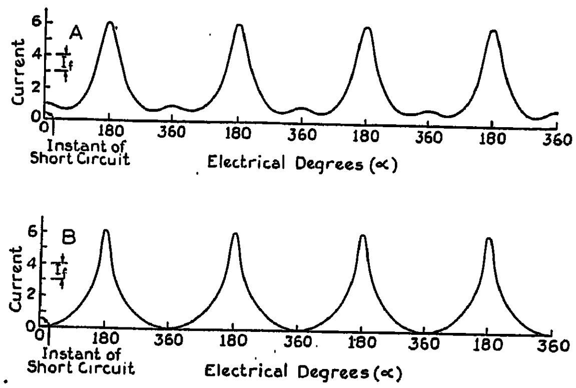

FIG. 3—INITIAL SHORT-CIRCUIT CURRENTS; CASES 1, 2 AND 3

Curve *A*—Field current. Eq.(10).
Curve *B*—Current in phase *a*. (Eq.11).

$$M_{fa} = M_{af} = M_0 \cos \alpha \tag{9}$$

Substituting this relation in (7) and (8) and dividing both numerator and denominator by $L_f L_a$,

$$i_f = I_f \frac{1 - K^2 \cos \alpha}{(1 - 0.5\, K^2) - 0.5\, K^2 \cos 2\,\alpha} \tag{10}$$

$$i_a = I_f \frac{M_0}{L_a} \frac{1 - \cos \alpha}{(1 - 0.5\, K^2) - 0.5\, K^2 \cos 2\,\alpha} \tag{11}$$

where, K = coefficient of magnetic coupling between the two circuits

$$= \frac{M_0}{\sqrt{L_f L_a}} \tag{12}$$

Equations (10) and (11) are plotted in Fig. 3 for

$$K = 0.85 \text{ and } \frac{M_0}{L_a} = 0.85.$$

(b) Two-phase alternators, single-phase terminal to terminal short-circuit, (Case 4, Fig. 1).

In this case there are only two circuits involved since armature phases a and b are connected in series, forming only one circuit $a\,b$. As seen in Fig. 2B the circuit $a\,b$ does not enclose maximum field flux when α equals zero, but when

$$M_{fab} = M_{fa} - M_{fb}$$

is a maximum that is, when

$$\frac{d\, M_{fab}}{d\, \alpha} = 0$$

From (9) and the relation

$$M_{fb} = M_0 \cos (\alpha - 90) = M_0 \sin \alpha \tag{13}$$

$$\frac{d\, M_{fab}}{d\, \alpha} = M_0 (- \sin \alpha - \cos \alpha) = 0$$

$$\text{or } \alpha = -\,45 \text{ deg.}$$

Therefore, for maximum field flux enclosure by the circuit $a\,b$ the short circuit must occur at $\alpha = -\,45$ deg. The flux linkages of the field and armature circuits at this value of α are,

$$\Omega_f = I_f L_f \tag{14}$$

$$\Omega_{ab} = \Omega_a - \Omega_b = I_f M_{af}' - I_f M_{bf}'$$

where, M_{af}' and M_{bf}' are the values of M_{af} and M_{bf} respectively at $\alpha = -\,45$ deg.

Hence from (9) and (13)

$$\Omega_{ab} = \sqrt{2}\, I_f M_0 \tag{15}$$

The linkages at any instant after short circuit are,

$$\Omega_f = i_f L_f + i_a M_{fa} + i_b M_{fb} \tag{16}$$

$$\Omega_{ab} = \Omega_a - \Omega_b = i_f (M_{af} - M_{bf}) + i_a (L_a - M_{ba}) + i_b (M_{ab} - L_b) \tag{17}$$

Due to reverse connection of a and b

$$i_{ab} = i_a = -\, i_b \tag{18}$$

Thus from (14) (15) (16) (17) and (18)

$$i_f L_f + i_{ab} (M_{fa} - M_{fb}) = I_f L_f \tag{19}$$

$$i_f (M_{af} - M_{bf}) + i_{ab} (L_a + L_b) = \sqrt{2}\, I_f M_0 \tag{20}$$

Since, the axes of the phases are at right angles,

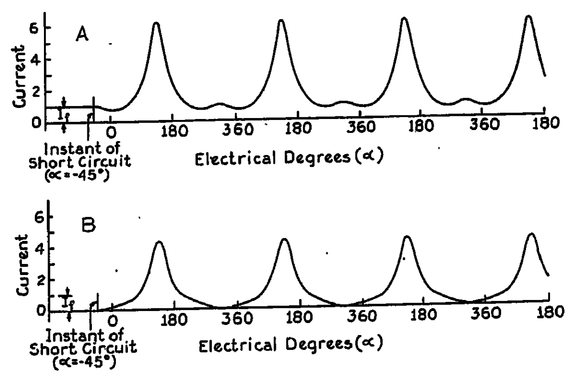

FIG. 4—INITIAL SHORT-CIRCUIT CURRENTS; CASE 4

Curve *A*—Field current. Eq.(23)
Curve *B*—Field current in circuit *a b*. Eq.(24)

$$M_{ab} = M_{ba} = 0 \tag{21}$$

Solving (19) and (20) simultaneously and substituting (9), (12), (13) and

$$L_a = L_b \tag{22}$$

$$i_f = I_f \frac{1 - K^2 \cos (\alpha + 45)}{(1 - 0.5\, K^2) - 0.5\, K^2 \cos 2\,(\alpha + 45)} \tag{23}$$

$$i_{ab} = \frac{1}{\sqrt{2}} I_f \frac{M_0}{L_a} \frac{1 - \cos (\alpha + 45)}{(1 - 0.5\, K^2) - 0.5\, K^2 \cos 2 (\alpha + 45)} \tag{24}$$

9. $M_{fa} = M_{af}$ when saturation is neglected.

These currents are plotted in Fig. 4 for $K = 0.85$ and

$$\frac{M_0}{L_a} = 0.85.$$

(c) Three-phase alternator, single-phase terminal to terminal short circuit, (Case 5, Fig. 1).

There are only two circuits to consider, the field circuit f and one armature circuit composed of phases a and b in series. The armature circuit encloses maximum field flux when M_{fab} is a maximum.

This occurs when

$$\frac{d\, M_{fab}}{d\, \alpha} = 0$$

Now since phases a and b are displaced 120 deg. from each other

$$M_{fb} = M_0 \cos (\alpha - 120) \qquad (25)$$

and

$$M_{fab} = M_{fa} - M_{fb} = M_0 [\cos \alpha - \cos (\alpha - 120)] \qquad (26)$$

Differentiating, equating to zero and solving for α,

$$\alpha = -30 \text{ deg.}$$

Thus the instant of short-circuit should be taken at

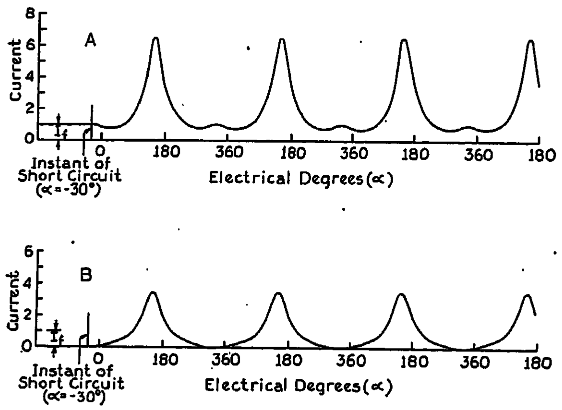

FIG. 5—INITIAL SHORT-CIRCUIT CURRENTS; CASE 5
Curve A—Field current. Eq. (40)
Curve B—Current in Circuit ab Eq. (41)

$\alpha = -30$ deg. The flux linkages of the two circuits at this instant are,

$$\Omega_f = I_f L_f \qquad (27)$$

$$\Omega_{ab} = \Omega_a - \Omega_b = I_f M_{af}'' - I_f M_{bf}'' \qquad (28)$$

where M_{af}'' and M_{bf}'' are the mutual inductances between the field circuit and phases a and b respectively at $\alpha = -30$ deg.

Thus from (9) and (25)

$$\Omega_{ab} = \sqrt{3}\, I_f M_0 \qquad (29)$$

The flux linkages of the two circuits at any instant after short-circuit are,

$$\Omega_f = i_f L_f + i_a M_{fa} + i_b M_{fb} \qquad (30)$$

$$\Omega_{ab} = \Omega_a - \Omega_b \qquad (31)$$

where,

$$\Omega_a = i_a L_a + i_f M_{af} + i_b M_{ab} \qquad (32)$$

$$\Omega_b = i_b L_b + i_f M_{bf} + i_a M_{ba} \qquad (33)$$

But due to reverse connection of a and b

$$i_{ab} = i_a = -i_b \qquad (34)$$

The coefficient M_{ab} is defined as

$$M_{ab} = k \sqrt{L_a L_b}$$

The coefficient of coupling k depends upon the relative positions of the two phases a and b and may be assumed to vary as the cosine of the angle between their axes. Thus in this case where the angle between phases is 120 deg.

$$k = \cos 120 \text{ deg.} = -0.5$$

and,

$$M_{ab} = -0.5\, L_a \qquad (35)$$

Substituting (34) in (30)

$$\Omega_f = i_f L_f + i_{ab} (M_{fa} - M_{fb}) \qquad (36)$$

Substituting (32) (33) (34) and (35) in (31)

$$\Omega_{ab} = i_f (M_{af} - M_{bf}) + i_{ab}\, 3\, L_a \qquad (37)$$

Equating (27) and (36), and (29) and (37)

$$i_f L_f + i_{ab} (M_{fa} - M_{fb}) = I_f L_f \qquad (38)$$

$$i_f (M_{af} - M_{bf}) + i_{ab}\, 3\, L_a = \sqrt{3}\, I_f M_0 \qquad (39)$$

Solving (39) and (40) simultaneously and substituting (9) (12) and (25),

$$i_f = I_f \frac{1 - K^2 \cos (\alpha + 30)}{(1 - 0.5\, K^2) - 0.5\, K^2 \cos 2\, (\alpha + 30)} \qquad (40)$$

$$i_{ab} = \frac{1}{\sqrt{3}} I_f \frac{M_0}{L_a} \frac{1 - \cos (\alpha + 30)}{(1 - 0.5\, K^2) - 0.5\, K^2 \cos 2 (\alpha + 30)} \qquad (41)$$

Equations (40) and (41) are plotted in Fig. 5 for

$$K = 0.85 \text{ and } \frac{M_0}{L_a} = 0.85.$$

2. Two-Phase Short Circuit

(a) Two-phase alternator, (Case 6, Fig. 2).

There are three circuits to consider; the field circuit, phase a and phase b. The flux linkages of these circuits at the instant of short-circuit, *i. e.*, when $\alpha = 0$ are,

$$\Omega_f = I_f L_f \qquad (42)$$

$$\Omega_a = I_f M_0 \qquad (43)$$

$$\Omega_b = 0 \qquad (44)$$

The flux linkages at any other field position are,

$$\Omega_f = i_f L_f + i_a M_{fa} + i_b M_{fb} \qquad (45)$$

$$\Omega_a = i_a L_a + i_f M_{af} \qquad (46)$$

$$\Omega_b = i_b L_b + i_f M_{bf} \qquad (47)$$

since $M_{ab} = 0$ as for the previous two-phase case considered.

Equating (42) and (45), (43) and (46), (44) and (47), solving simultaneously and substituting (9) (12) (13) and (22),

$$i_f = I_f \frac{1 - K^2 \cos \alpha}{1 - K^2} \qquad (48)$$

$$i_a = I_f \frac{M_0}{L_a} \frac{(1 - 0.5\, K^2) - \cos \alpha + 0.5\, K^2 \cos 2\, \alpha}{1 - K^2} \qquad (49)$$

$$i_b = -I_f \frac{M_0}{L_a} \frac{\sin \alpha - 0.5\, K^2 \sin 2\, \alpha}{1 - K^2} \qquad (50)$$

These currents are plotted in Fig. 6 for K = 0.85 and

$$\frac{M_0}{L_a} = 0.85.$$

(b) Three-phase alternator, (Case 7, Fig. 1).

There are three circuits, the field circuit, phase a and phase b. Maximum current is obtained in phase a if the short-circuit occurs at α = 30 deg. since at this armature position there is no field flux enclosed by phase b. The flux linkages of the three circuits at α = 30 deg. are

$$\Omega_f = I_f L_f \tag{51}$$

$$\Omega_a = 0.5 \sqrt{3}\, I_f M_0 \tag{52}$$

$$\Omega_b = 0 \tag{53}$$

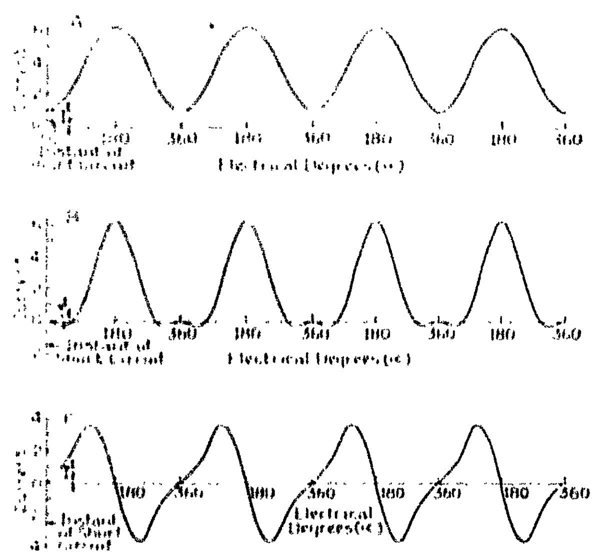

FIG. 6—INITIAL SHORT-CIRCUIT CURRENTS; CASE 6

Curve A—Field current. Eq. (48)
Curve B—Current in phase a. Eq. (49)
Curve C—Current in phase b. Eq. (50)

The flux linkages for any value of α are,

$$\Omega_f = i_f L_f + i_a M_{fa} + i_b M_{fb} \tag{54}$$

$$\Omega_a = i_a L_a + i_f M_{af} + i_b M_{ab} \tag{55}$$

$$\Omega_b = i_b L_b + i_f M_{bf} + i_a M_{ba} \tag{56}$$

Equating (51) and (54), (52) and (55), (53) and (56), solving simultaneously and substituting (9), (12), (22), (25), and (35)

$$i_f = I_f \frac{1 - K^2 \cos(\alpha - 30)}{1 - K^2} \tag{57}$$

$$i_a = \frac{2}{\sqrt{3}} I_f \frac{M_0}{L_a} \frac{(1-0.5\ K^2) - \cos(\alpha - 30) + 0.5\ K^2 \cos 2(\alpha - 30)}{1 - K^2} \tag{58}$$

$$i_b = \frac{2}{\sqrt{3}} I_f \frac{M_0}{L_a} \frac{0.5\ (1 - 0.5\ K^2) - \sin\alpha - 0.5\ K^2 \cos 2(\alpha + 30)}{1 - K^2} \tag{59}$$

These currents are plotted in Fig. 7 for K = 0.85 and

$$\frac{M_0}{L_a} = 0.85.$$

3. Three-Phase Short-Circuit

(a) Three-phase alternator, (Case 8, Fig. 1).

There are four circuits to consider; the field circuit, phase a, phase b and phase c. The flux linkages of these circuits at α = 0 are,

$$\Omega_f = I_f L_f \tag{60}$$

$$\Omega_a = I_f M_0 \tag{61}$$

$$\Omega_b = -\ 0.5\, I_f M_0 \tag{62}$$

$$\Omega_c = -\ 0.5\, I_f M_0 \tag{63}$$

The flux linkages at any value of α are,

$$\Omega_f = i_f L_f + i_a M_{fa} + i_b M_{fb} + i_c M_{fc} \tag{64}$$

$$\Omega_a = i_a L_a + i_f M_{af} + i_b M_{ab} + i_c M_{ac} \tag{65}$$

$$\Omega_b = i_b L_b + i_f M_{bf} + i_a M_{ba} + i_c M_{bc} \tag{66}$$

$$\Omega_c = i_c L_c + i_f M_{cf} + i_a M_{ca} + i_b M_{cb} \tag{67}$$

Equating (60) and (64), (61) and (65), (62) and (66), and (63) and (67), solving simultanelusly and substituting (9), (12), (13), (22), (35), and the three relations

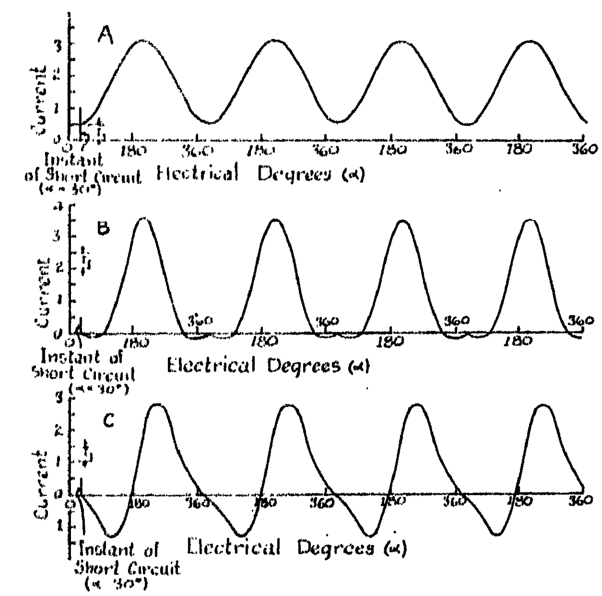

FIG 7—INITIAL SHORT-CIRCUIT CURRENTS; CASE 7

Curve A—Field current. Eq. (57)
Curve B—Current in phase a. Eq. (58)
Curve C—Current in phase b. Eq. (59)

$$L_a = L_c \tag{68}$$

$$M_{ac} = -\ 0.5\, L_a \tag{69}$$

$$M_{cf} = M_0 \cos(\alpha + 120) \tag{70}$$

$$i_f = I_f \frac{1 - K^2 \cos\alpha}{1 - K^2} \tag{71}$$

$$i_a = \frac{2}{3} I_f \frac{M_0}{L_a} \frac{(1 - 0.5\ K^2) - \cos\alpha + 0.5\ K^2 \cos 2\alpha}{1 - K^2} \tag{72}$$

$$i_b = -\frac{1}{3} I_f \frac{M_0}{L_a}$$

$$\frac{(1-0.5\,K^2)+2\cos(\alpha-120)-K^2\cos 2\,(\alpha+120)}{1-K^2} \quad (73)$$

$$i_c = -\frac{1}{3} I_f \frac{M_0}{L_a}$$

$$\frac{(1-0.5\,K^2)+2\cos(\alpha+120)-K^2\cos 2\,(\alpha-120)}{1-K^2} \quad (74)$$

These equations are plotted in Fig. 8 for $K = 0.85$, and

$$\frac{M_0}{L_a} = 0.85.$$

(b) Three-phase alternator (Case 9, Fig. 1)

The current equations obtained for a three-phase

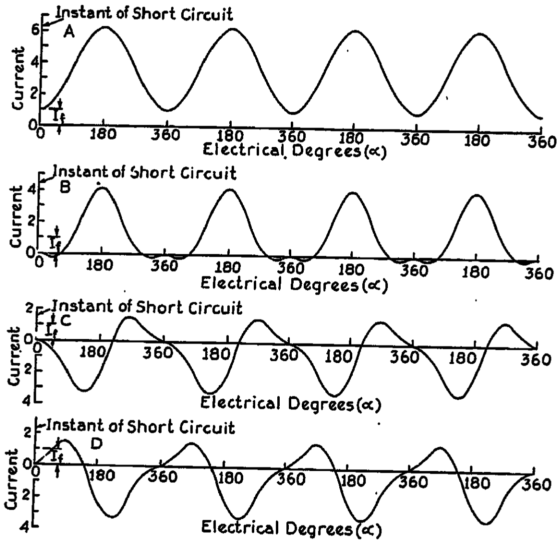

FIG. 8—INITIAL SHORT-CIRCUIT CURRENTS; CASES 8 AND 9

Curve *A*—Field current. Eq. (71)
Curve *B*—Current in phase *a*. Eq. (72)
Curve *C*—Current in phase *b*. Eq. (73)
Curve *D*—Current in phase *c*. Eq. (74)

short-circuit terminal-to-terminal are the same as those for a three-phase short-circuit terminal-to-neutral.

PERMANENT CONDITION

In the permanent condition, the algebraic sum of the flux linkages in each armature circuit must be zero since the flux linkages originally caught in these circuits have been dissipated during the transient period between the initial and permanent states. The flux linkages of the field circuit will be equal to those supplied by the exciter.

1. Single-Phase Short Circuit.

(a) Single-phase or polyphase alternator.

As in the corresponding case for the initial short-circuit condition a general formula can be obtained for the single-phase, short-circuit current of a single-phase, two-phase, or three-phase alternator, when only one armature phase is involved in the short circuit (Cases 1 to 3, Fig. 1.) The flux linkages of the two circuits involved, are,

$$i_f L_f + i_a M_{fa} = I_f' L_f \quad (75)$$

$$i_a L_a + i_f M_{af} = 0 \quad (76)$$

where I_f' is that constant value of field current that would be required on open circuit to produce the same number of flux linkages with the field circuit as exist under the permanent short circuit condition.

Solving these two equations simultaneously and substituting (9) and (12)

$$i_f = I_f' \frac{1}{(1-0.5\,K^2) - 0.5\,K^2 \cos 2\,\alpha} \quad (77)$$

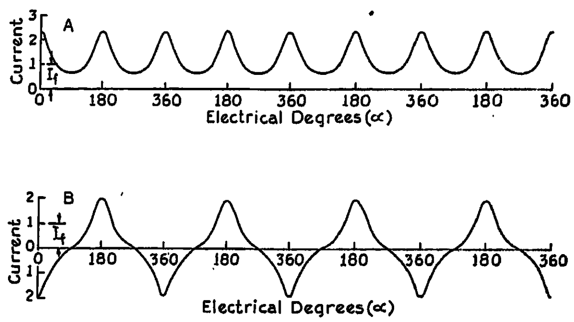

FIG. 9—PERMANENT SHORT-CIRCUIT CURRENTS; CASES 1, 2 AND 3

Curve *A*—Field current. Eq. (80)
Curve *B*—Current in phase *a*. Eq. (81)

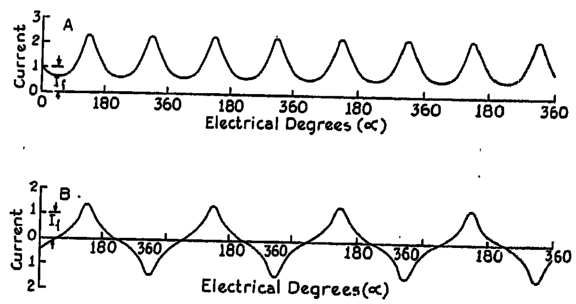

FIG. 10—PERMANENT SHORT-CIRCUIT CURRENTS; CASE 4

Curve *A*—Field Current. Eq. (86)
Current *B*—Current in circuit *a b*. Eq. (87)

$$i_a = -I_f' \frac{\cos\alpha}{(1-0.5\,K^2) - 0.5\,K^2\cos 2\,\alpha} \quad (78)$$

The direct component of the field current (77) is due to the flux linkages supplied by the exciter and is, therefore, equal to the field current I_f which flowed before short-circuit. This direct component is found by integrating (77) between proper limits and dividing by the abscissa. Thus,

$$I_f = \frac{2}{\pi}\int_0^{\frac{\pi}{2}} \frac{I_f'}{(1-0.5\,K^2) - 0.5\,K^2\cos 2\,\alpha}\, d\,\alpha$$

$$= \frac{I_f'}{\sqrt{1-K^2}}$$

or

$$I_f' = I_f \sqrt{1 - K^2} \tag{79}$$

Substituting (79) in (77) and (78),

$$i_f = I_f \frac{\sqrt{1 - K^2}}{(1 - 0.5\,K^2) - 0.5\,K^2 \cos 2\,\alpha} \tag{80}$$

$$i_a = -\,I_f \frac{M_0}{L_a} \frac{\sqrt{1 - K^2} \cos \alpha}{(1 - 0.5\,K^2) - 0.5\,K^2 \cos 2\,\alpha} \tag{81}$$

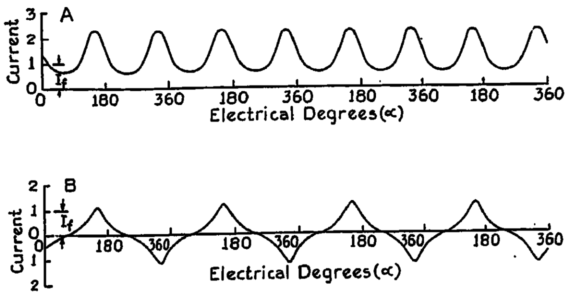

FIG. 11—PERMANENT SHORT-CIRCUIT CURRENTS; CASE 5
Curve A—Field current. Eq. (92)
Curve B—Current in circuit $a\,b$. Eq. (93)

These currents are plotted in Fig. 9 for $K = 0.85$ and

$$\frac{M_0}{L_a} = 0.85.$$

(b) Two-phase alternator, single-phase terminal-to-neutral short-circuit (Case 4, Fig. 1).

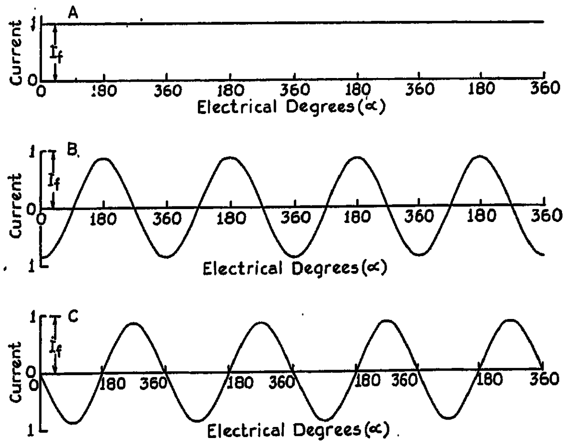

FIG. 12—PERMANENT SHORT-CIRCUIT CURRENTS; CASE 6
Curve A—Field current. Eq. (101)
Curve B—Current in phase a. Eq. (102)
Curve C—Current in phase b. Eq. (103)

The flux linkages of the two circuits involved are: [See (19) and (20)].

$$i_f\,L_f + i_{ab}\,(M_{fa} - M_{fb}) = I_f'\,L_f \tag{82}$$

$$i_f\,(M_{af} - M_{bf}) + i_{ab}\,(L_a + L_b) = 0 \tag{83}$$

Solving simultaneously and substituting (9), (12), (13) and (22).

$$i_f = I_f' \frac{1}{(1 - 0.5\,K^2) - 0.5\,K^2 \cos 2\,(\alpha + 45)} \tag{84}$$

$$i_{ab} = -\,\frac{1}{\sqrt{2}} I_f' \frac{\cos(\alpha + 45)}{(1 - 0.5\,K^2) - 0.5\,K^2 \cos 2(\alpha + 45)} \tag{85}$$

Since (84) is of the same form as (77) the value of I_f' for this case will be the same as that given by (79). Substituting (79) in (84) and (85),

$$i_f = I_f \frac{\sqrt{1 - K^2}}{(1 - 0.5\,K^2) - 0.5\,K^2 \cos 2\,(\alpha + 45)} \tag{86}$$

$$i_{ab} = -\,\frac{1}{\sqrt{2}} I_f \frac{M_0}{L_a} \frac{\sqrt{1 - K^2} \cos(\alpha + 45)}{(1 - 0.5\,K^2) - 0.5\,K^2 \cos 2\,(\alpha + 45)} \tag{87}$$

These currents are plotted in Fig. 10 for K and $\frac{M_0}{L_a}$ equal to 0.85.

(c) Three-phase alternator, single-phase terminal-to-terminal short-circuit (Case 5, Fig. 1).

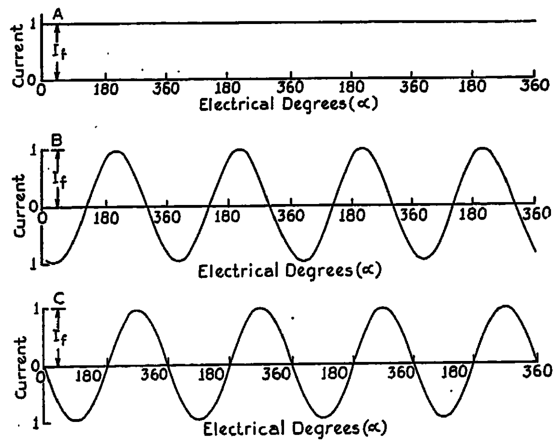

FIG. 13—PERMANENT SHORT-CIRCUIT CURRENTS; CASE 7
Curve A—Field current. Eq. (110)
Curve B—Current in phase a. Eq. (111)
Curve C—Current in phase b. Eq. (112)

The linkages of the circuits involved are from (36) and (37),

$$i_f\,L_f + i_{ab}\,(M_{fa} - M_{fb}) = I_f'\,L_f \tag{88}$$

$$i_f\,(M_{af} - M_{bf}) + i_{ab}\,3\,L_a = 0 \tag{89}$$

Solving simultaneously and substituting (9), (12) and (25),

$$i_f = I_f' \frac{1}{(1 - 0.5\,K^2) - 0.5\,K^2 \cos 2\,(\alpha + 30)} \tag{90}$$

$$i_{ab} = -\,\frac{1}{\sqrt{3}} I_f' \frac{M_0}{L_a} \frac{\cos(\alpha + 30)}{(1 - 0.5\,K^2) - 0.5\,K^2 \cos 2\,(\alpha + 30)} \tag{91}$$

Equation (93) is again of the same form as (77) so

that I_f' is given by (79). Substituting for I_f' in (90) and (91);

$$i_f = I_f \frac{\sqrt{1 - K^2}}{(1 - 0.5\,K^2) - 0.5\,K^2 \cos 2\,(\alpha + 30)} \tag{92}$$

$$i_{ab} = -\frac{1}{\sqrt{3}}\, I_f \frac{M_0}{L_a} \frac{\sqrt{1 - K^2}\cos(\alpha + 30)}{(1 - 0.5\,K^2) - 0.5\,K^2 \cos 2\,(\alpha + 30)} \tag{93}$$

These equations are plotted in Fig. 11 for K and

$$\frac{M_0}{L_a} = 0.85.$$

2. Two-Phase Short Circuit.

(a) Two-phase alternator, (Case 6, Fig. 1).

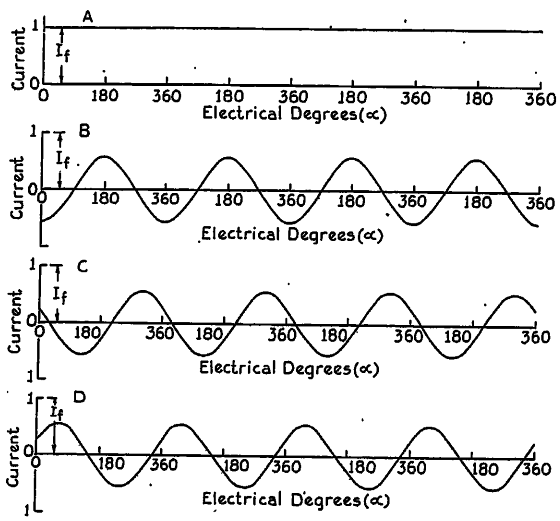

FIG. 14—PERMANENT SHORT-CIRCUIT CURRENTS; CASES 8 AND 9

Curve A—Field current. Eq. (117)
Curve B—Current in phase a. Eq. (118)
Curve C—Current in phase b. Eq. (119)
Curve D—Current in phase c. Eq. (120)

The flux linkages of the circuits involved, from (45), (46) and (47) are,

$$i_f L_f + i_a M_{fa} + i_b M_{fb} = I_f' L_f \tag{94}$$

$$i_a L_a + i_f M_{af} = 0 \tag{95}$$

$$i_b L_b + i_f M_{bf} = 0 \tag{96}$$

Solving simultaneously and substituting (9), (12), (13), and (22),

$$i_f = I_f' \frac{1}{1 - K^2} \tag{97}$$

$$i_a = -I_f' \frac{M_0}{L_a} \frac{\cos\alpha}{1 - K^2} \tag{98}$$

$$i_b = -I_f' \frac{M_0}{L_a} \frac{\sin\alpha}{1 - K^2} \tag{99}$$

The field current (97) has only a direct component, and is therefore equal to I_f.

Hence,

$$I_f' = I_f\,(1 - K^2) \tag{100}$$

Substituting (100) in (97), (98) and (99),

$$i_f = I_f \tag{101}$$

$$i_a = -I_f \frac{M_0}{L_a} \cos\alpha \tag{102}$$

$$i_b = -I_f \frac{M_0}{L_a} \sin\alpha \tag{103}$$

These currents are plotted in Fig. 12 for K and $\frac{M_0}{L_a}$ equal to 0.85.

(b) Three-phase alternator, (Case 7, Fig. 1).

The flux linkages of the circuits involved are from (54), (55) and (56),

$$i_f L_f + i_a M_{fa} + i_b M_{fb} = I_f' L_f \tag{104}$$

$$i_a L_a + i_f M_{af} + i_b M_{ab} = 0 \tag{105}$$

$$i_b L_b + i_f M_{bf} + i_a M_{ba} = 0 \tag{106}$$

Solving simultaneously and substituting (9), (12), (22), (25) and (35),

$$i_f = I_f' \frac{1}{1 - K^2} \tag{107}$$

$$i_a = -\frac{2}{\sqrt{3}} I_f' \frac{M_0}{L_a} \frac{\cos(\alpha - 30)}{1 - K^2} \tag{108}$$

$$i_b = -\frac{2}{\sqrt{3}} I_f' \frac{M_0}{L_a} \frac{\sin\alpha}{1 - K^2} \tag{109}$$

The field current (107) is the same as (94) so that the value of I_f' is given by (100). Substituting for I_f';

$$i_f = I_f \tag{110}$$

$$i_a = -\frac{2}{\sqrt{3}} I_f \frac{M_0}{L_a} \cos(\alpha - 30) \tag{111}$$

$$i_b = -\frac{2}{\sqrt{3}} I_f \frac{M_0}{L_a} \sin\alpha \tag{112}$$

These equations are plotted in Fig. 13 for $K = 0.85$ and

$$\frac{M_0}{L_a} = 0.85.$$

3. Three-Phase Short Circuit.

(a) Three-phase alternator, (Case 8, Fig. 1).

The flux linkage equations of the four circuits involved are,

$$i_f L_f + i_a M_{fa} + i_b M_{fb} + i_c M_{fc} = I_f' L_f \tag{113}$$

$$i_a L_a + i_f M_{af} + i_b M_{ab} + i_c M_{ac} = 0 \tag{114}$$

$$i_b L_b + i_f M_{bf} + i_a M_{ba} + i_c M_{bc} = 0 \tag{115}$$

$$i_c L_c + i_f M_{cf} + i_a M_{ca} + i_b M_{cb} = 0 \tag{116}$$

Solving simultaneously and substituting (9), (12), (22), (25), (35), (68), (69) and (70), and the value of I_f' given by (100) since i_f comes out the same as (97),

$$i_f = I_f \tag{117}$$

$$i_a = -\frac{2}{3} I_f \frac{M_0}{L_a} \cos \alpha \tag{118}$$

$$i_b = -\frac{2}{3} I_f \frac{M_0}{L_a} \cos (\alpha - 120) \tag{119}$$

$$i_c = -\frac{2}{3} I_f \frac{M_0}{L_a} \cos (\alpha + 120) \tag{120}$$

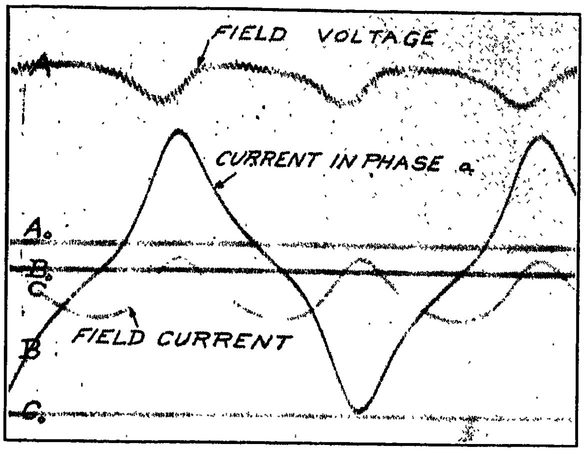

FIG. 15—OSCILLOGRAM OF THE PERMANENT SINGLE-PHASE SHORT-CIRCUIT CURRENTS OF A THREE-PHASE ALTERNATOR SHORT-CIRCUITED BETWEEN TWO TERMINALS

These currents are plotted in Fig. 14 for $K = 0.85$ and

$$\frac{M_0}{L_a} = 0.85.$$

(b) Three-phase alternator, (Case 9, Fig. 1).

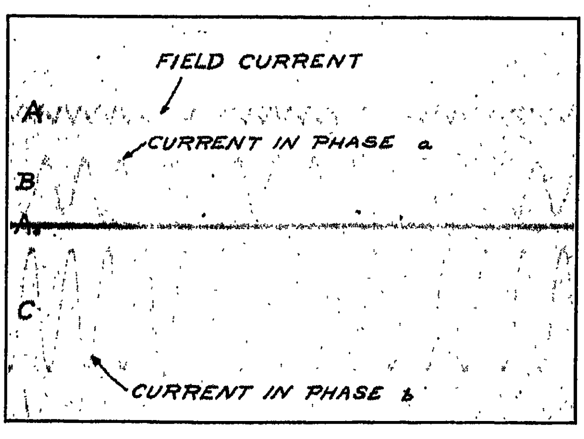

FIG. 16—OSCILLOGRAM OF THE PERMANENT TWO-PHASE SHORT-CIRCUIT CURRENTS OF A THREE-PHASE ALTERNATOR SHORT-CIRCUITED BETWEEN TWO TERMINALS AND NEUTRAL
The two armature currents are of different calibration.

The current equations for this case are the same as those for a three-phase short-circuit terminal-to-neutral.

NOTATION

α electrical angle of rotation of field. (See Fig. 2).

I_f value of field current in amperes before short-circuit.

I_f' the constant value of field current in amperes under the permanent short-circuit condition that would be required on open circuit to produce the same number of flux linkages with the field circuit as exist under the permanent short-circuit condition.

i_a, i_b, i_c instantaneous values of current in amperes in phases a, b and c respectively.

i_{ab} instantaneous values of current in amperes in the single-phase circuit composed of phases a and b in series.

i_f instantaneous value of field current in amperes.

K coefficient of magnetic coupling between any one armature phase and the field circuit. (See Eq. 12).

L_a, L_b, L_c true coefficient of self inductance in henrys of phases a, b and c respectively.

L_f true coefficient of self inductance in henrys of field current.

$M_{ab} = M_{ba}, M_{ac} = M_{ca}, M_{bc} = M_{cb}$ coefficient of mutual inductance in henrys between phases a and b, a and c, and b and c.

$M_{fa} = M_{af}, M_{fb} = M_{bf}, M_{fc} = M_{cf}$ coefficient of mutual inductance in henrys between the field circuit f and phases a, b and c respectively for any value of α

M_{fab} coefficient of mutual inductance in henrys between the field circuit and phases a and b in series for any value of α

M_0 coefficient of mutual inductance in henrys between the field circuit and any one armature phase when in the position of maximum coupling.

$\Omega_a, \Omega_b, \Omega_c$ flux linkages of phases a, b and c respectively for any value of α

Ω_{ab} flux linkages of the single-phase circuit composed of phases a and b in series for any value of α

Ω_f flux linkages of the field circuit for any value of α

Discussion

INITIAL AND SUSTAINED SHORT CIRCUITS IN SYNCHRONOUS MACHINES

(KARAPETOFF)

SHORT-CIRCUIT CURRENTS OF SYNCHRONOUS MACHINES

(FRANKLIN)

ST. LOUIS, MO., APRIL 14, 1925

R. E. Doherty: Progress in most investigations of the complexity of those taken up in the two papers on short-circuit currents is made step by step.

As Professor Karapetoff brought out, there are still further steps to take; saturation must be taken into account and also the effect of salient poles. But I think that the equations and the results which have been obtained by Mr. Franklin and which Professor Karapetoff's method has completely checked have formed another definite step in advance in this problem.

I wish to say a word about methods. In 1918, I was engaged in some work along these lines and I was confronted, like everybody else who has undertaken such studies, with the practically impossible undertaking of solving short-circuit problems when resistance is taken into account. In the investigation it appeared that sufficiently close approximation could be made in many instances by neglecting resistance.

I proposed, at that time, the constant-linkage theorem which Mr. Franklin has utilized in his paper. It is the simple relation which follows at once from Kirchoff's Law and the assumption of zero resistance. From these two premises, the theorem stated in Mr. Franklin's paper is this: In any closed circuit without resistance the flux linkages must remain constant. It doesn't matter how many secondary circuits there are, or what the network involves, the theorem is rigidly true.

Now, the question which I wish to raise with respect to Prof. Karapetoff's paper is that if this theorem is true (he makes the assumption that the resistance is zero), why is it necessary to go back to Kirchoff's equations in each particular case as he does, performing the integration and finding the integration constant, which in every case, of course, turns out to be the known magnetic linkages existing when the circuit was closed?

Prof. Karapetoff has stated that after making the integration, that is, dropping the derivative symbol, the problem is solved. That is exactly where you start if you apply the constant-leakage theorem. Mr. Franklin has followed the latter method. That is a point more of interest than of importance, but it is a question of ease with which the problem can be solved, if advantage is taken of the facilities afforded by a simple theorem.

R. W. Wieseman: In single-phase generators usually only two-thirds of the coils per pole are used and connected in series. This corresponds to a 120-deg. phase belt and is classified under Case 5 of Mr. Franklin's paper. From Table II we find that the initial single-phase short-circuit current peak value (Case 5) is only 86 per cent of the three-phase short-circuit peak, Case 9. Furthermore, the current wave of Case 5, Fig. 5, is more peaked than that of Case 9, Fig. 8, so that the effective value of the initial single-phase short-circuit current, Case 5, will be less than 86 per cent of the initial three-phase short-circuit current. Therefore, at the initial short circuit an armature coil in a single-phase generator will have only about half as much heat to dissipate as an armature coil in a three-phase generator. However, a study of a large number of oscillograms shows that the initial single-phase short-circuit current is practically the same as the three-phase short-circuit current.

The five assumptions which the author made in deriving the formulas are reasonable and they should not introduce an appreciable error in most cases. These assumptions must be made if a simple and practical solution of such a complicated problem is to be obtained. There are, however, a few cases which might be mentioned as a matter of interest in which different results are obtained in practise from those given by the formulas. I refer to the sustained short-circuit armature current waves of Cases 1, 2, 3, 4 and 5 shown by Figs. 9, 10 and 11 which show symmetrical short-circuit current waves. Fig. 1 accompanying this discussion shows a typical sustained armature current wave corresponding to the author's Case 5, Fig. 11, of a cylindrical-rotor generator without a pole-face damper winding. The five assumptions are realized in this type of a machine more than in any other type. Contrary to Fig. 11, Fig. 1 herewith is not a symmetrical wave and it contains cosine terms as well as sine terms. Fig. 2 herewith shows a typical sustained short-circuit current wave corresponding to Case 5, Fig. 11, of a salient-pole machine without a pole-face damper winding. Fig. 2 herewith is a symmetrical wave, but this machine does not fulfil condition *D* of the paper.

Fig. 14 of the paper shows the same short-circuit current waves for both Cases 8 and 9. For Case 8 the short-circuit armature current wave is rarely a sine wave as shown by Fig. 14. The short-circuit current wave for Case 8 usually contains a negative third harmonic which gives a peaked wave as shown by the accompanying Fig. 3. For Case 9 the sustained short-circuit current wave is practically a sine wave as shown by the accompanying Fig. 4. It should be noted that this Fig. 4 agrees with Fig. 14 in the paper.

In addition to the five assumptions made in deriving the formulas of this paper, there is another assumption which the author made but apparently neglected to mention, namely, that the machines have no pole-face damper windings. All synchronous motors are furnished with pole-face starting windings and many generators have pole-face damper windings. If the machines whose sustained short-circuit armature current waves are shown by Figs. 1 and 2 herewith are equipped with pole-face windings, the short-circuit current waves will now be as shown by Figs. 5 and 6 herewith respectively. It is apparent that these waves are as nearly true sine waves as can be obtained. The addition of a good damper winding short circuits the double-frequency armature-reaction component which induces (by transformer action) a triple-frequency voltage in the armature winding. Since the phase belt is 120 deg. (Case 5) the third-harmonic voltage induced (by dynamic action) in the armature winding by the third harmonic of the flux wave cannot appear at the terminals of the machine. Consequently, a nearly true sine wave of current results.

Fig. 16 of the paper shows an oscillogram of the sustained two-phase short-circuit currents of a three-phase alternator short-circuited between two terminals and neutral, Case 7. It is pointed out in the paper that the alternating component induced in the field winding in this case is very small and the field-current Curve *A*, Fig. 13, is shown as a straight line. Fig. 16 shows a double-frequency component in the field current of only plus or minus 9 per cent. The generator which was used in this particular case was equipped with a pole-face damper winding which tends to damp the single-phase double-frequency pulsations in the field circuit. Fig. 7 herewith shows an oscillogram of the armature current and field current for the same conditions as shown by the author's Fig. 16 taken from a generator which had no pole-face winding. It should be noted that the variation in the field current is plus or minus 33 per cent. Therefore, Case 7 is in reality a partial single-phase load (the two armature currents being out of phase by 120 deg.) and results in the usual

double-frequency pulsation in the field winding. Of course, Case 7 does not give so great a double-frequency pulsation as Cases 3 and 5, but it is decidedly more than Cases 8 and 9. If the value of the coupling coefficient K is calculated for this particular machine, it is found to be from -0.35 to -0.40 instead of cosine 120 deg. which equals -0.5.

J. F. H. Douglas (by letter): The points that impress one most forcibly in Professor Karapetoff's paper are the mathematical elegance and the generality of the relations discussed,

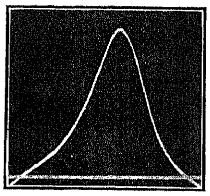

Fig. 1—Sustained Single-phase, Short-Circuit Current, Terminal to Terminal, (Case 5). Cylindrical Rotor Generator without Damper Winding

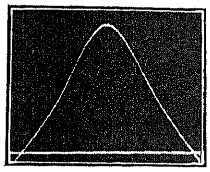

Fig. 2—Sustained Single-Phase Short-Circuit Current Terminal to Terminal (Case 5) Salient Pole Generator without Damper Winding

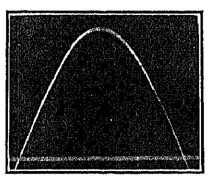

Fig. 6—Sustained Single-Phase, Short-Circuit Current, Terminal to Terminal (Case 5) Salient Pole Generator with Damper Winding

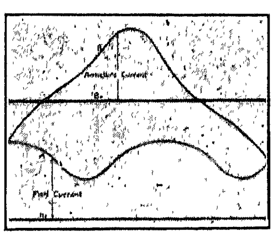

Fig. 7—Sustained Two-Phase, Short-Circuit Current of a Three-Phase Generator between Two Terminals and Neutral, without Damper Winding

together with the space-vector diagrams. There are a few points which I should like to mention.

In the first place it should be noted that the equations (21) to (25) are really of great simplicity. The chief difficulty in the appendices that follow lies in the determination of the constants of integration. Whether one reads the latter appendices or not, the first appendix should be of great general interest, in that it proves the general principle involved.

The physical interpretation of Equations (21) to (25) is that there is continuity and approximate constancy in the linkages existing at the instant of short circuit, so that, the armature drags its linkages around with it. A picture of my interpretation of these equations is shown in Fig. 8 herewith, where a two-phase machine is shown with 50 per cent pitch armature coils. At the top of the picture are shown conditions at instant of short circuit. Phase A links with useful flux, phase B with no flux and the field with the total flux. Phase A has no leakage locally around the slots at this instant. The middle figure shows flux lines 90 deg. later in time phase. Phase A has dragged its linkages around into the interpolar region. Phase B has reflected or warded the pole flux away from entering the armature. The lowest portion of the figure shows flux lines 180 electrical degrees from the start. Phase A is now feeding flux into the

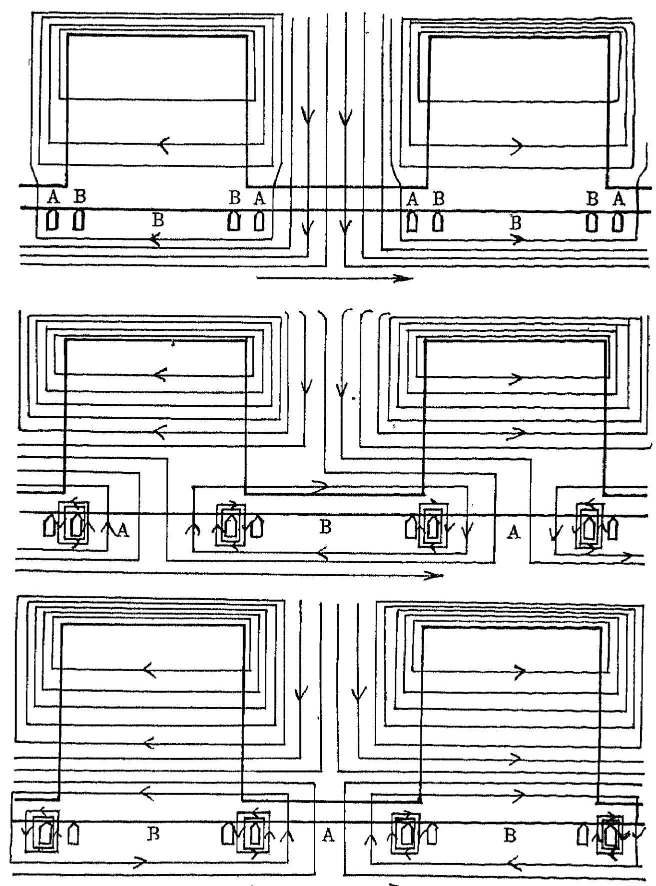

Fig. 8—Diagram Showing Continuity of Flux Leakages During Short Circuit

pole, and the leakage flux is immensely increased, both locally and between the poles. This picture shows perhaps more clearly than any formula the advantage of having the values of σ and τ less than one and a value of K considerably less than unity, if possible. It is readily seen that the values of armature current and field current corresponding to the bottom diagram must be very large to force the flux through paths of such high reluctance. A similar condition obtains in the case of a machine with a distributed field.

In the fifth paragraph of the paper the assumption is made that the field winding is placed upon a cylindrical rotor, so that the self and mutual inductances of the armature windings may be considered to remain constant throughout a cycle. These constants are treated as absolute constants, however, and so it

may be said that saturation is also neglected. These assumptions are the same assumptions upon which the idea of "synchronous impedance" is based. The first of these assumptions is not true in any machine, for normal field currents. The principle of continuity in the linkages existing at short circuit, would tend to perpetuate saturation existing at the instant of short circuit. Nevertheless, the assumption of uniform air-gap permeance, constant inductances, and synchronous impedance, based upon them, all are useful as first approximations.

As a second approximation, in the case of sinusoidal and steady load currents, I have found the idea of synchronous impedance useful even in the case of salient-pole machines, because of its simplicity. But, one must point out that at high saturations the numerical value of this constant is reduced, and that at high power factors the numerical value is also decreased. Whether, this same second assumption of an average and constant L

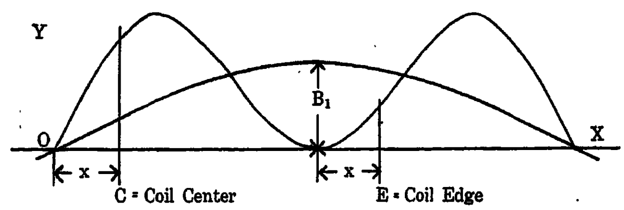

FIG. 9—TRANSVERSE FLUX WAVE SHAPE

is also applicable to the case of the transient condition of short circuit I am not prepared to state. It would certainly be some simplification in the theory if it should prove to be the case.

It occurs to me that a third approximation ought to take in the variation of the permeance of the air-gap with the angle from the pole center. Perhaps this can be best done by considering the flux resolved into two components, along the polar, and transverse to the polar axis. The flux produced by the direct ampere-turns, may be considered substantially as sinusoidally distributed, while that caused by any transverse ampere-turns may be considered as distributed as in Fig. 9 herewith, the equation of which is $Y = B_1 (\sin x + \sin 3x)$.[1] The m. m. fs of the armature are to be thought of as sinusoidally distributed, the direct flux as sinusoidal, but the transverse flux as non-sinusoidal.

Let us assume a two-phase machine, with the windings identical, and displaced 90 deg. on the armature surface. Let, τ, σ, N_a, N_f, I_f, i_f, L_a, L_f, α, have the meaning in Prof. Karapetoff's article. Let the direct flux be ϕ'_d, the transverse ϕ_t'. Let χ be the ratio of the transverse flux set up by 1 ampere-turn to the direct flux (sine-wave component). Let the arrangement of the circuits be as shown in Fig. 10 herewith. Then we should note that equations (1), (2), (3), (10a), (10b) and (10c) are not correct, since although M_{ab} would appear to be zero, there is mutual induction between the phases owing to differing air-gap permeance in different directions.

$$\phi_t = \chi\,(L_a/N_a)\,(i_a \sin\alpha - i_b \cos\alpha) \qquad (1)$$

$\phi_d = (L_a/N_a)\,(i_a \cos\alpha + i_b \sin\alpha),\ + i_f\,\tau\,L_f/N_f$ linking with armature (2)

$\phi_f = (L_a\,\sigma/N_a)\,(i_a \cos\alpha + i_b \sin\alpha) + i_f L_f/N_f$ linking with field (3)

The linkages in phase with a coil in position x is, of course,

$$\phi_x = \phi_d \cos x + \phi_t\,(\sin x - 0.33 \sin 3x) \qquad (4)$$

When x is changed to α equation (4) herewith becomes equation for ϕ_a.

To find ϕ_b we let x = 90 deg. $- \alpha$, and get

$$\phi_b = \phi_d \sin\alpha + \phi_t\,(\cos\alpha + 0.33 \cos 3\alpha) \qquad (5)$$

If the initial value of the field current if I_f and the short circuit occurs when the phase a is in maximum linkage with the pole.

1. Distribution of Φ_t is in accordance to density $(\sin x + \sin 3x)$ and according to linkage $(\sin x - {}^1/_3 \sin 3x)$.

$$\phi_f = I_f L_f/N_f,\quad \phi_b = 0,\quad \phi_a = \tau\,I_f L_f/N_f \qquad (6)$$

The constants in equations (3), (4) and (5) herewith, are given in (6) or in similar equations for other initial conditions. The variables ϕ_t and ϕ_d can be obtained from equations (1) and (2). These equations contain only three unknown quantities i_a, i_b, and i_f, and therefore, permit us to solve simultaneously. Rather, however, pursuing the matter further, I call upon Professor Karapetoff to state, whether in his judgment, this reasoning is valid and if it would, or would not, lead to materially different results.

It is interesting to note that in equations (10a) and (10c) if θ_{ab} and θ_{ac} are each 120 deg. and if $N_a = N_b = N_c$, that $M_{ab} = M_{ca} = -0.5\,L_a$. It is interesting also to note that equation (1) might apply individually to phases even though a short circuit were not present. In equation (1) if we let $L = 0$, and remove the short circuit, the voltages e are replaced by e_a, e_b, e_c. Let us now assume, that i_a, i_b, and i_c, are sinusoidal, equal in magnitude, and displaced by 120 deg. time phase, then

$$(d\,i_b/d\,t) + d\,i_c/d\,t = -\,(d\,i_a/d\,t),$$

$$d\,i/d\,t = j\,2\,\pi f\,\dot{I} \text{ and } d\,(M_{af}\,i_f)\,d\,t = \dot{E}_o$$

and equation (1) reduces to the familiar form

$$\dot{E}_o - j\,2\,\pi f\,(3/2)\,L_a\,\dot{I}_a = \dot{E}_a \qquad (7)$$

Or, stated in words, the terminal voltage in any phase with balanced load, is equal to the voltage induced in that phase at no load, minus a drop in time quadrature with the current, a drop which is usually called the synchronous reactance drop.

Inasmuch as I have been questioned by Professor Karapetoff in discussion of a recent article of the JOURNAL for the use of synchronous impedance even as a second approximation, I should like him to explain clearly for the benefit of the readers of the JOURNAL his position on this subject so far as it is implied in his paper.

R. H. Park (Communicated after adjournment): On the second page of his paper in referring to the coefficient of coupling between the phases of an alternator, Mr. Franklin states,

"Thus, for a three-phase alternator, this coupling coefficient was assumed equal to cos 120, or -0.5. This ideal value of coupling is seldom obtained in practise."

Actually, it may be shown that for a symmetrical three-phase

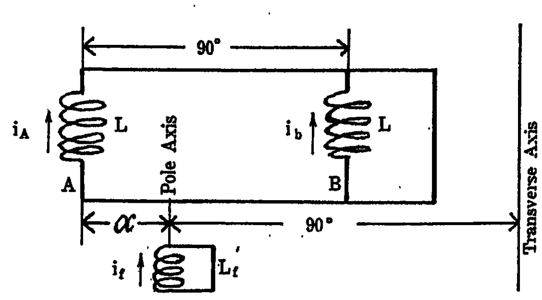

FIG. 10—DIAGRAM OF TWO-PHASE ALTERNATOR

alternator the numerical value of the mutual inductance M between phases must be less than the self inductance L per phase, that is, $L + 2\,M > 0$.

For suppose the alternator of Fig. 11 herewith to be used as a transformer, power being supplied to Phase 1 as the primary and taken from Phase 2 and 3 in parallel as the secondary.

The statement of Kirchoff's law is for the primary,

$$r\,i_1 + L\frac{d\,i_1}{d\,t} + \frac{M\,d\,(i_2 + i_3)}{d\,t} = e_1$$

and for Phase 2 of the secondary,

$$r\,i_2 + L\frac{d\,i_2}{d\,t} + \frac{M\,d\,(i_3 + i_1)}{d\,t} = e_2$$

But by symmetry it follows that the currents in Phases 2 and 3 are equal, that is, $i_2 = i_3$. Substituting and rearranging gives,

$$r\, i_1 + L \frac{d\, i_1}{d\, t} + \frac{M\, d\,(2\, i_2)}{d\, t} = e_1 \qquad \textbf{(c)}$$

$$r\, i_2 + \frac{L + M}{2} \frac{d\,(2\, i_2)}{d\, t} + \frac{M\, d\, i_1}{d\, t} = e_2 \qquad \textbf{(d)}$$

Since in equation (**d**) $2\, i_2$ represents the total current entering the secondary of the transformer, $\frac{L + M}{2}$ becomes the equivalent self-inductance of the secondary of the transformer.

In order that the coefficient of coupling of the transformer shall

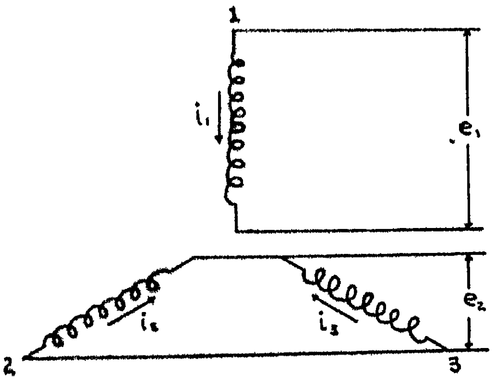

FIG. 11

be less than unity, it is necessary that $L_1 L_2 > M^2$ where L_1 is the primary and L_2 the secondary self-inductance and M is the mutual inductance of transformer. Therefore it follows that

$$L_1 L_2 = \frac{L\,(L + M)}{2} > M^2 \qquad \textbf{(e)}$$

$$L^2 + L\, M - 2\, M^2 = (L - M)\,(L + 2\, M) > 0 \qquad \textbf{(f)}$$

or since M is essentially negative $L + 2\, M > 0$.

N. S. Diamant (by letter): One of the interesting features of these papers is the extensive use of the ideas of mutual and self inductance and fluxes instead of reactances. There was a time when the use of these more elementary notions was not very popular and we had to use reactances and impedances. In this connection Prof. Karapetoff's method of dealing with permeances is very interesting and should prove useful. After a little practise the expressions (**7**) to (**11c**) should prove very simple and useful in general engineering work. One of the great advantages of such expressions is the fact that they keep before us a clear mental picture of the underlying physical phenomena. In this connection it is very important to remember the meaning of $K = M^2/L_f\, L_a$. If $K = 1$ then $M^2 = L_f\, L_a$ and there is no leakage flux between armature and field; this is a condition never realized and thus K is always smaller than 1 and $K^2 = \sigma\, \tau$ where σ and τ are the leakage coefficients for the armature and field respectively.

The fundamental treatment of the subject is the same in both papers although equations (**1**) to (**4**) of Prof. Karapetoff have been written in terms of e. m. f. and Mr. Franklin's equations (**3**) to (**6**) in terms of flux. For example, translating into English equation (**1**) of Prof. Karapetoff we have: e. m. f., e induced in phase A = the e. m. f. of self-inductance of phase A + the e. m. f. of mutual inductance of phases B and C + the e. m. f. of rotation due to the field flux. Similar to this is Mr. Franklin's equation (**113**) for a three-phase alternator or the simple equations (**3**) to (**6**).

Returning to Prof. Karapetoff's fundamental equations, it may be well to call attention to the fact that the total induced e. m. f., e is arbitrarily assumed to be a function of s and to be equal to $S + A$ for phase A; $S + B$ for phase B, etc. Then the value of s is taken as equal to S at the instant of short circuit and a new arbitrary relation involving angle ξ is introduced in equations (**26**) to (**28**).

Translating this statement into mathematical shorthand we obtain:

$$L_a\, i_a + M_{ab}\, i_b + M_{ca}\, i_c + M_{fa}\, i_f = (N_a\, \Phi \sin \omega\, t)\, \epsilon^{-\alpha_a (t - t_1)}$$

for phase A, and similar expressions for the other phases. For the field we have:

$$L_f\, i_f + M_{fa}\, i_a + M_{fb}\, i_b + M_{fc}\, i_c$$
$$= N_f\, [\, \Phi_{fasc} + (\Phi_f - \Phi_{fasc}\,)\, \epsilon^{-\alpha_f (t - t_1)}]$$

I have used the same notation as Prof. Karapetoff and t_1 or θ_1 is the time or the corresponding time angle at which the sudden short circuit occurs.

All this is very good, but an engineer will do well to keep in mind always the physical meaning and interpretation of the fundamental equations. Unlike the pure mathematician, when an engineer introduces arbitrary functions, he will do well to try to understand the physical side of his mathematics. If he does not, he will be merely riding through a tunnel, having left the light behind him and he may emerge again into light or he may not. I have tried to look over Prof. Karapetoff's paper from this point of view of coordinating mathematics with their physical meaning and although I had some difficulty in understanding the physical meaning of the functions introduced, no doubt this was my fault. Prof. Karapetoff with his usual clearness no doubt has presented the subject thoroughly but it may require more study to understand the physical meaning of all the fundamental concepts involved.

There is another very important point to be considered in connection with these papers, namely, that they give expression for instantaneous and sustained short-circuit currents but none for the transient.

It is simple to obtain the fundamental expression whose solution will give the transient currents as well as their initial and final values. Consider one of the phases of a three-phase alternator and suppose that phase No. 1 is at the position indicated in Fig. 12 herewith, when the three phases are suddenly and simultaneously short-circuited. Assuming a sinusoidal flux

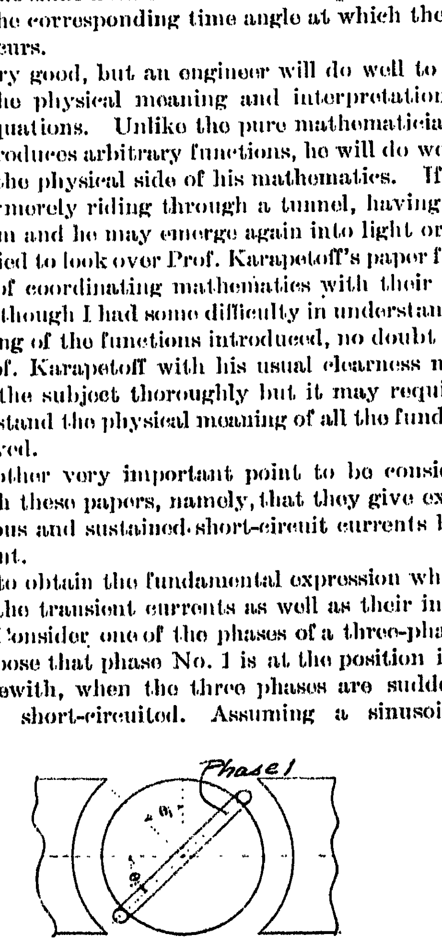

FIG. 12—CONDITION ASSUMED FOR DISCUSSION

distribution, the flux inclosed by phase No. 1 at the instant of the short circuit will be:

$$N_a\, \Phi_a \sin \omega\, t_1 = N_a\, \Phi_a \sin \theta_1$$

where $N_a\, \Phi_a$ = maximum flux inclosed by the N_a turns of any given phase. The flux inclosed by phase No. 2 at the instant of the sudden short circuit will be $N_a\, \Phi_a \sin (\theta_1 + 2\, \pi/3)$, and similarly for the third phase.

As is well known, the flux inclosed by any given phase under sustained short circuit is a very small fraction of $N_a\, \Phi_a$. Therefore, if it is assumed that the sustained short-circuit armature reaction (a) is wholly demagnetizing (b) and sinusoidally distributed like the field flux, and that (c) *the armature resistance drop is negligible compared to the reactance drop*; then a little consideration will show that the armature flux under sustained short circuit will be zero. Thus the flux linking with phase No. 1 is $N_a\, \Phi_a \sin \theta_1$, at the instant of the sudden short circuit when $t = t_1$; it is reduced to zero at the end of the short circuit when $t = \alpha$, and it is $(N_a\, \Phi_a \sin \omega\, t)\, \epsilon^{-\alpha_a (t - t_1)}$ at any time t during

the interval of sudden short circuit, α_a being the attenuation factor of the armature. Under normal or transient conditions the *flux linking phase No. 1 is equal at every instant to the mutually inductive flux coming from the field plus the self-inductive flux of phase No. 1 itself.* The corresponding condition holds true for the other phases. Compare Karapetoff's equations (1) to (4).

The field flux, which is $N_f \Phi_f$ under normal conditions, dies down to $\Phi_{fs\,c}$ at the end of the sudden short circuit or at the beginning of the sustained short circuit; at any time after the sudden short circuit it is equal to (See Fig. 14)

$$\Phi_f = \Phi_{fssc} + (\Phi_f - \Phi_{fssc})\, \epsilon^{-\alpha_f (t - t_1)}$$

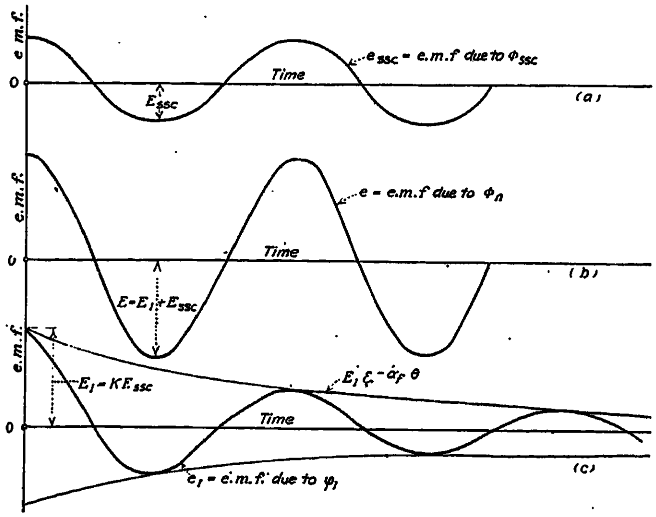

FIG. 13—E.M.FS. PRODUCED BY CONDUCTORS CUTTING ϕ_{ssc}, ϕ_n AND $(\phi_n - \phi_{ssc})$

where α_f is the attenuation factor of the field. Under normal or transient conditions this flux *is equal at every instant to the mutually inductive flux coming from the three phases plus the self-inductive flux of the field itself.*

With reference to Table II in Mr. Franklin's paper it was very gratifying for me to see that Cases 3 and 5 act so differently. In 1915 I had noticed this and in view of my meager data stated: "the case of single-phase short circuits, between two terminals or terminal and neutral, present considerable difficulties; the latter seems to give much higher current rushes than a short circuit between terminals," and as seen from the table the ratio is 1 to 1.732.

The sustained short-circuit phenomena are very interesting and particularly the flux distribution is quite fascinating. As a result of a fairly elaborate investigation I had shown in 1918[2] that the armature current and the e. m. f. waves may be nearly sinusoidal but the resultant flux wave may be extremely distorted for the simple reason that with the very low voltages which obtain under s. s. c. conditions the fundamental is so greatly reduced that the higher harmonics assume a very predominant role. For example, if the field flux consists of: Fundamental, 100 per cent; third harmonic + 10 per cent, and fifth harmonic + 5 per cent, while the armature flux consists of: Fundamental − 95 per cent; third harmonic, + 10 per cent, and fifth harmonic, + 5. per cent; then the resultant will be: Fundamental, + 5 per cent; third harmonic, + 20 per cent and fifth harmonic, + 10 per cent, — which will be a very distorted wave.

C. M. Laffoon (by letter): The general method of solution as used by Mr. Franklin in determining the magnitude of the short-circuit currents during the first cycle after the short-circuit occurs is the same as was used in my paper[3] on the same subject at the 1924 Midwinter Convention of the A. I. E. E. Moreover, the various cases of generator winding combinations and short-circuit conditions are also practically the same.

The expressions for the maximum or peak values of the short-circuit waves as derived by Mr. Franklin are in general, the same as given in my paper. However, there are two features or discrepancies to which it is necessary to call attention. It is indicated in Table II that the peak value of the current in the case of a single-phase short circuit between main terminals is irrespective of the width of the single-phase winding belt. The general expression for the peak value of the armature current in a single-phase short circuit is

$$i_a = \frac{2\, I_f\, M_o}{L_a - \dfrac{M_o^2}{L_f}}$$

Hence in order for the armature current of a single-phase generator with any width of winding belt to have a constant ratio with respect to a terminal-to-terminal three-phase short-circuit current, it is necessary for both numerator and denominator of the above expression to vary in the same way with respect to the width of the winding belt. There can be no question but that the quantity $2\, I_f\, M_o$, varies as the sine of the width of the winding belt. My analysis shows that the quantity $L_a - \dfrac{M_o^2}{L_f}$ varies approximately as the sine-square of the width of the winding belt. These relations are shown in Figs. 18 and 19 of my original paper. The general shape of the curve of $L_a - \dfrac{M_o^2}{L_f}$ as a function of the width of the winding belt has been checked experimentally by (a) locking the rotor so that the axis of the field winding coincides with the axis of the portion of the armature winding under consideration; (b) short-circuiting the field-winding; and (c) then applying single-phase voltage to the armature winding. The test results which were obtained on a 6250-kv-a. turbo generator are shown in Figs. 15 and 16 herewith. On this basis, the general relations between the different armature currents of a single-phase generator with different widths of winding belts are shown in Fig. 5 of my paper.

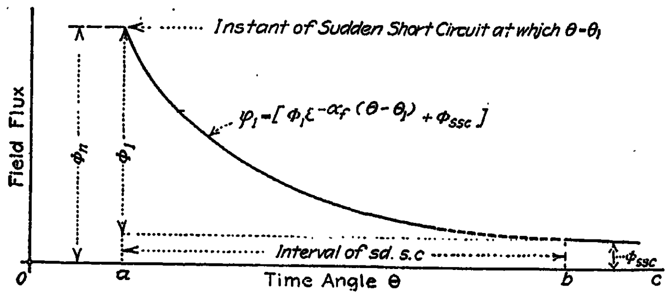

FIG. 14—ATTENUATION OF FIELD FLUX

In my paper, the maximum value of the armature current for a three-phase alternator when the short circuit occurs between terminals as given in Case 10 of Table I is based on the condition that the short circuit occurs when the axis of the field winding coincides with the axis of the portion of the armature winding included between two main terminals. If the short circuit occurs at the instant when the axis of the field winding coincides with the axis of one phase, terminal to neutral, the peak value of the maximum current will be the same as in Cases 7, 8 and 9 of my paper and Cases 8 and 9 of Mr. Franklin's paper.

V. Karapetoff: In my paper I assume that there is no saturation and no salient poles, but, as has been pointed out by Professor Douglas before this problem is finished, we ought to extend the solution to machines with definite poles and

2. Sustained Short-Circuit Phenomena and Flux Distribution of Salient-Pole Alternators, by N. S. Diamant, A. I. E. E. TRANSACTIONS, Vol. XXXVII, page 1141.

3. Short-Circuits Current of Alternating-Current Generators, by C. M. Lafoon, A. I. E. E. JOURNAL, August 1924, page 737.

machines involving saturation. In the initial short circuit, if there is saturation in the beginning and the field persists, that field will also contain saturation, after the instant of short circuiting. Mr. Franklin points out in his paper that this factor may be approximately taken into account by properly modifying the values of self and mutual induction.

Another answer to Professor Douglas is this: When we investigate the operation of a machine under normal conditions, we want to know its characteristics more or less exactly, but in the case of a short circuit, the indefinite resistance of the leads

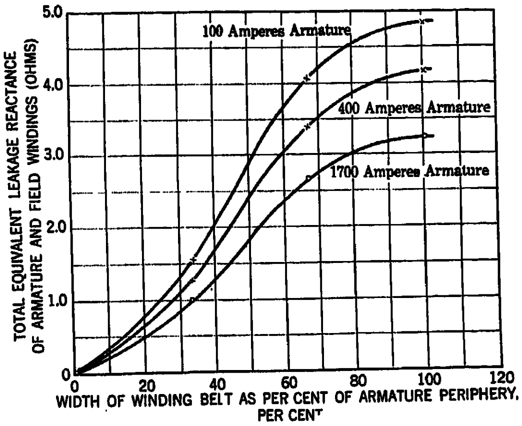

Fig. 15—Total Equivalent Leakage Reactance of Armature and Field Windings Combined. Axes of Two Windings Coincide, Single-Phase Armature Winding

and of the nature of the phenomenon itself are such that we can seek hardly a definite solution, but only a possible maximum. So that no such accuracy is required in problems involving short circuits as in problems referring to operating conditions.

Mr. Doherty wishes to know why I start with differential equations rather than using directly the condition of constant magnetic linkages. One reason is that in most of our problems we have resistance as a factor, and for one problem that involves no resistance, I probably have a dozen which contain resistances. So it seems more natural always to start with Kirchoff's Law. The other reason is this: In a star-connected combination, constant flux linkages refer to a closed circuit, which, in this case, contains two phases in series. Two equations of constant linkages may be written, and these equations will contain, say, phase No. 1 twice; but phases No. 2 and No. 3 only once. Therefore, the equations are not symmetrical. From a mathematical point of view, it is better to have symmetrical equations, and this is done in my paper by introducing an auxiliary voltage e. However, I grant that it is possible to introduce a fictitious flux Φ and in this manner keep the flux equations symmetrical. In other words, instead of writing the flux linkage equations in the form

$$\Sigma \Phi_1 - \Sigma \Phi_2 = \text{Const.}$$
$$\Sigma \Phi_1 - \Sigma \Phi_3 = \text{Const.}$$

they can be written in the symmetrical form

$$\Sigma \Phi_1 = \Phi + A$$
$$\Sigma \Phi_2 = \Phi + B$$
$$\Sigma \Phi_3 = \Phi + C$$

R. F. Franklin: The method of solution is, as stated in the introduction, the same as that used several times by R. E. Doherty in the solution of various kinds of short-circuit problems, and by C. M. Laffoon in his recent paper on alternator short-circuit currents. However, whereas Mr. Laffoon's paper deals principally with formulas for initial values and a physical interpretation of short-circuit phenomena by the constant-linkage method, the present paper gives the derivation of the formulas for the instantaneous values of both the initial and sustained short-circuit currents for all the ordinary alternator connections. These formulas will be found very valuable to the designer in many problems where a knowledge of short-circuit currents or forces is desired.

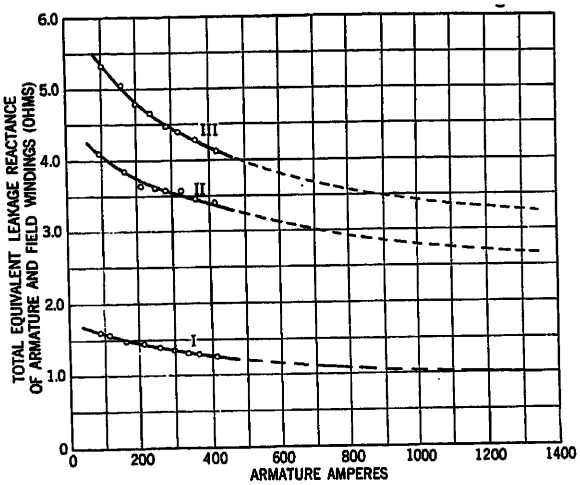

Fig. 16—Total Equivalent Leakage of Armature and Field Windings Combined. Axes of Two Windings Coincide. Single-Phase Armature Winding

I. One-Third of Armature Conductors in Series
II. Two-Thirds of Armature Conductors in Series
III. Three-Thirds of Armature Conductors in Series

I am indebted to Mr. Laffoon for calling attention to several errors in the table of maximum peak values of initial short-circuit currents (Table II). The wrong ratios were those for the single-phase and two-phase alternator cases which should have been divided by 2 and $\sqrt{2}$ respectively in order to reduce them to the bases of constant conductors per inch. This revision has been made in Table II. The value for the single-phase alternator case (case 1) depends upon the width of the phase belt as also pointed out by Mr. Laffoon. The width of the phase belt for the ratio given in Table II is 180 deg.

A Two-Speed Salient-Pole Synchronous Motor

BY ROBERT W. WIESEMAN[1]
Associate, A. I. E. E.

Synopsis.—The design features and performance characteristics of salient-pole synchronous motors are well known and have been thoroughly covered in the technical press. The synchronous motor has been handicapped in the past because it is inherently a single-speed machine, and a change in speed could be obtained only by a change in the frequency of the power supply. Changing the frequency, however, is not practical in most applications.

The special pole described in this paper which allows two-speed operation of a synchronous motor to be obtained at high efficiency is a new feature[2]. The same principle applied to a generator enables two frequencies to be obtained at the same speed or the same frequency at two different speeds. All that is necessary to change the speed (or frequency) is a pole-changing switch for the stator winding and a reversing switch for the rotor winding. A 5000/2500-h. p., 600/300-rev. per min., two-speed synchronous motor was built without having first constructed a model of any kind. This motor proved to be entirely satisfactory and its characteristics obtained by test agreed very closely with the calculated characteristics.

At either speed the two-speed synchronous motor functions exactly as the ordinary synchronous motor. There is nothing special or complicated about its construction, it does not require any more attention than the ordinary synchronous motor, and its expense of maintenance is just the same. The first cost of such a motor is only slightly more than that of the ordinary synchronous motor whose rating is equal to the low-speed rating of the two-speed motor. Therefore, the two-speed synchronous motor is a practical machine and it should open a new field for synchronous motor application.

* * * * *

Purpose

The purpose of this paper is to present the theory of the two-speed (constant torque) salient-pole synchronous motor, to describe a 5000/2500-h. p., 600/300-rev. per min., unity power-factor, 60-cycle, 2300-volt machine of this type. It will also be shown that its characteristics can be predetermined with the same degree of accuracy as those of the ordinary synchronous motor, and that this machine, when driven at constant speed, can be made to function as a two-frequency generator.

Introduction

The ordinary synchronous motor is inherently a one-speed machine because its revolving field, which is excited by direct current, must rotate in exact synchronism with the gliding magnetomotive force of the stator. Induction motors can be built to operate at two, three, and four speeds because the induction motor has a cylindrical rotor, a uniform air-gap, and a distributed rotor winding. These features make it easy to change the synchronous speed by regrouping the stator and the rotor coils. In the synchronous motor with the usual salient-pole construction, the air-gap is not uniform and the field winding is concentrated. Therefore, to operate a salient-pole synchronous motor from a constant-frequency supply at more than one synchronous speed, a special design is necessary. Such a motor is particularly suitable for constant-torque loads because synchronous motors are most efficient when operated at normal magnetic flux and current densities at either speed.

The multi-speed synchronous motor can operate at unity power-factor (or at any desired leading power-factor), whereas the multi-speed induction motor usually has a rather low lagging power-factor at the lower speed, unless a special compensating arrangement is used. It will be seen later that the particular two-speed synchronous motor described has an efficiency of 95.6 per cent when operating at 5000 h. p., 600 rev. per min., and at 2500 h. p., 300 rev. per min. It can thus be seen that the possibility of obtaining two speeds from synchronous motors opens a new field of application which so far has been covered by induction motors.

This particular motor (described later) was built to drive an a-c. generator at two speeds in order to obtain two frequencies. This motor can function equally well as a two-frequency generator when driven at constant speed. Thus a frequency converter set, consisting of two of these machines, could supply three different frequencies.

In some mine fan installations the full capacity of the fan is not required at certain periods. In cases where a speed ratio of one to two is satisfactory, the two-speed synchronous motor should be suitable. Although this load would not be a constant-torque load, the efficiency at both speeds could probably be made higher than that of a corresponding two-speed induction motor. Furthermore, the synchronous motor could be operated at any power factor to obtain power-factor correction. Thus, at the one-half speed condition only about one-eighth power is required and the remaining synchronous motor capacity can be utilized for power-factor correction. One difficulty in this application is that 100 per cent pull-in torque is required which necessitates a heavy starting winding. The ordinary starting winding can be used if a clutch is installed or if the motor is equipped with a rotating frame (supersynchronous motor).

Synchronous motors are now being used for ship propulsion. Changes in motor speed are accomplished by changing the generator frequency by varying the turbine speed. With a two-speed motor half speed can be obtained at normal frequency. The advantage of this scheme lies in the operation of the steam turbine at normal speed where the efficiency is maximum.

2. U. S. Patent No. 1,491,451 April 22, 1924.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925 and at the Regional Meeting of Dist. No. 1, Swampscott, Mass., May 7-9, 1925.

Backwater conditions at certain waterpower plants are such that the effective head is much less (sometimes one-half) during the rainy season than during the dry season. For efficient operation the water turbine speed should be reduced with the head, a condition which gives a much lower turbine speed during the rainy season. In cases where the turbine speed is reduced to

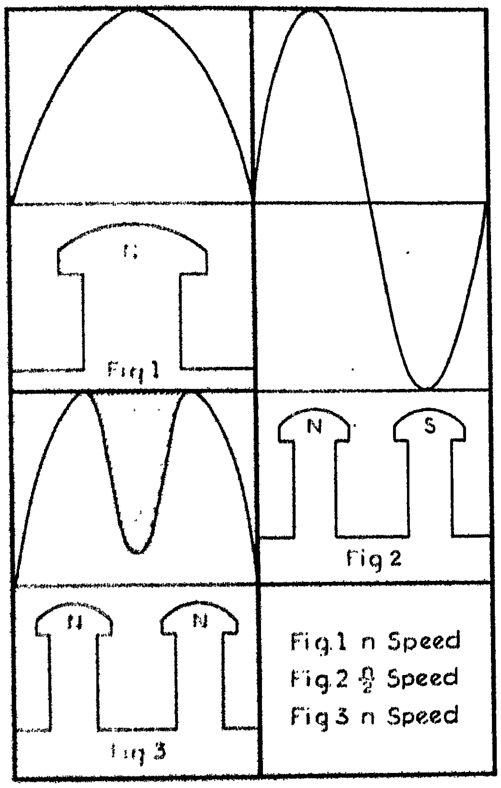

Fig. 1-2—Flux Distribution in the Air-Gap of an Ordinary Salient Pole Machine at no Load

Fig. 3—Flux Distribution in the Air-Gap of an Ordinary Salient Pole Machine at no Load when One Pole is Reversed

one-half, a two-speed generator would give normal frequency at both normal speed and one-half normal speed of the turbine.

It was originally hoped that the two-speed synchronous motor could be used advantageously for refrigeration. In the summer the ammonia compressors are usually worked continuously at full capacity. In the winter the compressors are unloaded (two-cylinder compressor operated with only one cylinder), a condition which requires abnormally large fly-wheels. Otherwise trouble due to hunting and excessive current pulsations will be experienced. This difficulty is now being overcome by using the modern clearance pockets in the cylinder of the compressor. With a two-speed motor both cylinders could be used at one-half speed which would give the same degree of refrigeration as at full speed with only one cylinder; but about five times the normal speed fly-wheel effect is necessary to prevent excessive current pulsations. Thus the fly-wheel for this condition is nearly as large as the one required when the compressor is unloaded, and the advantage of the two-speed synchronous motor in this case is not so marked.

Special Pole Necessary for Two Speed Operation

Fig. 1 shows diagrammatically the flux distribution in the air-gap over a pole-pitch in an ordinary salient-pole synchronous motor. In order to make this machine operate at half of its normal speed, the number of poles must be doubled and the armature winding must be reconnected accordingly. Thus, to have a motor which will operate at normal and one-half normal speed, it is necessary to arrange the armature and field windings so that they can be connected for either normal or twice normal number of poles. Fig. 2 shows the flux distribution in the air-gap over two poles of opposite polarity which are placed in the same space as that shown in Fig. 1. This represents at one-half speed the

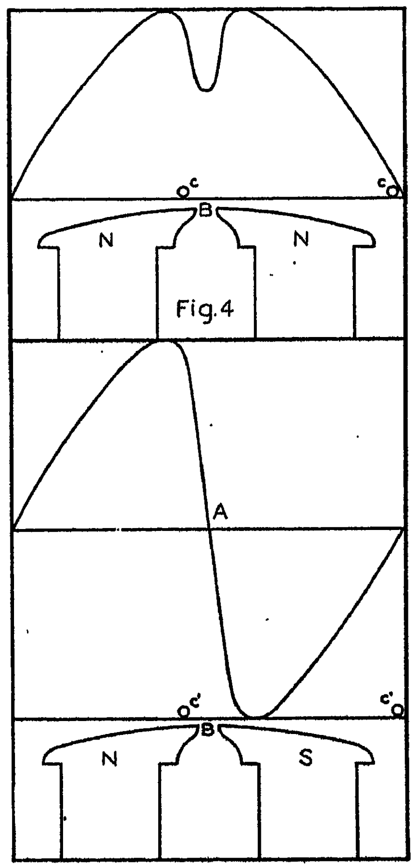

Fig. 4-5—Flux Distribution in the Air-Gap of a Salient Pole Machine at no Load with Special Poles at the High and Low Speeds Respectively

flux distribution, which is the same as in an ordinary machine. Now, to operate this machine (Fig. 2) at normal speed, the polarity of one of the poles must be reversed; the flux distribution will then take the form shown in Fig. 3. This condition gives a flux wave with a pronounced third harmonic which gives a very high core loss due to excessive hysteresis. Furthermore, the flux represented by the shaded area is lost and thus the capacity of the machine is decreased.

To overcome the objectionable condition shown in Fig. 3, the author devised a special pole piece. Figs. 4 and 5 show the flux distribution in the air-gap with this special pole shape for the high and low speeds respectively. Comparing the flux wave of Fig. 4 with that of Fig. 3, it will be apparent that the core loss will be be much less for the flux distribution represented by Fig. 4. Tests have shown that, with the special pole, (Fig. 4), at normal speed, the core loss is only 15 per cent greater than that of the ordinary salient-pole machine (Fig. 1); but this is not objectionable. At half speed, (Fig. 5), this special pole increases the core loss over that shown in Fig. 2. The hysteresis loss is the same in

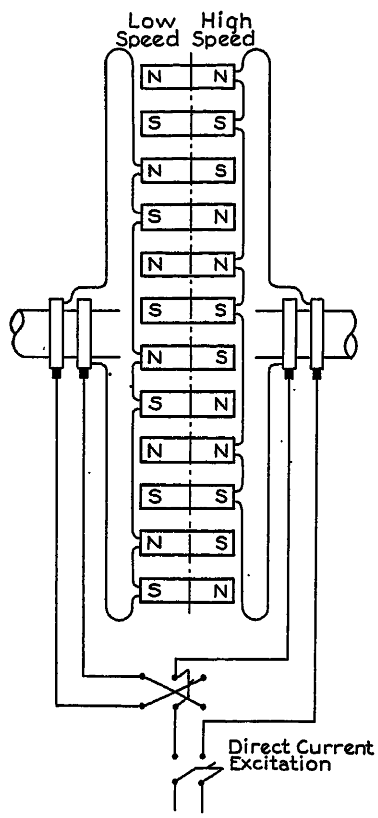

Fig. 6—Method of Changing Poles on the Rotor of a Two-Speed Synchronous Motor

both cases, but the eddy-current loss is greater due to the steep wave front at A. Tests show, however, that the core loss for the half speed condition, (Fig. 5), is also only about 15 per cent greater than that of an ordinary salient-pole machine, (Fig. 2). The distance between the poles B should be made large enough to prevent a high leakage flux for the low speed condition, (Fig. 5). This leakage flux would be high only in a machine with a very large number of narrow poles. The shape of the pole face is a compromise between the best shapes required at the two speeds respectively. If the motor is to operate most of the time at the high speed, the distance between the pole pieces B, (Fig. 4), should be made relatively small. Conversely, if the motor is to operate mostly at the low speed, the distance B should be increased.

Scheme for Changing Number of Rotor Poles

The scheme for changing the number of effective rotor poles in the ratio of two to one is shown by Fig. 6. The polarity of the polar projections for the high speed is indicated by N, S, S, N, etc., to the right of the vertical center line and the polarity for the low speed is indicated

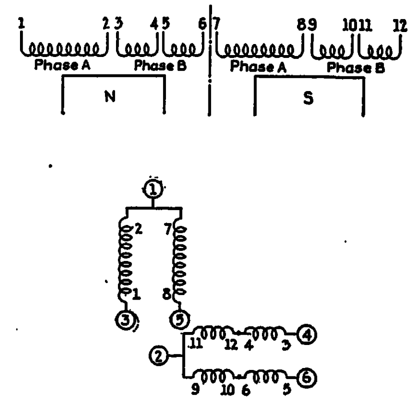

Fig. 7

by N, S, N, S, etc., to the left of the vertical center line. To simplify the method of connecting the field coils, half of the coils have their connections made on one end of the rotor and the other half are connected on the opposite end. It should be noted that every other pair of polar projections have the same polarity for both the high and low speed conditions and the field coils on these polar projections are connected to one set of collector

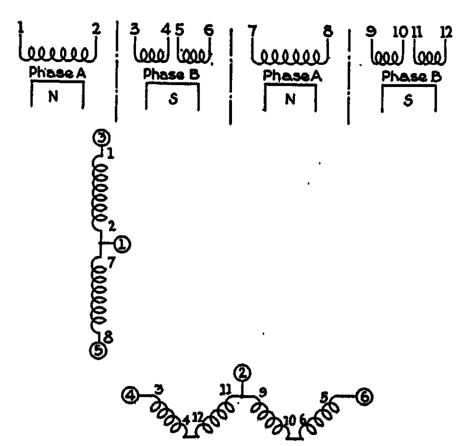

Fig. 8

rings—to the right. The pairs of polar projections whose polarities must be reversed when changing from the high to the low speed, or vice versa, are connected to the other set of collector rings—to the left. The two sets of collector rings are connected in series through a reversing switch. The number of rotor poles is changed in the ratio one to two,—high to low speed, or vice

versa, by throwing the reversing switch to the right or to the left.

Description of Stator

The stator of a two-speed synchronous motor is practically the same as the stator of an ordinary synchronous motor. The stator frame and stator punchings are exactly the same. No special arrangement of the turns or the conductors in the coil is necessary. The only difference is in the stator coils and coil connections. The coils usually have a smaller pitch than those used on ordinary synchronous machines and thus the coil and projection is less. The stator coil pitch can be varied within certain limits to accommodate the conditions of design. At the high-speed connection the coil pitch can be made 50 to 60 per cent (coil $c\,c$, Fig. 4), which makes the pitch 100 to 120 per cent (coil $c'c'$, Fig. 5) at the low speed connection.

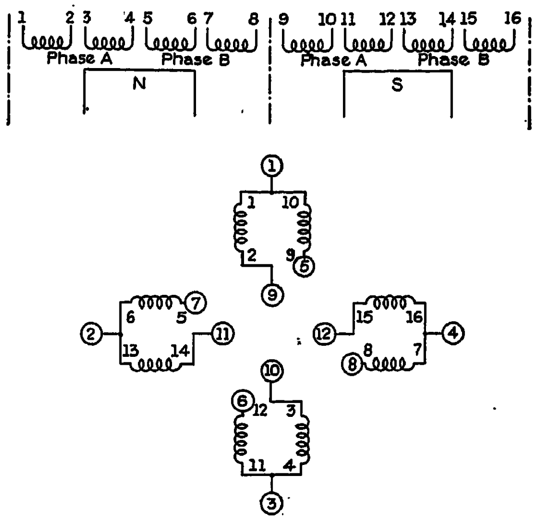

Fig. 9

A-c. motors are usually supplied with electric power from constant potential lines. Since it is desirable to have the magnetic flux density in the air-gap approximately the same at both speeds, it follows that the number of turns in series per phase of the stator winding at low speed must be twice the number in series at high speed. Therefore, changing the number of stator poles in the ratio of one to two consists of changing the number of circuits in the ratio of two to one in such a manner that half of the phase groups are reversed. The method of reconnecting one phase of the stator winding by reversing every other phase group is similar to reconnecting the field coils as shown by Fig. 6.

Two-Phase Stator Windings

Figs. 7 and 8 show the method of connecting a two-phase stator winding for the high and low speeds respectively. This connection requires only six terminals and it can be used for either three- or four-wire two-phase circuits. The advantage of this connection is its simplicity. For this reason it is used on induction motors. Its disadvantage is that the phase belt is 180 deg. at the low-speed condition. A 180-deg. phase belt is not recommended for a two-speed synchronous motor because the short-circuit core loss with a 180-deg. phase belt is nearly twice that obtained when the phase belt is 90 deg. Furthermore, the flux per pole is 41 per cent greater with the 180-deg. phase belt, and thus the core

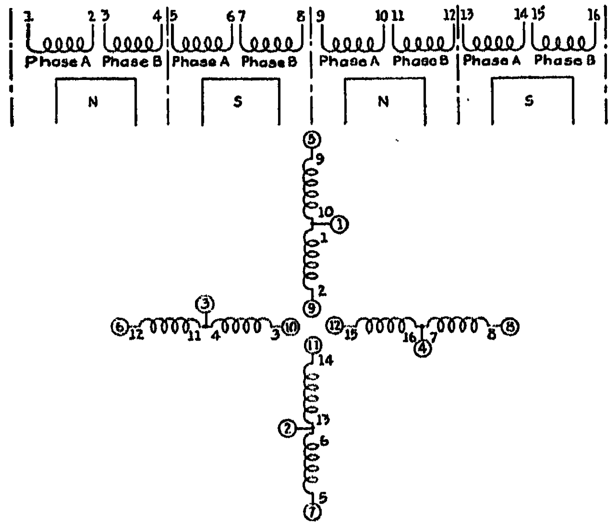

Fig. 10

loss is about 90 per cent greater and the field $R\,I^2$ loss about 250 per cent greater.

To overcome the objectionable features of the 180-deg. phase belt at the low-speed condition, a 90-deg. phase belt should be used and the stator winding connected as shown by Figs. 9 and 10. In Fig. 9, each phase is split into two 45-deg. belts, which become 90

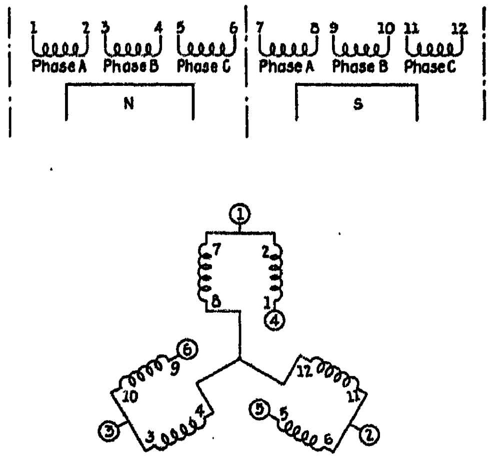

Fig. 11

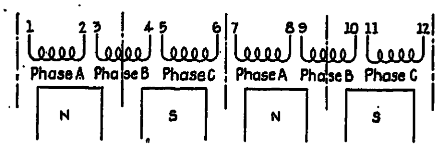
deg. belts in Fig. 10. Twelve terminals are required when the two-phase power supply is three-wire. If the power supply is four-wire, the leads 9, 10, 11, and 12, (Figs. 9 and 10), can be connected internally and then only eight terminals are necessary. In this case the line terminals for the high speed, Fig. 9, will be 1-3,

2-4, and the leads 5, 6, 7, and 8 are connected. For the low speed, Fig. 10, the lines will be 5-7, 6-8, and no connection will be necessary.

Three-Phase Stator Winding

Figs. 11 and 12 show the wiring diagrams for a three-phase stator winding which requires only six terminals.



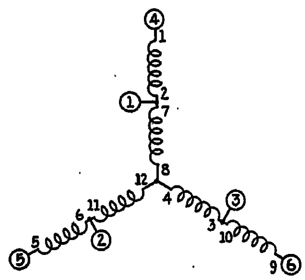


Fig. 12

The phase belt for the high-speed condition is 60 deg. and for the low-speed condition 120 deg. The increase in the phase belt from 60 deg. to 120 deg. helps to counteract the decrease in flux due to the increase of the stator coil pitch when changing from high to low speed.

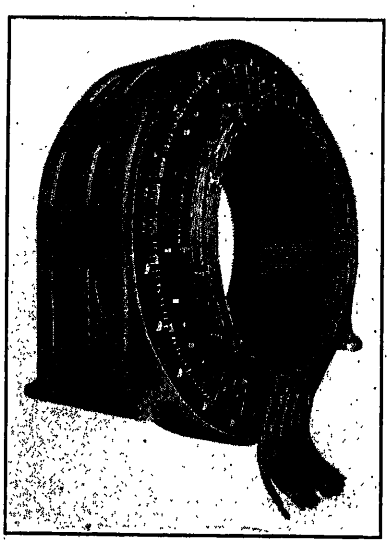

Fig. 13—Stator of a 12/24-Pole, 5000/2500-H. P. 600/300-Rev. per Min. Two-Speed Synchronous Motor

Description of a 5000/2500-H. P., 600/300-Rev. per Min., Two-Speed Synchronous Motor

Fig. 13 shows the stator of a 5000/2500-h. p., 600/300-rev. per min., 12/24-pole, 60-cycle, unity power-factor, two-phase, 2300-volt, two-speed, synchronous motor with the end shields removed. The stator winding is arranged so that a 90-deg. phase belt is obtained at both speeds.

Fig. 14 shows the rotor completely assembled. The poles are equally spaced so that the maximum amount of interpolar space can be utilized for the field coils. This motor is used on a 24,000-kv-a. frequency converter set where it was desirable to place the motor coupling between the rotor and the bearing. In order to reduce the axial length of the set to a minimum, all four collector rings were placed at one end of the rotor. The usual practise is to place the coupling beyond the bearing and then it is desirable to place two collector rings on each side of the rotor.

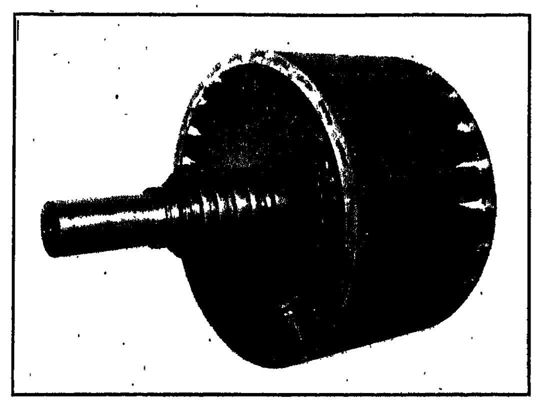

Fig. 14—Rotor of a 12/24-Pole, 5000/2500-H. P. 600/300-Rev. per Min. Two-Speed Synchronous Motor

Fig. 15 gives a section view of the motor showing the unsymmetrical pole tip. The poles are equipped with an amortisseur starting winding, consisting of five bars per pole. Starting tests show that the unsymmetrical pole face has no tendency to cause the motor to lock at a sub-synchronous speed when it is connected for either speed.

An interesting feature in the rotor construction of this two-speed motor is the possibility of arranging the field coils at the high speed connection to form a two-phase winding which would give considerable starting torque when the motor is operated as an induction motor. This can be done by dividing the coils into two independent groups, each group consisting of alternate

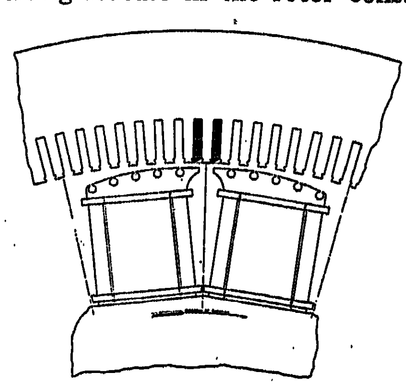

Fig. 15—Section View of Two-Speed Synchronous Motor

coils connected in series, and by short-circuiting the groups separately. The disadvantage of this scheme is that eight collector rings would be required and thus

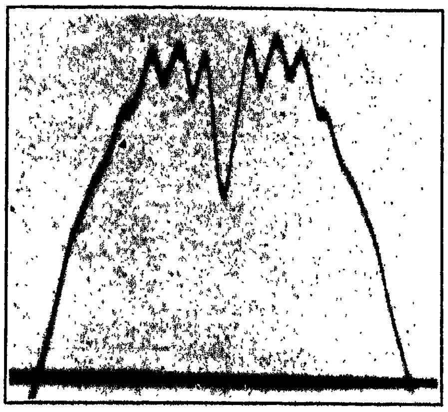

FIG. 16—FLUX WAVE IN AIR-GAP AT HIGH SPEED NO LOAD

the axial length of the motor would be materially increased.

PREDETERMINATION OF MOTOR CHARACTERISTICS

The actual flux distribution in the air-gap is obtained by taking an oscillogram of the voltage induced in an exploring coil placed on the armature face. Figs. 16 and 17 show the flux waves obtained by tests for the high and low speed conditions respectively.

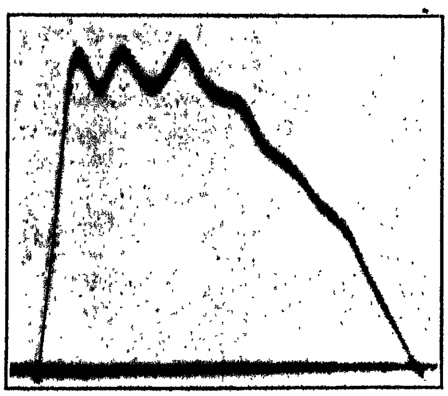

FIG. 17—FLUX WAVE IN AIR-GAP AT LOW SPEED NO LOAD

Fig. 18 shows the outline of the magnetic field structure drawn to scale. The flux distribution in the air-gap is obtained graphically by plotting the equipotential lines of magnetomotive force and the tubes of magnetic flux. The influence of the stator and rotor slots is neglected. The dotted lines in Fig. 18 give the calculated flux distribution in the air-gap and the full lines show the flux distribution obtained by test. In plotting the actual flux waves (Figs. 16 and 17) in Fig. 18 the ripples due to the rotor amortisseur winding slots were neglected. It should be noted that in Fig. 18 the full wave (one-half cycle) of the low-speed flux wave is shown and only half (one-quarter cycle) of the high-speed flux wave is shown, since this is a symmetrical wa e (Fig. 16). The calculated flux waves agree very closely with those obtained by test. Since the predetermination of the flux distribution in the air-gap is the foundation upon which the design calculations are based, it follows that the characteristics of a two-speed synchronous motor can be readily predetermined.

Fig. 19 shows the calculated and test saturation, syn-

chronous impedance, and no-load phase characteristic curves for the high-speed condition; Fig. 20 gives similar low-speed characteristics. Figs. 21 and 22 give the starting torque and starting current for the high and low-speed conditions respectively. A comparison of Figs. 21 and 22 will show that the starting torque developed with the high-speed connection is much higher than that developed under the low-speed con-

dition. The flux density in the air-gap is higher and the reactance is lower for the high-speed condition, and since the starting torque varies approximately as the square

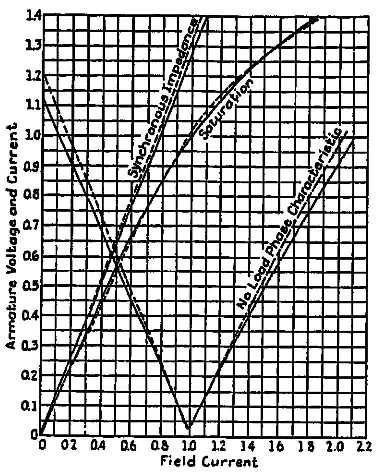

FIG. 20—CHARACTERISTIC CURVES 12/24-POLE 5000/2500-H. P. 600/300-REV. PER MIN. TWO-SPEED SYNCHRONOUS MOTOR AT 300-REV. PER MIN. NORMAL VOLTAGE

———— TEST
- - - - - - - - - - CALCULATED

of the flux density and inversely as the reactance, it follows that the high-speed condition should give a higher starting torque.

The efficiency curves of this motor at the high and low

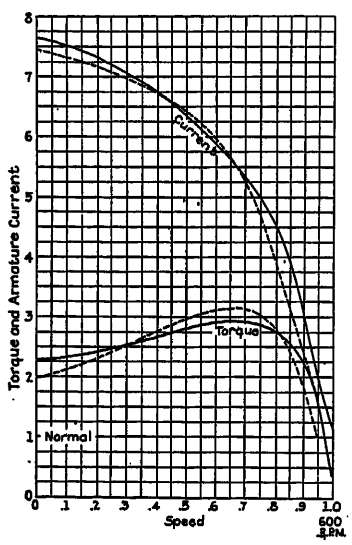

FIG. 21—STARTING TORQUE 12/24 POLE 5000/2500-H. P. 600/300-REV. PER MIN. TWO-SPEED SYNCHRONOUS MOTOR NORMAL VOLTAGE 600-REV. PER MIN. CONNECTION

speeds are shown in Fig. 23. These efficiencies were obtained experimentally by the segregated-loss method and they include the windage and friction loss, open-circuit core loss, short-circuit core loss, armature and field RI^2 losses. These efficiency curves show that at normal load the efficiency is about the same at both speeds. This refers to 5000 h. p., 600 rev. per min., and

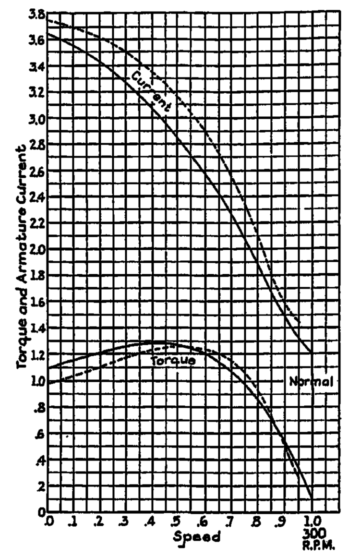

FIG. 22—STARTING TORQUE 12/24 POLE 5000/2500-H. P. 600/300-REV. PER MIN. TWO-SPEED SYNCHRONOUS MOTOR NORMAL VOLTAGE 300-REV. PER MIN. CONNECTION

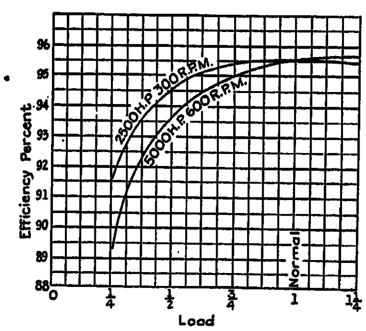

FIG. 23—EFFICIENCY 12/24 POLE 5000/2500-H. P. 600/300 REV. PER MIN. TWO-SPEED SYNCHRONOUS MOTOR

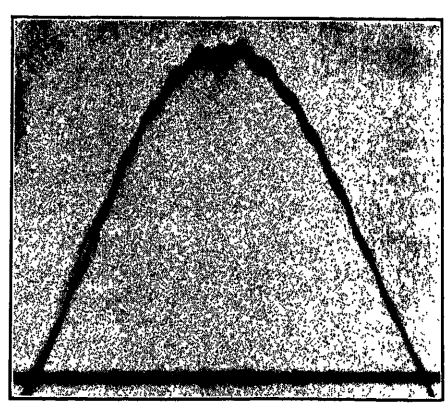

FIG. 24—VOLTAGE WAVE AT HIGH SPEED NO-LOAD

to 2500 h. p., 300 rev. per min. The stator RI^2 losses are about the same in either case, but the windage and core losses are much less at the low speed. This accounts for the high efficiency at the low speed.

Two-Frequency Generator

A two-speed synchronous motor can also function as a two-frequency a-c. generator when driven at constant speed. Although the flux wave at either frequency deviates appreciably from a sine wave, the voltage wave can be made nearly sinusoidal by a suitable choice of the number of slots and of fractional pitch of the arma-

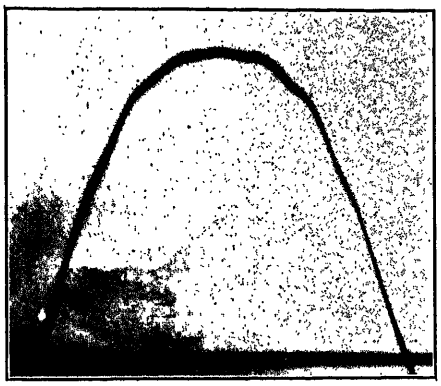

Fig. 25—Voltage Wave at Low Speed No-Load

ture coils. Fig. 24 shows an oscillogram of the no-load voltage wave when the above described machine is connected for the normal number of poles, and Fig. 25 for twice the normal number of poles. These voltage waves are really good waves when we consider that the machine was connected two-phase and had an integral number of armature coils per pole per phase. The voltage waves would be much better in a three-phase machine with a fractional number of stator coils per pole per phase. By comparing the flux wave, Fig. 16, with its voltage wave, Fig. 24, and similarly, Fig. 17 with Fig. 25, it will be seen how much the pitch and distribution of the armature coils reduce the various flux ripples and harmonics.

The efficiency of this machine obtained by test, when used as a multi-frequency generator, is as follows:—

300 Rev. per Min.

12 poles, 30 cycles	24 poles, 60 cycles
2000 kw., 1.0 P. F.	2000 kw., 1.0 P. F.
Efficiency 95.4 per cent	95.6 per cent

600 Rev. per Min.

12 poles, 60 cycles	24 poles, 120 cycles
4000 kw., 1.0 P. F.	4000 kw., 1.0 P. F.
Efficiency 95.7 per cent	95.8 per cent

The efficiency at 300 rev. per min., 60 cycles is slightly higher than at 300 rev. per min., 30 cycles because the field $R\,I^2$ loss is less for the 24-pole connection.

Conclusion

There is nothing special or complicated about the construction of the two-speed synchronous motor. Its performance can be predetermined with the same degree of accuracy as that of the ordinary synchronous motor. It does not require any more attention than an ordinary synchronous machine, and its maintenance expense is just the same. The cost of such a motor is only slightly higher than that of an ordinary synchronous motor whose rating is equal to the low-speed rating of the two-speed motor. Therefore, this new synchronous motor is a practical machine and should open a new field for synchronous motor application.

Discussion

S. H. Mortensen: Mr. Wieseman's paper brings out, clearly, the fact that two-speed synchronous motors can be built economically, and that a machine of this kind properly proportioned will practically maintain all the virtues of the standard salient-pole synchronous motor. The field of application for a motor of this kind is at the present time rather limited. The only application the speaker can think of in addition to the ones Mr. Wieseman has mentioned is that for driving two-speed pumps such as are sometimes used with condenser installations.

This type of drive would, of course, not be a constant-torque proposition at the two speeds any more than the mine fans mentioned by Mr. Wieseman. The horse power required at either of these drives varies approximately with the cube of the speed of operation. A study of the starting characteristics shown in Figs. 21 and 22 indicates that with 12-pole stator connections, this machine can start and synchronize more than full load. With 24-pole connections, its starting characteristics are much inferior. However, very large loads corresponding to the 24-pole operation could be brought into synchronism by starting the motor as a 12-pole machine, bring it up to a speed beyond the 24-pole synchronous speed and then by suitable switching, change its stator connections from a 12-pole to a 24-pole winding. The fields could then be excited and the motor would slow down and lock into synchronism. If this procedure is followed for fans, pumps and similar drives, the motor could be started upon a comparatively low starting voltage and brought into synchronism without causing undue line disturbances.

In connection with the starting-torque curves, Figs. 21 and 22, it would be of interest to know if these curves were obtained with the motor fields short-circuited on themselves, or through a resistance, or, possibly, with the field circuit open at the starting period.

The efficiencies shown in Fig. 23 are at full load from 1 per cent to 1½ per cent lower than the efficiencies that might be expected upon a single-speed machine of this rating. At fractional loads, this condition will be even more favorable to the standard machine. In this connection it would be of interest to know what class of steel is used in the stator of this particular machine. The flux-distribution curves shown suggest that high-silicon steel would have a decided advantage over standard steel to the extent of reducing eddy-current and hysteresis losses. As the flux waves shown in Figs. 16 and 17 have very decided ripples, it would be of interest to know whether this machine was noisy during operation.

Regarding Mr. Wieseman's statement that a machine of this design is only slightly more expensive than a standard machine, it would seem to the speaker that this would apply only to high-speed machines, where the field leakage and heating of the rotor coils is not a limiting feature. Where slow-speed machines are involved, the increased field leakage, in addition to the reduced field ventilation caused by the proximity of the pole tips, would limit the output and make it necessary to supply a considerably larger machine for two-speed operation than would be necessary for a standard one-speed machine.

H. Weichsel: We have been accustomed for many years to hear and talk about multiple-speed induction motors, and, on the other hand, we had a more or less deep-rooted belief that synchronous motors are inherently single-speed machines.

This limitation has been taken more or less as a matter of course without analyzing the underlying reasons why synchronous motors were not built as multiple-speed machines.

During the last few years, the general interest in the synchronous motor has grown enormously. This is largely due to the better understanding of the tremendous losses and engineering difficulties which are created in a-c. systems when energy is transmitted under low power factor. The operating difficulties and economic losses, due to low power factor, hit the operating engineer first, then the consumer, and, finally, reacted upon the manufacturer of the electric machinery.

We are now in the third stage, as is evidenced by the fact that a very large number of operating engineers and power consumers have turned for help to the motor manufacturers, asking them to assist in solving the tremendously important question of power-factor correction. The result of this appeal has been that during the last few years, great efforts have been made to introduce more generally the application of such motors as inherently operate at unity or even leading power factor. It is a well-known fact that the synchronous motor has the desired property of operating with leading or unity power factor. Unfortunately, while the conventional type of synchronous motor possesses the desirable ability of good power factor, yet it is also guilty of several serious shortcomings in comparison with the induction motor so generally used at present.

The designing engineers, as well as the inventors, have worked diligently during the last few years on the problem of freeing the conventional synchronous motor of its shortcomings. It is well-known that during the last few years remarkable progress has been made in approaching the goal of an ideal single-speed synchronous motor, but thereby still leaving the field of multiple-speed motors to the induction machines. This, on the other hand, is particularly undesirable from the power factor viewpoint, as all induction motors, and especially multiple-speed induction motors, have a poor power factor at low speeds.

Mr. Wieseman is, therefore, to be congratulated for having attacked the problem of two-speed synchronous motors and solved it in a remarkably satisfactory manner.

As far as I can see, in analyzing the problems of two-speed synchronous motors, it appears that the real problem lies in the rotating or d-c. member. The regrouping of the d-c. pronounced poles, such as are used in the conventional type of synchronous motor, is extremely simple in principle when a speed ratio of 1-to-2 is desired and has been understood for many years. Unfortunately, such a regrouping of the poles of a standard synchronous motor produces an entirely unsatisfactory field distribution which results in excessive losses and low weight efficiency of the machine. The problem of producing two-speed primary windings, on the other hand, is in principle the same as that which for many years has been solved in connection with two-speed induction motors.

The important question is, therefore, the creation of a d-c. member which can be satisfactorily excited for two different numbers of poles. In order to accomplish this result, Mr. Wieseman found it necessary to reduce the distance between the pairs of poles to a value very materially below the distance between pole horns as found in standard designs. From Fig. 4 of the paper, it appears that the gap between two adjacent pole horns is made so small that the surface of those poles which form one pair approaches, in its appearance, the cylindrical surface of an induction-motor pole. The following question arose in my mind:

Why not go the whole way and construct the rotor entirely on the lines of an induction motor and provide the rotor with a winding which allows the regrouping of poles in the ratio of 2-to-1. It is well known that such an arrangement can readily be obtained, for instance, by winding the rotor exciting winding as per Fig. 1 herewith. This winding consists of two groups of poles which can be reversed against each other, similar to the arrangement shown in Fig. 6 of Mr. Wieseman's paper. Single-speed synchronous motors without pronounced poles, using a kind of induction motor rotor, have been built very successfully for several years, especially by some European concerns. They are known under the name of "synchronous induction motors."

These motors have shown themselves in several respects superior to the conventional type with pronounced or salient poles. It is possible to obtain with this type of synchronous motor starting and synchronizing characteristics which are superior to those usually available in pronounced pole synchronous motors. This advantage is obtained by using the rotor during starting as the wound secondary of an induction motor.

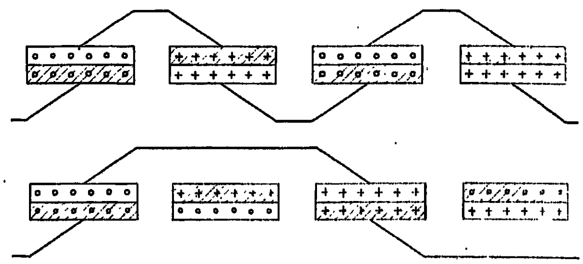

Fig. 1

By introducing resistance in this winding, a high starting torque with low starting current can be obtained, and when machine has come up to speed, the induction motor slip can be held very low, as the winding is completely short-circuited. This low slip, on the other hand, results in a good synchronizing torque.

I have made some very rough calculations for a medium-size machine of moderate speed which seem to indicate that two-speed synchronous induction motors are quite feasible. I would like to ask Mr. Wieseman's opinion on the possibility of such a type of machine. No doubt, Mr. Wieseman has investigated this problem and is in a position to point out the shortcomings of a two-speed synchronous induction motor when compared with a two-speed salient-pole synchronous motor.

Mr. Wieseman makes a statement which is particularly interesting to me, namely, that the stator winding for the high-speed connection should have a coil pitch of about 50 per cent to 60 per cent which makes the coil pitch 100 per cent to 120 per cent for the low-speed connection.

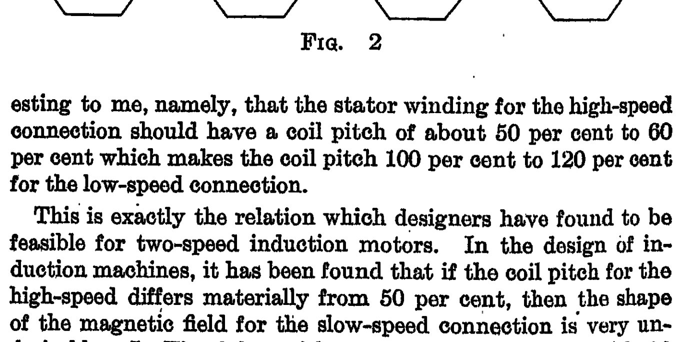

Fig. 2

This is exactly the relation which designers have found to be feasible for two-speed induction motors. In the design of induction machines, it has been found that if the coil pitch for the high-speed differs materially from 50 per cent, then the shape of the magnetic field for the slow-speed connection is very undesirable. In Fig. 2 herewith, a three-phase winding with 66 per cent for high-speed (4 poles) and 132 per cent for low-speed (8 poles) has been shown. The field for the slow speed can be considered as being made up of a symmetrical 8-pole field and superposed over this are fields with a different number of poles than desired. These higher "harmonic" fields are quite detri-

mental for multiple-speed induction motors and are often responsible for subsynchronous speeds and also for abnormally large leakage with consequent reduced output of the machine. I surmise that this is the reason why Mr. Wieseman recommends for two-speed synchronous motors, a coil pitch of 50 per cent to 60 per cent of the high-speed pole pitch.

The starting performance of the two-speed synchronous motor as given on the seventh page of Mr. Wieseman's paper is very satisfactory. It would be of interest, however, if we could hear from Mr. Wieseman regarding the synchronizing torque which these machines are capable of developing, and in this connection, he might enlighten us also on the question as to whether these machines can be switched from low-speed connection to full-

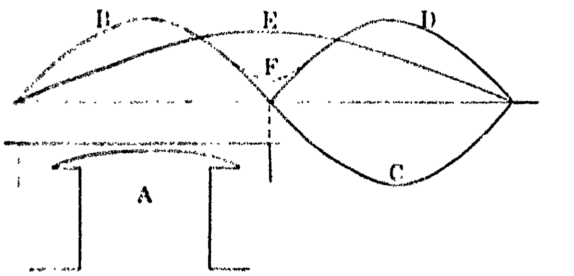

FIG. 3 POLE SHOE GIVING IDEAL WAVE FORM AT HALF SPEED

speed connection, and vice versa when operating under full load. In other words, is or is it not necessary to remove the load before the windings can be switched from one speed to another?

In Figs. 16 and 17 of Mr. Wieseman's paper, oscillographic records are given of the voltage in a search coil. Mr. Wieseman then draws in Fig. 18, the "tested" field shape by using the oscillogram records for the voltage neglecting the ripples in the voltage oscillograms.

In the A. I. E. E. PROCEEDINGS 1912, page 526, I pointed out that the photographic records of the voltage induced in a search coil do not represent the true field distribution, because due to the passing of the teeth, the magnitude as well as the shape of the magnetic field produced by the d-c. winding is not constant but changes rapidly when the teeth pass each other, due to the movement of the rotor.

I presume that this phenomenon induced Mr. Wieseman to draw the tested field curve from the oscillograph record by neglecting the ripples and thereby obtaining a kind of an average.

J. F. H. Douglas and E. W. Kane (by letter): One understands upon reading the section headed "Special Pole Necessary for Two-Speed Operation," that this pole contributes to the efficiency of the motor's operation, and that the core loss is kept within 15 per cent of the value usual in single-speed motors of this size, and with a reasonable leakage. However, it does not appear that the more usual shapes of pole shoe would be inoperative, nor is it claimed that the pole shown is a form giving maximum effectiveness or that the wave form is good. Data on the maximum power factor obtainable with this motor running light would be of interest in this connection.

One understands that the poles are close together to cut down core loss, yet by referring to Figs. 16 and 17, we see pronounced ripples which must increase core loss. These ripples are of the 31st and 33rd order in Fig. 16 where the stator teeth per pole are 16. Fig. 17 has large 15th and 17th harmonics when the stator teeth per pole are 8. Both cases come under the general rule applying to tooth harmonics, namely, if N is the number of teeth per pole (being an integral number) then they may cause harmonics of the $(2\,N \pm 1)$ order. They may be eliminated, of course, by partly closing the slots, but they can be also eliminated by eliminating harmonics of tooth-ripple frequency from the pole shoe. The proof of this proposition was given in an appendix to a paper we read in Chicago, June 1924, before A. I. E. E. on "Potential Gradient and Flux Density."[2] At any rate, a Fourier analysis of curves in Fig. 18 was made, and even without pronounced ripples of flux showing, harmonics of considerable size of the above orders were found.

An ideal wave form for low speed is shown in Fig. 3 herewith by curve $B\ C$ from poles A. When the poles are reversed for high-speed operation the curve $B\ D$ would probably result with the cusp replaced by F. The core loss of this wave would probably be 50 per cent greater than a sine wave, but the flux lost would not be the area between the two peaks B and D but merely the difference between the peak B, and the peak of E the fundamental sine-wave component. The T. I. F. of the wave was computed as 235, and while interference is of no particular interest in this connection, this factor will serve as well as any for relative comparisons.

An ideal wave form for the high speed is shown in Fig. 4 herewith by the curve $B\ C$ produced by the split pole A. When the pole halves are properly reversed for half speed, the wave $B\ D\ E$ results, which has a T. I. F. of 1040, worse than the first wave in Fig. 3. With the pole tips separated to point F, we have the arrangement devised by Mr. Weiseman, with rounded corners H for the low speed, and the dip or dimple G for the high speed. We analyzed the wave forms shown in Mr. Weiseman's paper in Fig. 18, and found that for the low speed the T. I. F. was 140, and for the high speed the T. I. F. was 286.

It is plain then that a perfect wave cannot be found for both speeds, but that a compromise must be made. If it were thought desirable, we have no doubt further improvements could be made. How well this design secures a favorable compromise on all of the questions involved in the design is truly remarkable.

R. W. Wieseman: The twelve-pole starting characteristics, Fig. 21, are much better than the twenty-four-pole characteristics, Fig. 22, as Mr. Mortensen has pointed out. This was mentioned in the paper and the reasons for this difference were given. In a three-phase motor the difference between the two starting characteristics would not be so pronounced because in a three-phase

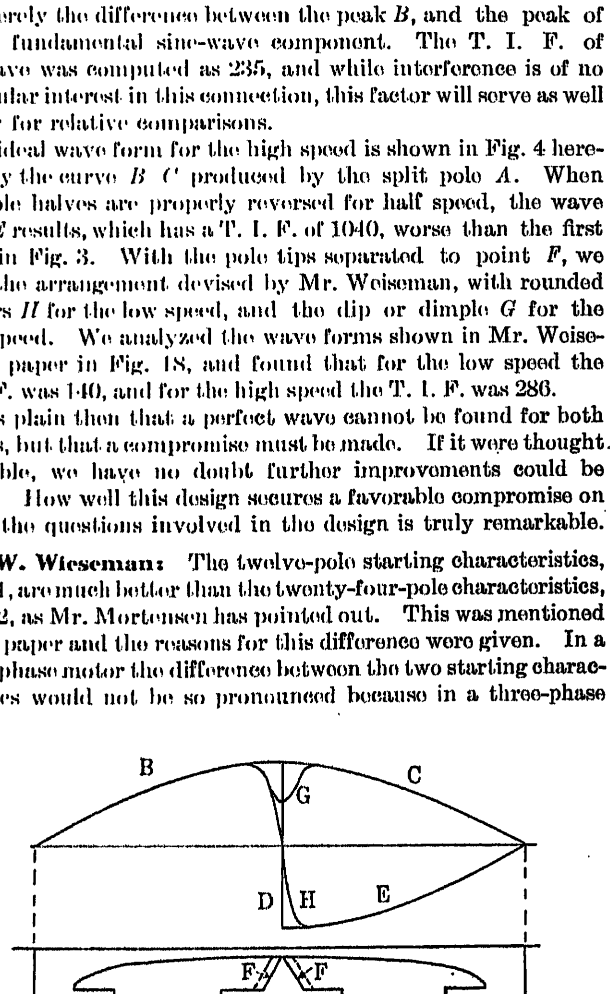

FIG. 4—POLE SHOE GIVING IDEAL WAVE FORM AT HIGH SPEED

machine the air-gap flux density can be more readily made the same for both the high- and the low-speed conditions. The starting characteristics, Figs. 21 and 22, were taken with the field winding open circuited. If the field winding had been short-circuited through a suitable resistance, the starting torque (at zero speed) would have been a little lower, but the pull-in torque (at 95 per cent speed) would have been considerably higher.

Mr. Mortensen stated that the full-load efficiencies are from 1 to 1.5 per cent lower than the efficiencies that might be expected from a single-speed machine of the same rating. Whether an efficiency is high or low is a matter of opinion. The efficiency of a machine depends largely upon the amount and kind of material which is used in its construction. With a better grade of iron and additional copper, there is no question that the effi-

ciency of the motor could be increased. This increased efficiency, however, would increase the cost of the motor and, consequently, it depends upon how much a per cent of efficiency can be capitalized. A machine which is used continuously should naturally have a higher efficiency and cost more than a machine which is used periodically.

Mr. Mortensen also stated that since the flux waves, Figs. 16 and 17, have very decided ripples, it would be of interest to know whether this machine is noisy during operation. At the low speed the motor is very quiet, having no magnetic noise and only a little windage noise. At the high-speed there is no magnetic noise, but the windage noise is much more pronounced.

Mr. Mortensen has called attention to the fact that a low-speed motor of this type would be considerably larger than a standard single-speed motor. I agree that a low-speed machine of this type is larger, and, therefore, more expensive than the standard motor. However, this motor is in reality two synchronous motors in one so that it is natural that the motor should cost more than one standard motor. Just how much more a two-speed motor would cost depends somewhat upon the speed.

The cylindrical rotor with a distributed rotor field winding could be used successfully in a two-speed synchronous motor as described by Mr. Weichsel. This construction would be advantageous only for small machines; for large motors I think the salient-pole and concentrated-field winding would be more economical and more efficient.

The choice of armature coil pitch for a two-speed synchronous motor is determined by the same principles as the case of the two-speed induction motor as Mr. Weichsel has pointed out.

The possibility of changing from low to high speed when operating under full load depends upon the design of the pole-face starting winding and the moment of inertia of the load. Synchronous motors can be built with very heavy starting windings (with a large thermal capacity) which can furnish full-load torque for an appreciable time. This type of machine is naturally more expensive than the ordinary motor. Furthermore, a large pole-face winding requires a deep pole tip which reduces the available space for the rotor field coil and it also increases the field leakage flux. Consequently, a synchronous motor (single-speed or multi-speed) which is designed to accelerate normal torques is not so good a synchronous motor as one which has the usual starting winding. The motor described in this paper is capable of giving full-load torque from 50 to 90 per cent speed at the high-speed connection with 65 per cent armature voltage. By short-circuiting the field winding with a suitable resistance, and then exciting the field winding, the motor should pull into synchronism. If the inertia of the load is such that this operation could be accomplished in less than a minute the motor would not overheat. In changing from the high speed to the low speed under load, the problem is not so difficult. With a little practise, I think an operator could synchronize the motor as it comes down through half-speed with a reduced voltage impressed on the armature winding.

The voltage wave induced in an exploring coil is not strictly the same as the flux wave as pointed out by Mr. Weichsel. My reason for omitting the ripples in the flux waves, Fig. 18, was to check the predetermined flux waves. The usual design calculations will not give very accurate results when they are applied to a machine which has a special field structure as shown in Fig. 15. Therefore, it was necessary to predetermine the flux distribution over the poles and then obtain the various flux-distribution coefficients which are used in the design calculations. In predetermining the flux distribution in the air-gap graphically by plotting the equipotential lines of magnetomotive force and the tubes of magnetic flux, it is convenient to neglect the influence of the stator slots and the rotor pole-face winding bars. It is assumed that the flux waves obtained in this manner will be average waves and that the distribution coefficients obtained from these flux waves will, therefore, represent the average condition. In this way the characteristics of the motor, Figs. 19 and 20, were predicted very closely.

Messrs. Douglas and Kane stated that it did not appear that the more usual shapes of pole shoe would be inoperative. Of course not, and the paper contains no statement to the contrary. However, the usual pole shape would not be so efficient as the one shown in Figs. 4 and 5. The maximum power factor obtainable when this motor is running light at either speed is 100 per cent.

I am at a loss to know why Messrs. Douglas and Kane calculated the telephone interference factor (T. I. F.) of the flux waves and not the voltage waves. The T. I. F. factor is the number of micro-amperes per volt flowing in a tuned network which is weighted so that the current will be a maximum at 1120 cycles. Since the flux wave cannot appear at the terminals of the motor, it cannot affect a telephone circuit, so that the T. I. F. of the flux wave is useless. Furthermore, the T. I. F. reading favors the seventeenth and the nineteenth harmonic in a 60-cycle wave while other harmonics have a reduced effect. Consequently the T. I. F. is only an indication of the relative value of a few harmonics in the wave and not a measure of all of the harmonics. The discussion of the pole shape by Messrs. Douglas and Kane, as shown in their Figs. 3 and 4, is practically the same as that given in the paper.

Self-Excited Synchronous Motors

BY J. K. KOSTKO[1]

Associate, A. I. E. E.

Synopsis:—*The theory and applications of self-excited synchronous motors have been repeatedly discussed in the literature, but the subject has been usually presented as a study of some special variety of this type. It now seems timely to give an outline of the general theory of the subject as a basis of comparison of the proposed types and a starting point for further development work.*

The study of a self-excited motor is mainly a study of its exciting system. The writer shows that any combination of the exciting circuits is equivalent to one comparatively simple type, and studies two problems in connection with this standard type; (1) determination of performance of a given motor; (2) determination of design constants giving a desired performance. In this study stress is laid on the elements peculiar to this type of motor; but no attempt is made to treat fully the elements which the self-excited motor has in common with other, better known, motor types. The current locus of the motor is found to be a circle, and it is shown that any circle in the plane can be obtained by a suitable choice of the exciting system.

The subject of synchronising is treated by a method showing an intimate connection between the synchronising process and the synchronous operation. The discussion of synchronising can thus be limited to the standard type, because the equivalence of the synchronous operation means also the equivalence of the synchronising features. It is shown that very high torque can be obtained during synchronising.

The theory is applied to a brief study of a few types of the self-excited motor.

DURING the last few years the increasing importance of a good power factor gave a fresh impetus to the study of the possibilities of synchronous motors. Naturally enough, the efforts of the inventors and manufacturers were directed primarily against the greatest drawback of synchronous motors—their poor starting characteristics; the result was the appearance of a number of "self-starting" synchronous motors of the Danielson type; these motors are structurally similar to the induction motors with phase-wound secondaries, and act as such during the starting period, but later are converted into synchronous motors by supplying one phase (or a combination of phases) of the secondary with direct current.

This type requires a separate source of excitation and is suitable only for large outputs; but it becomes increasingly evident that efforts are being made on many sides to extend the self-starting principle to the smaller sizes by making them self-excited. For this purpose the primary member carries in addition to the main a-c. winding a small d-c. type winding connected to a commutator; the secondary member carries a field winding and brushes bearing on the commutator and connected to the field winding. At synchronism the magnetic field is at rest with respect to the brushes; a continuous e. m. f. appears at the brushes and supplies the excitation. As in the Danielson motor, the secondary is of the polyphase type, with one or several phases used as the field winding.

In connection with the non-salient pole motors the principle of self-excitation was found to possess remarkable advantages which go far towards compensating for the complication of the commutator and brushes:

1. A synchronous motor develops a field of armature reaction whose direction and magnitude are determined by the load; since this field is stationary with respect to the secondary, *i. e.*, brushes, it is possible to make use of it in order to obtain some desired relation between the voltage at the brushes and the load; usually an increase of excitation with the load.

2. As the motor approaches synchronism, its induction motor torque approaches zero, and the final synchronization is accomplished by the synchronous torque. In a separately excited motor the synchronous torque, considered as a function of the coupling angle, is approximately alternating, with the average value zero; in a well-designed self-excited motor the synchronous torque is pulsating, with the positive part far in excess of the negative part, *i. e.*, with a definite positive (motoring) average value; synchronizing becomes a very simple, entirely automatic process.

It was only natural that the first motors built or theoretically investigated were of the simplest kind: a single axis field winding and a single set of brushes[2]; in the great majority of cases this arrangement is quite satisfactory; but it is not the only possible form; motors with several angularly displaced field windings and brush sets possess some valuable features not obtainable with the single axis field winding. The added complication is not very great because the self-starting feature requires in any case several angularly displaced secondary windings (phases).

The self-excited motor is still in the first stages of development; as in the case of the single-phase commutator motor the experimental research is complicated by the great number of possible combinations of as yet unknown relative merit. The purpose of this paper is to systematize the subject by reducing this apparent variety to a few fundamental types, and to develop for these types a method of theoretical investigation such as should always go hand in hand with the

1. Consulting Engineer, Palo Alto, Calif.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925.

2. A brush set will always mean two diametrically opposite brushes in a bipolar motor, or their equivalent in a multipolar motor. The theory, of course, holds good with any angle A between the brushes of a set, because, with sinusoidal fields, the voltage across them is in a constant ratio with the voltage across two diametrically opposite brushes standing on the line perpendicular to the bisector of A.

practical work if the waste of haphazard experimenting is to be avoided.

In the writer's opinion the graphical method is best adapted to give an idea as to the possibilities and limitations of a new motor type; the study is made on the basis of the current locus, and all the performance elements are derived from it. The subject is treated with the usual assumption of sine wave voltages and currents, uniform air-gap, proportionality between the m. m. fs. and the fluxes, and the sinusoidal distribution of the latter.

Since the polyphase feature of the secondary is of importance only at starting, a perfect symmetry is not essential; in the matter of distribution of copper between the phases and the interconnection of windings the designer has a considerable freedom, which can be used to obtain a good wave of m. m. f. and a small loss in the field winding. The main a-c. winding, of any polyphase type, may be either interconnected with the d-c. winding or independent from it. As a rule, the advantages of interconnection are small in comparison with mechanical complications of bringing out a number of taps; in what follows the windings will be assumed independent and, for the sake of simplicity, the connection diagrams will show only the exciting circuits.

At present the practise is to use the rotor as the primary member, connected to the supply by slip rings; the d-c. winding and the commutator are then on the rotor; the field windings and the brushes are stationary; this arrangement is adopted in the figures of the paper. The inverted arrangement, however, has many points in its favor.

The flux F_f due to a field winding is proportional to the e. m. f. at the brushes connected to this winding; this e. m. f. is proportional to the component F_n of the total flux of the motor normal to the line of brushes; therefore, for each exciting circuit consisting of the d-c. armature winding, a set of brushes, and a field winding, there is a constant ratio between F_f and F_n. This ratio will be called "circuit constant;" in a motor with several field windings and sets of brushes each exciting circuit has a circuit constant. The calculation of these constants for given electric and magnetic circuits is very simple, and will not be considered here.

At synchronism the action of a field winding is fully determined by its circuit constant and the position of the brushes; but it must be remembered that in a self-starting motor the field winding is used as the secondary of an induction motor, and must be designed so as to give a safe open-circuit voltage at starting. It is found that even with high open-circuit voltages the proportions of the field winding are such that the d-c. exciting voltage is very low; the variable brush resistance causes a variation of the circuit constant, especially at light loads, when the voltage at the brushes is low. This may cause the observed performance points to deviate from the positions indicated by the theory. Another cause of discrepancy is that the brushes short-circuit coils moving in a magnetic field; the influence of the circulating currents cannot be determined by calculation.

In the most general case the motor may have any number of field windings and brush sets, the angular spacing of windings and sets being entirely arbitrary; but the theory is greatly simplified by the following remarks based on the assumptions stated above:

1. *Two field windings connected to the same brush set are obviously equivalent to a single winding connected to this brush set.*

2. *Any number of coaxial field windings 1, 2, etc., Fig. 1, connected to different brush sets 3, 4, etc., are equivalent to a single winding of the same axis connected to a suitably located brush set.* This will be proved for two coaxial windings, but the demonstration is quite general. Let F be the total flux of the motor, α, β, δ = angles counted from a fixed axis OX, and a, b, the circuit constants of the windings 1 and 2; the fluxes due to 2 and 1 are then $a\,F \sin(\delta - \alpha)$ and $b\,F \sin(\delta - \beta)$. The constant c of the equivalent circuit and the angle γ between OX and its brush line must satisfy the equation:

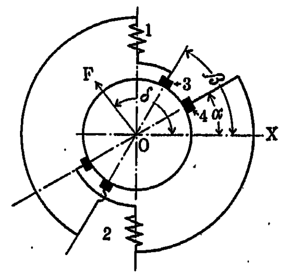

FIG. 1

$a\,F \sin(\delta - \alpha) + b\,F \sin(\delta - \beta) = c\,F \sin(\delta - \gamma)$ for all values of F and δ; this equation has always a solution: $c = \sqrt{a^2 + b^2 + 2ab\cos(\alpha - \beta)}$; $\tan\gamma = (a \sin\alpha + b \sin\beta) \div (a\cos\alpha + b\cos\beta)$.

3. *An exciting system consisting of any number of angularly displaced field windings and brush sets is equivalent to two field windings acting along arbitrarily selected axes and connected to two suitably located brush sets.* For, by paragraph 1, each field winding can be resolved into two windings acting along two arbitrary axes and connected to the original brush set; and by the paragraph 2 each of these two sets of coaxial windings is equivalent to a single winding connected to a suitably located brush set.

The choice of the axes being arbitrary, it is possible to further simplify the problem without restricting its generality by taking a set of rectangular field axes.

To sum up: *The most general exciting system is equivalent to two field windings displaced 90 electrical degrees and connected to two angularly displaced brush sets.*[3]

3. It can also be shown that it is equivalent to two arbitrarily spaced brush sets connected to two suitably proportioned and located field windings.

This system will be studied in the paper. The equivalence of the synchronous performance means the equivalence of the synchronizing features, as will be shown below.

The fundamental difference between a motor with a single set of brushes or its equivalent (paragraph 2) and the general case is the fact that in the former the axis of the d-c. excitation remains fixed with respect to the brushes, while in the latter the resultant axis of the d-c. excitation moves relatively to the brushes. In what follows, these two classes of motors will be denoted as "fixed axis" and "variable axis" motors.

Fig. 2 shows the general form of the exciting system. It is determined by four arbitrary constants: two circuit constants of the field windings 1 and 2 and two constants determining the positions of the brush sets. Since it is impossible to tell beforehand what values of these constants are of practical importance, no restriction will be made in this respect. The geometrical figures are apt to be misleading in such a case, and it is necessary to adopt a convention of signs for the fluxes and the angles. Positive directions are assumed for all axes, and a component of a flux along an axis is always

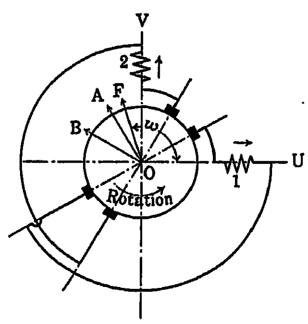

Fig. 2

taken with a sign. The positive directions of the field axes $O\,U$, $O\,V$, marked by the arrows, are denoted by $\overline{U}$, $\overline{V}$. The positive direction of angles and the rotation of the primary relative to the secondary are assumed counterclockwise. The angle between any two vectors $\overline{A}$ and $\overline{B}$ (or between the positive directions of two directed axes) is denoted by $(\overline{A}, \overline{B})$ or simply (A, B); it is positive or negative according as a rotation which makes $\overline{A}$ parallel to and of the same direction as $\overline{B}$ is in the positive or negative direction of angles; thus, $(\overline{U}, \overline{V}) = \dfrac{\pi}{2}$. The angle between any two vectors $\overline{A}$ and $\overline{M}$ of a system of vectors $\overline{A}, \overline{B}, \overline{C}, \ldots. \overline{L}, \overline{M}$, is given by the well-known relation $(\overline{A}, \overline{M}) = (\overline{A}, \overline{B}) + (\overline{B}, \overline{C}) + \ldots. + (\overline{L}, \overline{M})$.

The position of the brushes is determined as follows: let $\overline{A}$ and $\overline{B}$ be arbitrarily selected positive directions of the axes of the brush sets (axes perpendicular to the lines of brushes); the connections between the field windings and the brushes will be assumed such that, when the positive directions of the axes of a brush set and of the winding coincide, the action is as in a true self-excited motor, *i. e.*, an originally existing flux along the axis is then increased by the exciting current. With this convention the fluxes F_f and F_n whose ratio is the circuit constant have always the same sign, *i. e.*, the circuit constant is always positive. The position of the brushes is now fully determined by the angles $\alpha = (\overline{U}, \overline{A})$ and $\beta = (\overline{V}, \overline{B})$.

Let $\overline{F}$ be the vector and F = the numerical value of the flux of the a-c. armature reaction stationary with respect to the secondary; let ω be the angle $(\overline{U}, \overline{F})$; the components F_u and F_v of $\overline{F}$ along $O\,U$ and $O\,V$ are $F_u = F \cos(\overline{U}, \overline{F}) = F \cos \omega$, and $F_v = F \cos(\overline{V}, \overline{F}) = F \cos[(\overline{V}, \overline{U}) + (\overline{U}, \overline{F})] = F \sin \omega$. If F_1 and F_2 are fluxes set up by the windings 1 and 2, then the total fluxes along $O\,U$ and $O\,V$ are $F_u + F_1$ and $F_v + F_2$ (neglecting the small flux due to the currents in the d-c. armature winding), and the total flux along the brush axis $O\,A$ is $(F_u + F_1) \cos(\overline{U}, \overline{A}) + (F_v + F_2) \cos(\overline{V}, \overline{A}) = (F_u + F_1) \cos \alpha + (F_v + F_2) \sin \alpha$. Similarly, the total flux along $O\,B$ is $(F_u + F_1) \cos(\overline{U}, \overline{B}) + (F_v + F_2) \cos(\overline{V}, \overline{B}) = -(F_u + F_1) \sin \beta + (F_v + F_2) \cos \beta$. Let a and b be the circuit constants of the windings 1 and 2; their definition gives the equations: $F_1 = a\,[(F_u + F_1) \cos \alpha + (F_v + F_2) \sin \alpha]$ and $F_2 = b\,[-(F_u + F_1) \sin \beta + (F_v + F_2) \cos \beta]$. These equations, solved for F_1 and F_2, give: $F_1 = m_1 F_u + n_1 F_v$; $F_2 = m_2 F_v - n_2 F_u$, where

$$\left.\begin{aligned}
m_1 &= \frac{a \cos \alpha - a\,b \cos(\alpha - \beta)}{1 - a \cos \alpha - b \cos \beta + a\,b \cos(\alpha - \beta)} \\
m_2 &= \frac{b \cos \beta - a\,b \cos(\alpha - \beta)}{1 - a \cos \alpha - b \cos \beta + a\,b \cos(\alpha - \beta)} \\
n_1 &= \frac{a \sin \alpha}{1 - a \cos \alpha - b \cos \beta + a\,b \cos(\alpha - \beta)} \\
n_2 &= \frac{b \sin \beta}{1 - a \cos \alpha - b \cos \beta + a\,b \cos(\alpha - \beta)}
\end{aligned}\right\} \quad (1)$$

Substitution of the expressions of F_u and F_v found before gives

$$\left.\begin{aligned}
F_1 &= F\,(m_1 \cos \omega + n_1 \sin \omega) \\
F_2 &= F\,(m_2 \sin \omega - n_2 \cos \omega)
\end{aligned}\right\} \quad (2)$$

Let r and x be the primary resistance and leakage reactance per phase, and X = armature reactance corresponding to the flux F. Fig. 3 is the vector diagram of the motor. $O\,X_1$ and $O\,Y_1$ are rectangular axes, $O\,I'$ is the current I' per phase, $O\,A' = r\,I'$, $A'\,B' = x\,I'$, $B'\,C'$ = counter – e. m. f. $X\,I'$ due to the flux F, $C'\,M'$ = e. m. f. E_1 due to the flux F_1, $M'\,N'$ = e. m. f. E_2 due to F_2; $C'\,N'$ is the resultant counter – e. m. f. E, and $N'\,O$ is the applied voltage. The e. m. f.s. E_1 and E_2 are functions of ω; for a given ω their vectors $C'\,M'$ and $M'\,N'$ are found as follows:

it is seen in Fig. 2 that, with the adopted counter-clockwise rotation of the primary, a positive flux along $O\,U$ sets up an e. m. f. whose vector makes with the vector $B'\,C'$ an angle ω, laid off from $B'\,C'$ with due regard to the sign of ω; if the flux along $O\,U$ is negative, the vector obtained by this rule should be reversed. Hence the general rule; the numerical expression of an e. m. f. due to a flux along $O\,U$ in Fig. 2 is given the same sign as the flux; its vector in Fig. 3 is then obtained by laying off the algebraic value of the e. m. f. along a directed axis whose positive direction $\overline{L}$ is defined by the relation $(\overline{X}', \overline{L}) = \omega$. The rule for e. m. fs. due to the fluxes along $O\,V$ is similar, the positive direction $\overline{T}$ of vectors being defined by $(\overline{X}', \overline{T})$

$$= \omega - \frac{\pi}{2}.$$

Since the armature reaction flux F sets up an e. m. f. numerically equal to $X\,I'$, the algebraic values E_1 and E_2 of the e. m. fs. set up by F_1 and F_2 (*eq.* **2**) are

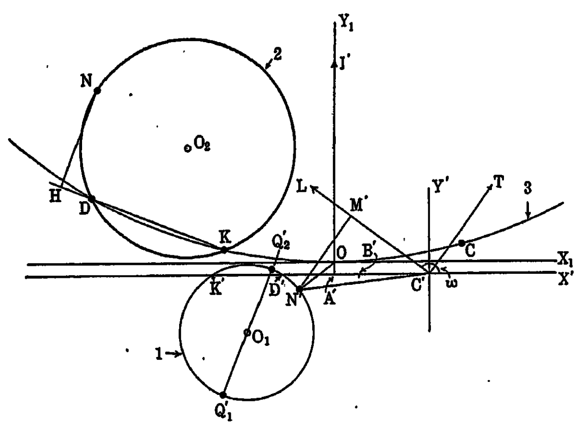

Fig. 3

$$\left.\begin{aligned} E_1 &= X\,I'\,(m_1 \cos\omega + n_1 \sin\omega) \\ E_2 &= X\,I'\,(m_2 \sin\omega - n_2 \cos\omega) \end{aligned}\right\} \quad (3)$$

If I' is kept constant, the point N' describes the locus of the applied voltage at constant current. Let $C'\,X'$ and $C'\,Y'$ be a set of coordinate axes with positive directions $\overline{X}'$ and $\overline{Y}'$ parallel to $\overline{X}_1$ and $\overline{Y}_1$; the projections of the vectors $\overline{E}_1$ and $\overline{E}_2$ on $C'\,X'$ are $E_1 \cos(\overline{X}', \overline{L}) = E_1 \cos\omega$ and $E_2 \cos(\overline{X}', \overline{T}) = E_2 \sin\omega$. Their projections on $C'\,Y'$ are $E_1 \cos(\overline{Y}', \overline{L}) = E_1 \sin\omega$, and $E_2 \cos(\overline{Y}', \overline{T}) = -E_2 \cos\omega$; therefore, the coordinates x' and y' of the point N' are

$$\left.\begin{aligned} x' &= E_1 \cos\omega + E_2 \sin\omega \\ y' &= E_1 \sin\omega - E_2 \cos\omega \end{aligned}\right\} \quad (4)$$

From these two equations E_1 and E_2 can be obtained and substituted in eq. (**3**); this gives:

$$x' \cos\omega + y' \sin\omega = X\,I'\,(m_1 \cos\omega + n_1 \sin\omega)$$
$$x' \sin\omega - y' \cos\omega = X\,I'\,(m_2 \sin\omega - n_2 \cos\omega)$$

The elimination of ω between these equations gives

$$\begin{vmatrix} y' - n_1\,X\,I' & x' - m_1\,X\,I' \\ x' - m_2\,X\,I' & -y' + n_2\,X\,I' \end{vmatrix} = O$$

which can be written:

$$(x' - x_c')^2 + (y' - y_c')^2 = R^2 \quad (5)$$

with

$$x_c' = \frac{X\,I'}{2}\,(m_1 + m_2) \qquad y_c' = \frac{X\,I'}{2}\,(n_1 + n_2),$$

$$R = \frac{X\,I'}{2}\,\sqrt{(m_1 - m_2)^2 + (n_1 - n_2)^2} \quad (6)$$

This shows that the locus of the point N' is a circle 1 of center (x_c', y_c') and radius R. Therefore, the current locus at constant voltage E_0 is another circle 2 of center O_2, obtained from circle 1 by inversion with O as center and $E_0\,I'$ as constant of inversion, followed by a rotation over 180 deg. around $O\,I'$.

In what follows the corresponding points in the constant current (*c. c.*) and constant voltage (*c. v.*) diagrams will be denoted by the same capitals with and without accent, respectively. The same convention will be applied to the applied voltage E_0, current I and e. m. fs. E, E_1, and E_2 at the corresponding points of the two diagrams, so that

$$I = I' \times \frac{E_0}{E_0'} \qquad E = E' \times \frac{E_0}{E_0'} \text{ etc.}$$

Part 1. Determination of Performance of a Motor of Given Constants

The constants of a motor are r, x, X, a, b, α, β. Instead of the last four it is convenient to use m_1, m_2, n_1, n_2, because they have an important geometrical meaning: the points Q_1' of coordinates $X\,I'\,m_1$ and $X\,I'\,n_1$, and Q_2' of coordinates $X\,I'\,m_2$ and $X\,I'\,n_2$ are diametrically opposite points on the circle 1, as can be proved by the substitution in the eq. (**5**), and by observing that x_c' and y_c' are coordinates of the middle point of the segment $Q_1'\,Q_2'$.

Construction of the current locus. Torque. The current locus 2 can be drawn as follows: let $p\,I'$ and $q\,I'$ be coordinates (with reference to $C'\,X'$ and $C'\,Y'$) of any point N' of the *c. c.* diagram: the coordinates with respect to $O\,X_1$ and $O\,Y_1$ are $(p + x + X)\,I'$ and $(q - r)\,I'$; the applied voltage $N'\,O$ is $I' \sqrt{(p + x + X)^2 + (q - r)^2}$ and the corresponding point N of the locus at the applied voltage E_0 can be found by observing that the current vector $O\,N$ is equal to $\dfrac{E_0}{\sqrt{(p + x + X)^2 + (q - r)^2}}$, and is symmetrical to $O\,N'$ with respect to $O\,X_1$, *i. e.*, it makes with $O\,X_1$ an angle δ such that $\tan\delta = \dfrac{q - r}{p + x + X}$.

By this rule the two points Q_1 and Q_2 corresponding to

Q_1' and Q_2' can be obtained. Moreover, the line $O\,O_2$ makes with $O\,X_1$ an angle η such that

$$\tan \eta = \frac{y_c' - r\,I'}{x_c' + (x+X)\,I'} = -\frac{X\,(n_1 + n_2) - 2\,r}{X\,(m_1+m_2+2) + 2\,x};$$

the center O_2 is the intersection of $O\,O_2$ with the perpendicular bisector of $Q_1\,Q_2$.

The circle diagram shows clearly the difference between the motors with fixed and variable axes of excitation. In the former $b = O$, so that $m_2 = n_2 = O$, *i. e.*, the circle 1 passes through the fixed point C', independent of the exciting system. The current locus 2, therefore, always passes through the fixed point C; theoretically C is the no-load point of the induction motor having the same r, x and X. The motor with a variable axis of excitation is free from this limitation; in fact, as will be shown, any circle in the plane can be obtained by a suitable choice of constants.

At D' and K' the torque is zero because the resultant e. m. f., $E = C'\,N'$, is normal to the current $O\,I'$; in the *c. v.* diagram the points of zero torque are D and K, on the inverse of the line $O\,X'$, *i. e.*, on a circle 3 of radius $\frac{E_0}{2\,r}$, tangent to $O\,X_1$ at O and having its center on $O\,I'$.

It is known that in the *c. v.* plane the loci of points of constant power transferred from the primary to the secondary are circles concentric with the circle 3 which corresponds to zero torque; the radius of the circle corresponding to the torque of P synchronous watts is

$$\sqrt{\left(\frac{E_0}{2\,r}\right)^2 - \frac{P}{r}}.$$

These circles are convenient for comparison of polyphase motors having the same r, whether synchronous or induction type, because they represent the torque regardless of the type of the rotor. The torque at any point N is proportional to the distance $N\,H$ from the line $D\,K$. These theorems are well known; their proof can be found in the article 2 of the bibliography.

The torque comprises the friction torque and the torque exerted by the field on the d-c. winding; the latter, expressed in synchronous watts, is the power consumed in the exciting circuits.

The circle 1 intersects $C'\,X'$ only if $R > |\,y_c\,|$, *i. e.*, if $(a \cos \alpha - b \cos \beta)^2 > 4\,a\,b \sin \alpha \sin \beta$. This condition is always satisfied in motors with a fixed axis of excitation ($b = O$); but motors with a variable axis can be designed so that $R < |\,Y_c\,|$ as will be shown; such a motor has not only a maximum torque, but also a minimum torque, below which the synchronous operation is not possible.

Analytical expression of the torque. Maximum torque. Let $\theta = (\bar{L}, N'\,O) = (\bar{L}, \bar{E}_0')$ be the angle between the vector $N'\,O = \bar{E}_0$ of the applied voltage and $\bar{L}$, which may be considered as a directed axis attached to the secondary member; then

$$(\bar{T}, \bar{E}_0') = (\bar{T}, \bar{L}) + (\bar{L}, \bar{E}_0') = \frac{\pi}{2} + \theta;$$

$$(\bar{I}', \bar{L}) = (\bar{I}', \bar{X}') + (\bar{X}', \bar{L}) = -\frac{\pi}{2} + \omega;$$

$$(\bar{I}', \bar{T}) = (\bar{I}', \bar{L}) + (\bar{L}, \bar{T}) = \omega - \pi.$$

Projecting the closed line $O\,A'\,B'\,C'\,M'\,N'\,O$ on the directions $\bar{L}$ and $\bar{T}$ it is found with the aid of the foregoing relations:

On $\bar{L}$: $-r\,I \sin \omega + (x+X)\,I \cos \omega + E_1 = -E_0 \cos \theta$

On $\bar{T}$: $r\,I \cos \omega + (x+X)\,I \sin \omega + E_2 = E_0 \sin \theta$

With E_1 and E_2 from eq. (3) these equations, solved for $I \sin \omega$ and $I \cos \omega$, give:

$$\left.\begin{aligned} I \sin \omega &= E_0\,(A \cos \theta + B \sin \theta) \\ I \cos \omega &= E_0\,(A' \cos \theta + B' \sin \theta) \end{aligned}\right\} \quad (7)$$

where

$$A = -\frac{X\,n_2 - r}{C}, \quad B = \frac{x+X+X\,m_1}{C},$$

$$A' = -\frac{x+X+X\,m_2}{C}, \quad B' = -\frac{X\,n_1 - r}{C}$$

and $C = (X\,n_1 - r)\,(X\,n_2 - r) + (x + X + X\,m_1)\,(x + X + X\,m_2)$.

The torque per phase in synchronous watts (considering a motoring torque as positive) is $-\,I'E_1 \cos(\bar{I}'\,\bar{L}) - I\,E_2 \cos(\bar{I}', \bar{T}) = -\,I\,E_1 \sin \omega + I\,E_2 \cos \omega$. The negative torque acting on the d-c. winding is the power consumed in both exciting circuits; it can be represented by $k_1\,E_1^2 + k_2\,E_2^2$ (k_1 and k_2 = constants referred to one phase, whose numerical values can easily be calculated from the electrical and magnetic data of the motor). This assumption disregards the fact of the superposition of the two exciting currents in the d-c. winding; but the loss in it is relatively very small. The torque per phase T exerted on the shaft is $T = -\,I\,E_1 \sin \omega + I\,E_2 \cos \omega - k_1\,E_1^2 - k_2\,E_2^2$. The substitution of E_1 and E_2 from eq. (3) gives: $T = -X\,I^2\,(f \sin^2 \omega + g \cos^2 \omega + h \sin \omega \cos \omega)$, with $f = n_1 + k_1\,X\,n_1^2 + k_2\,X\,m_2^2$; $g = n_2 + k_2\,X\,n_2^2 + k_1\,X\,m_1^2$, and $h = m_1 - m_2 + 2\,k_1\,X\,m_1\,n_1 - 2\,k_2\,X\,m_2\,n_2$. With $I \sin \omega$ and $I \cos \omega$ from eq. (7) this becomes $T = -\,X\,E_0^2\,(p \sin^2 \theta + q \cos^2 \theta + t \sin \theta \cos \theta)$, where $p = f\,B^2 + g\,B'^2 + h\,B\,B'$; $q = f\,A^2 + g\,A'^2 + h\,A\,A'$; and $t = 2\,f\,A\,B + 2\,g\,A'\,B' + h(A\,B + B\,A')$. Finally, let an angle θ_0 be defined by the relations

$$\sin 2\,\theta_0 = \frac{p - q}{\sqrt{(p-q)^2+t^2}} \text{ and } \cos 2\,\theta_0 = \frac{t}{\sqrt{(p-q)^2+t^2}}$$

then $T =$

$$-\frac{X}{2}E^2_0 \left[(p+q) + \sqrt{(p-q)^2+t^2} \times \sin 2(\theta - \theta_0) \right] \quad (8)^*$$

The extreme values of the torque are

$$-\frac{X}{2}E_0^2 \left[p + q \pm \sqrt{(p-q)^2 + t^2}\right].$$

E. m. fs. E, E_1, and E_2 in the Circle Diagram. E_1 and E_2 determine the loss in the field windings. Fig. 4

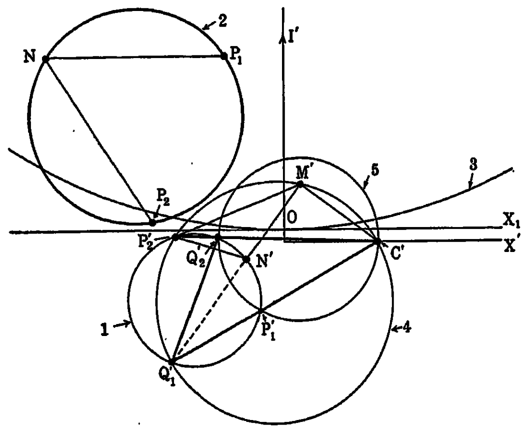

FIG. 4

reproduces some essential parts of Fig. 3. The points Q_1' and Q_2' have for coordinates $(X\,I'\,m_1, X\,I'\,n_1)$ and $(X\,I'\,m_2, X\,I'\,n_2)$. On the basis of eq. (3) it can easily be seen that when ω varies the ends of the vectors $\overline{E}_1'$ and $\overline{E}_2'$ drawn from C' move on the circles 4 and 5 described on $C'\,Q_1'$ and $C'\,Q_2'$ as diameters, and that these diameters pass through the common points P_1' and P_2' of the circles 1 and 5, and 1 and 4. For a given point M' on 4 the vectors $\overline{E}_1'$ and $\overline{E}_2'$ are $C'\,M'$ and $M'\,N'$ respectively; if N' moves on the circle 1, the angles of the triangle $P_2'\,M'\,N'$ remain constant because two of them are subtended by constant arcs $Q_1'\,P_2'$; therefore, there is a constant ratio between the segment $P_2'\,N'$ and the vector $M'\,N'$ of E_2. Let N, P_1 and P_2 be the corresponding points in the *c. v.* diagram. By the well-known property of the inverse points

$$P_2\,N = P_2'\,N' \times \frac{\text{inversion const.}}{O\,P'_2 \times N'\,O}$$

$$= P_2'\,N' \times \frac{E_0\,I'}{O\,P_2' \times N'\,O}.$$

*Starting from this formula the performance can be determined entirely by calculation: it gives θ for a definite output; equations (7) give I and ω; the e. m. fs. E, and E_2 result from eq. (3); the power factor $\cos\varphi$ is given by the relation $(\overline{I}', \overline{N}'\,O) = (\overline{I}', \overline{X}') + (\overline{X}', \overline{L}) + (\overline{L}, N'\,O) = -\frac{\pi}{2} + \omega + \theta$, hence $\cos\varphi = \sin(\omega + \theta)$.

But P_2' is a fixed point, so that $O\,P_2' = I' \times$ constant, where the constant depends only on the constants of the motor; as shown above $P_2'\,N'$ is proportional to the e. m. f. E_2' at voltage E_0', and $N'O = E_0'$; therefore,

$P_2\,N$ is proportional to $\frac{E_2' \times E_0\,I'}{I' \times E_0'}$ = proportional to $E_2' \times \frac{E_0}{E_0'}$ = proportional to E_2. By the same reasoning, the segment $P_1\,N$ is proportional to the e. m. f. E_1. The coefficients of proportionality can be found as follows: the segment $C'\,N'$ represents the resultant e. m. f. E' of E_1' and E_2'; but

$$C\,N = C'\,N' \times \frac{E_0\,I'}{O\,C' \times N'\,O}$$

$$= C'N' \times \frac{E_0\,I'}{I'\sqrt{r^2 + (x+X)^2} \times E_0'}$$

$$= \frac{E}{\sqrt{r^2+(x+X)^2}}$$

i. e., $C\,N$ represents the resultant e. m. f. E. When the point N coincides with P_2, the e. m. f. E_2 vanishes; $C\,P_2$ and $P_1\,P_2$ represent then the same e. m. f. E_1; therefore, for every point N,

$$E_1 = P_1\,N \times \frac{C\,P_2}{P_1\,P_2}\sqrt{r^2 + (x + X)^2};$$

similarly,

$$E_2 = P_2\,N \times \frac{C\,P_1}{P_1\,P_2}\sqrt{r^2 + (x + X)^2}.$$

The expression $E = C\,N\sqrt{r^2 + (x + X)^2}$ shows that for given r, x and X the total e. m. f. due to the field

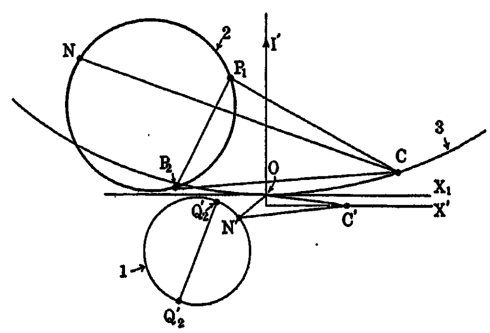

FIG. 5

windings is constant at a given point N, regardless of the locus to which N may belong. This remark should be borne in mind when choosing the working region of the plane for a new motor. It may also be noted that

$O\,C = \frac{E_0}{\sqrt{r^2 + (x + X)^2}}$, *i. e.*, $O\,C$ represents the applied voltage E_0 at the same scale as $C\,N$ represents the resultant e. m. f. E.

Stability. When the load increases the rotor falls back, *i. e.*, the angle θ increases. In general, the operation can be stable only on the part of the circle where an increase of θ corresponds to an increase of the torque. The eq. (3) and (4) give, after elimination of E_1 and E_2 and a few simple transformations: $x' - x_c = R \cos(2\,\omega - \epsilon)$ and $y' - y_c = R \sin(2\,\omega - \epsilon)$, where ϵ is a constant; R and $2\,\omega - \epsilon$ can be considered as the polar coordinates of the circle 1 with its center as origin and $2\,\omega - \epsilon$ as the polar angle. This shows that when the point N' moves on the circle 1 in a definite direction, the sense of the variation of $2\,\omega - \epsilon$ (therefore, of ω) remains the same.

Since the coordinates of C' relative to $O\,X_1$ and $O\,Y_1$ are $(x + X)\,I'$ and $-\,r\,I'$, the expressions of A, B, A' and B' in eq. (7) show that their nominators are proportional to the coordinates of Q_1' and Q_2' relative to $O\,X_1$ and $O\,Y_1$. Let a_1, b_1, and a_2, b_2, denote these coordinates; equations (7) give by division

$$\tan \omega = \frac{b_2 \cos\theta - a_1 \sin\theta}{a_2 \cos\theta + b_1 \sin\theta},$$

hence, after some transformations,

$$\frac{d\,\omega}{d\,\theta} = -\frac{(a_1\,a_2 + b_1\,b_2)\cos^2\omega}{(a_2\cos\theta + b_1\sin\theta)^2}.$$

But $a_1\,a_2 + b_1\,b_2$ is the scalar product of $O\,Q_1'$ and $O\,Q_2'$ and has the sign of $\cos \angle\, Q_1'\,O\,Q_2'$ which is positive or negative according as the point O is outside or inside of the circle 1, because $Q_1'\,Q_2'$ is a diameter. Therefore, when N' moves on the circle 1 in the clockwise direction (decreasing ω), θ increases if O is outside of the circle, and decreases if O is inside. The locus 2 is obtained from 1 by an inversion and a rotation over 180 deg. around $O\,Y_1$; if O is outside of 1, each operation reverses the rotation of N once; if O is inside of 1, only the last operation reverses the rotation. As O is either inside of both circles 1 and 2, or outside of both, it follows that the clockwise motion of N on the locus 2 always corresponds to an increase of θ: *the stable operation corresponds to that part of the current locus on which the point of maximum torque is reached from the point of zero torque by a motion in the clockwise direction.*

PART 2. DETERMINATION OF THE EXCITING SYSTEM FOR A GIVEN CURRENT LOCUS

The constants r, x and X will be assumed as known. Let a circle, such as 2 in Fig. 3, be a locus, presumably within the capacity of the motor; it is desired to check this assumption by determining the exciting system and the excitation losses.

Since a circle is an inverse figure of itself, it is convenient to take for the constant current locus 1 a circle symmetrical of 2 relative to $O\,X_1$. The value of the constant current I' is obtained from the fundamental relation of the inverse points, by drawing any convenient secant. The points A', B' and C' can now be located as in Fig. 3. Let $Q_1'\,Q_2'$ be an *arbitrary* diameter; it follows from what was found in Part I that, if the coordinates (with respect to $C'\,X'$ and $C'Y'$) of the points Q_1' and Q_2' be divided by $B'\,C' = X\,I'$, and the quotients substituted for m_1, m_2, n_1 and n_2 in eq. (1) the numbers a, b, α and β in these equations are the constants giving the locus 2. The solutions of these equations are

$$\left.\begin{aligned}
a &= \frac{\sqrt{n_1^2 + (m_1 + G)^2}}{S},\\
\sin\alpha &= \frac{n_1}{\sqrt{n_1^2 + (m_1 + G)^2}},\\
\cos\alpha &= \frac{m_1 + G}{\sqrt{n_1^2 + (m_1 + G)^2}}\\
b &= \frac{\sqrt{n_2^2 + (m_2 + G)^2}}{S},\\
\sin\beta &= \frac{n_2}{\sqrt{n_2^2 + (m_2 + G)^2}},\\
\cos\beta &= \frac{m_2 + G}{\sqrt{n_2^2 + (m_2 + G)^2}}
\end{aligned}\right\} \quad (9)$$

where $S = 1 + m_1 + m_2 + m_1\,m_2 + n_1\,n_2$; $G = m_1\,m_2 + n_1\,n_2$, and the radicals are taken with the signs giving positive values for a and b. The roots are always real; therefore, theoretically, *there always exists an exciting system giving any desired locus in the plane.* In fact, the problem has an infinity of solutions because the diameter $Q_1'\,Q_2'$ is arbitrary. The study of the constants a, b, α, β, corresponding to different diameters is facilitated by the following remarks: (1) since $Q_1'\,Q_2'$ is a diameter, S and G are independent from the choice of $Q_1'\,Q_2'$ because they are proportional to the scalar products $\overline{B'\,Q_1'} \times \overline{B'\,Q_2'}$ and $\overline{C'\,Q_2'} \times \overline{C'\,Q_1'}$ respectively; (2) the radicals in (9) are proportional to the distances of Q_1' and Q_2' from a fixed point on the axis $C'\,X'$ whose abscissa (with respect to C') is $x' = -\,X\,I' \times G$; the coefficient of proportionality $X\,I'$ is the same as for G and S. For instance, in the case when the circle 1 passes through C' (*i. e.*, $G = O$), let Q_2' coincide with C'; this gives $m_2 = n_2 = O$, $b = O$; the motor has a fixed axis of excitation and a single field winding; if Q_1' and Q_2' are different from C', the condition $G = m_1\,m_2 + n_1\,n_2 = O$ gives $\cos(\alpha - \beta) = O$, $\alpha - \beta = \dfrac{\pi}{2}$, *i. e.*, the brush sets coincide and are equivalent to a single set; the motor has two field windings connected to the same brush set and is equivalent to the first case.

Synchronising. When a motor, carrying a reasonable load as an induction motor, comes up to speed, the slip of the rotor is low and the conditions are similar to the synchronous performance with the rotor gradu-

ally falling back under the influence of the load. The torque is the sum of the induction torque and the synchronous torque, the latter passing through a sequence of values corresponding to a complete cycle of synchronous performance represented by the current locus. In a separately excited motor the torque is nearly alternating, with a small negative average value; in a self-excited motor, however, the choice of the locus is arbitrary; if the exciting system is such as to give a circle similar to Figs. 9 or 11, entirely or for the most part inside of the circle 3, *i. e.*, in the region of positive (motoring) torques, the torque during the synchronising process either remains positive, or is mostly positive, with a small negative interval of short duration. Analytically, the synchronizing torque is expressed by eq. (8).

A commercial synchronous motor must have a synchronous no-load point, *i. e.*, the circles 2 and 3 must have common points; the pulsations of the current and of the torque are inavoidable during the synchronising process, whether the axis of excitation is fixed or variable; but in the latter case it is possible to adjust the constants (for instance, the position of brushes) temporarily so as to throw the locus toward the center of the circle 3 in the region of the high-torque points of the plane, and out of contact with 3; and to reduce its diameter; in this way the synchronising torque may be considerably increased and the pulsations reduced until the motor reaches synchronism, when, with a little care, the change back can be accomplished without causing an undue shock to the system.

PART III. EXAMPLES

It is intended here to pass rapidly in review some of the types of the self-excited motor and to show that, with the aid of the diagrams and formulas of the paper, an idea as to the possibilities and limitations of a type can often be obtained without any extensive calculations. This study is facilitated by observing that, since the angle of two curves remains unchanged by the inversion, the angle γ between the circles 2 and 3 is the same as between the circle 1 and the line $A'X'$; it is given by $\cos \gamma = \dfrac{y_c'}{R}$, eq. (6).

1. *Fixed Axis of Excitation.* In all motors of this class it can be assumed that $b = O$, $m_2 = n_2 = O$, so that $\cos\gamma = \dfrac{n_1}{\sqrt{m_1^2 + n_1^2}} = \sin \alpha$, *i. e.*, $\gamma = \dfrac{\pi}{2} - \alpha$.
All fixed axis motors pass through a fixed point C, the no-load point of the induction motor having the same r, x and X.

Example 1. Brushes on neutral axis, Figs. 6 and 7. In this case $\alpha = O$, $\gamma = \dfrac{\pi}{2}$, the circle 2 is normal to the circle 3. For comparison. let $2'$ be the locus of an induction motor of the same constants r, x and X; $2'$ is also normal to the circle 3 (see, for instance, JOURNAL, A. I. E. E., April 1921, p. 326). If both motors have the same maximum torque, 2 and $2'$ are tangent to the same constant torque circle $3'$ and, if the synchronous motor is designed for leading power factor, as shown, the excitation must be so strong that its no-load current $O\,D$ is of the same order of magnitude as the locked current of the induction motor. More-

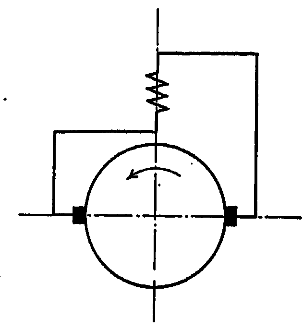

FIG. 6

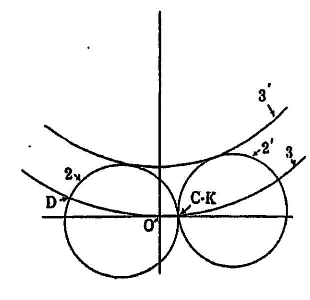

FIG. 7

over, the synchronous torque which is proportional to the distances of the points of the circle to the line K-D is very nearly alternating, so that the synchronising characteristics are very poor.

Example 2. Brushes on the axis of the fieldwinding, Figs. 8 and 9. Here $\gamma = O$; the circles 2 and 3 are tangent. The torque is always positive (motoring); the synchronising features are excellent, but the motor

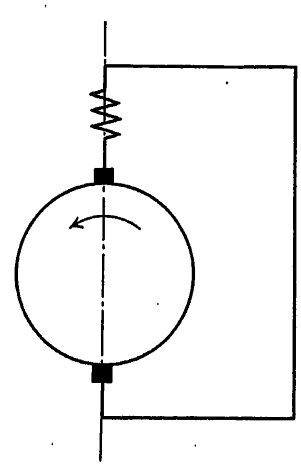

FIG. 8

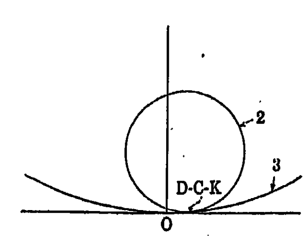

FIG. 9

is very sensitive to the brush position, and the power factor at light loads is not as good as can be expected in a synchronous motor.

The correct setting of the brushes is as in Fig. 10, intermediate between Figs. 6 and 8, but nearer to the latter than to the former. The locus is then as in Fig. 11.

2. *Variable Axis of Excitation.* Example 3: One might be tempted to improve the starting characteristics and to simplify the construction by using two identical exciting circuits displaced 90 deg. against one

another; but in this case $a = b$, $\alpha = \beta$; hence, $m_1 = m_2$, $n_1 = n_2$, therefore $R = O$ eq. (6): the circles 1 and 2 collapse each into a point; the synchronous performance is simply the synchronous point of a more general, variable speed performance of the motor.

Example 4. Fig. 12. The windings are connected to the brushes so that $\alpha = O$, $\beta = \pi$; 1 is the exciting winding proper, while 2 opposes the transverse arma-

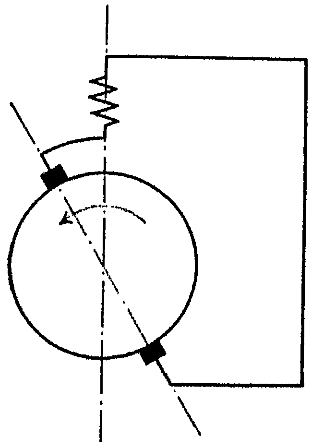

FIG. 10

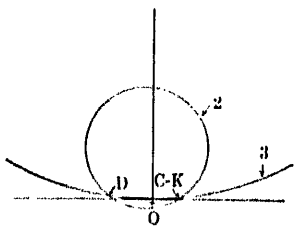

FIG. 11

ture reaction. Equations (1) give $n_1 = n_2 = O$, therefore, $\cos \gamma = O$, $\gamma = \pi/2$; the locus 2 is normal to the circle of zero power 3, as in the example 1, Figs. 6 and 7, but is not restricted to pass through C; the synchronising torque is alternating, therefore, the synchronising characteristics are poor.

Example 5. Fig. 13. Both windings act along the lines of brushes, $\alpha = \beta = \pi/2$; if the windings are

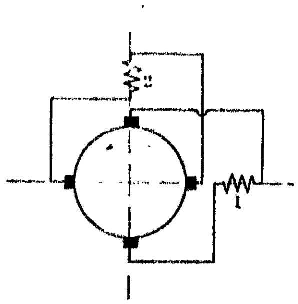

FIG. 12

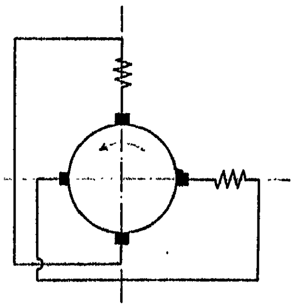

FIG. 13

indentical, the locus is a point, as explained above; if a is not equal to b, the locus is a circle, but, since the condition $(a \cos \alpha - b \cos \beta)^2 > 4\, a\, b \sin \alpha \sin \beta$ cannot be satisfied, this circle has no common points with the circle 3: the motor has no synchronous zero torque points.

Discussion

H. Weichsel: The self-excited synchronous motor has, during the last few years, forged its way rapidly to the front and promises to take a very important part in the lay-outs and designs of future power plants, distribution systems and consumers' plants.

Mr. Kostko's paper on this type of machine is, therefore, to be welcomed, as it deals with the general theory governing the different machines which belong to this general class of self-excited synchronous motors.

Mr. Kostko has, in an admirable manner, gone to remarkable details in deriving the general locus for the current vector of these machines and in doing so has made full use of the principle of inversion, which is an extremely useful mathematical tool when it is desired to derive the current locus of an electric machine which is connected to a supply of constant potential. It is to be regretted that this method is not more generally known and used, and, therefore, it is to be hoped that Mr. Kostko's elegant application of this principle will help to stimulate the general interest in this method of attack for deriving the current locus of electric machines.

Personally, I have been, for a great number of years, an ardent advocator of graphical methods for the solution of a-c. electrical phenomena and, therefore, welcome heartily Mr. Kostko's method of deriving circle diagrams for this type of machine.

Experience has shown that the circle diagram of a simple induction motor has contributed more than any other factor to the full understanding of the performance and the interaction of the different phenomena which take place in this type of machine. The graphical methods readily give an answer to the behavior of the machine under most any imaginable operating condition.

The induction-motor circle diagram has also largely contributed to the high state of development of the present induction motor. The economic savings which have resulted from the general application of the induction-motor circle diagram must be enormous and no doubt run into millions of dollars.

There are two kinds of circle diagrams for the induction motor; namely, the so-called Heyland or Behrend diagram and the Osanna diagram.

The first-mentioned diagram neglects in the derivation of the current locus the influence of the ohmic resistance. The second-mentioned diagram considers the ohmic resistance and, is, therefore, of particular interest from the theoretical point of view.

The mathematical derivation of the first-mentioned diagram is extremely simple. The contrary is true for the Osanna diagram. Also, the actual construction and application of the Hyland diagram is the simplest possible, while this cannot be said for the Osanna diagram. The additional accuracy obtainable by the use of the more complicated Osanna circle over the extremely simple Heyland circle is small and often even of doubtful value. For this reason, the Heyland circle has found a very wide field of application, while the Osanna circle is used only for special cases.

Another reason for the general preference of the Heyland circle will be found in the fact that both diagrams are based on certain assumptions, such as constant leakage reactance and proportionality between magnetic lines and ampere-turns. It is a well established fact that the assumptions are not completely fulfilled in practical machines. Why, therefore, go into

the complication of considering the influence of the ohmic resistance, which, in the majority of cases, produces a very much smaller effect on the current locus than the variable leakage and saturation which is found in nearly every actual machine. The great popularity of the extremely simple Heyland diagram is, therefore, entirely justified. Especially if we consider that by a very slight addition to the Heyland diagram, it is possible to obtain the exact theoretical performance with due consideration of the resistance.

Similar conditions exist in self-excited synchronous motors. The influence of the leakage reactance and especially ohmic drop on the current locus is small.

In actual machines, neither the assumption that proportionality exists between magnetic lines and ampere-turns nor the assumption that the reactance is constant is fulfilled.

In addition to this, there exists a magnetizing effect due to the currents under the brushes which cannot be readily considered in a diagram. The details of this can be seen in the paper I presented before the Midwinter Convention of the A. I. E. E., 1925.[2]

The great complications introduced in the derivations of the circle diagram due to the influence of ohmic resistance, as well as the complications produced thereby in the construction and application of these diagrams may quite possibly prove themselves to be so large in comparison with the available increased accuracy, that the exact diagram will find only a relatively small field of practical application, but it will always be considered as a very important feature from the strictly theoretical point of view. At least, this would be in agreement with the experience of the Osanna circle diagram for induction motors.

On the other hand, a circle diagram for self-excited synchronous motors which neglects such minor effects as ohmic resistance promises to find a wide field of practical application on account of the extreme simplicity of its derivation and construction. Its simplicity, similar to the Heyland diagram, makes it further extraordinarily easy to understand at a glance the influence of the main factors which enter in the design and operation of these motors.

Furthermore, similar to the Heyland diagram, it is possible to derive from this simple diagram by relatively simple means the performance even under cases where it is desired to consider the factors which have been neglected in the derivation of the diagram. For the last few years, I have successfully used in practical design work, such a simplified circle diagram. Its derivation is based on the fact that the resultant field in any a-c. motor must be constant when constant voltage is impressed on its terminals and the influence of the ohmic resistance and reactance is negligible. With this assumption as a basis, it requires about two lines of mathematical formulas to derive the current locus.

Fig. 1, herewith, shows a current locus derived in such a manner for a machine connected in accordance with Fig. 8 of Mr. Kostko's paper. In this particular case, the ordinates of the circle are positive for all load conditions. Therefore, the very interesting result can immediately be seen from this diagram that a machine connected as per Fig. 8 is unable to operate as a synchronous generator as long as the field and armature are in the motoring connection and the direction of rotation for generating and motoring is assumed to be alike.

Many other extremely interesting conclusions can quickly be drawn from such simplified diagrams. For instance, by constructing the diagram for different angles between brush axis and field axis, it will be seen at a glance that under idle running conditions the voltage across brushes is not zero when the brush axis coincides with the field axis and does not reverse when the brush axis is displaced in either direction from the field axis, but follows a law given in full lines in the Fig. 2 herewith and does not follow the dotted lines, as one is inclined to expect. This simplified method of attack lends itself equally well to any kind of self-excited synchronous motor. A further discussion of the details of the general principle and application involved in these simplified diagrams would lead too far on this occasion.

There are a few statements in Mr. Kostko's paper which might lead a casual reader to wrong conclusions and a few words to prevent such pitfalls may be appropriate.

Mr. Kostko states that any number of coaxial field windings connected to different brush sets are equivalent to a single winding of the same axis connected to a suitably located brush set. This statement might lead to the conclusion that *equal performance* could be obtained by a machine with one field winding and one set of brushes and a machine of *equal dimensions* but possessing two field windings and two sets of brushes. However, a number of electrical, as well as mechanical reasons, exist, which make this impossible and invariably result in a materially poorer performance for the machine with two brush and field sets.

Mr. Kostko's statement regarding the synchronizing torque may leave the impression that the torque existing during the synchronizing period is in every respect equal to the torque of the machine at synchronous operation. This, however, is not the case under all conditions, but is true just at the theoretical dividing point between synchronism and slip. At speeds below synchronism, the voltage induced in the secondary windings due to the speed between resultant motor field and secondary winding produces an additional induction-motor torque, as shown in my paper mentioned before.

There is another very interesting feature which might be mentioned in this connection: If the load on a self-excited synchronous motor is suddenly increased, the motor can momentarily develop more than its so-called maximum synchronous torque, because a sudden load causes the resultant magnetic field of the motor to fall back suddenly and the velocity of the falling-back magnetic field produces, by induction, an e. m. f. on the field winding which strengthens the excitation until the field has assumed its final position in space. If the machine has an auxiliary secondary winding for starting purposes, then, under the conditions described, a current is induced in this winding also during the falling-back period of the resultant field which adds further to the motor torque until such time when the field has taken its final position in space.

In conclusion, may I state that Mr. Kostko's paper offers a tremendous amount of interesting information and my remarks advocating the attack of the problems of these motors on the simplified basis by neglecting ohmic resistance and leakage reactance, are, in no manner, intended to criticize or minimize the excellent work done by him, but are intended to point out that for the purpose of practical application, the simplified method of dealing with the subject will probably find a wider field of usefulness for the same reasons which made the Heyland circle so much more popular than the Osanna circle, but from the truly theoretical viewpoint, the complete diagram will always remain the most important and the most interesting one.

V. Karapetoff: It would be of interest to go over Mr. Kostko's deduction of the circular locus, using the vector analysis method.[3] With this method, the whole statement of the problem is first written down in the form of vectorial equations, and then some of the variables are eliminated by short-cut methods not possible with elementary algebra or geometry.

Let I be a variable current vector whose locus is a circle of diameter D passing through the origin. The vector connecting the ends of the vectors D and I is $D - I$, a geometric subtraction being understood. According to a familiar property of the circle, the vectors I and $(D - I)$ are perpendicular to each other; hence, in the language of Vector Analysis,

2. A New A-C. General-Purpose Motor, H. Weichsel, TRANS. A.I.E.E., 1925, p. 7.

3. See V. Karapetoff, The Use of the Scalar Product of Vectors in Locus Diagrams of Electrical Machinery; A. I. E. E. JOURNAL, 1923, Vol. 42, p. 1181. A good elementary book on Vector Analysis is by J. G. Coffin (Wileys).

$$(D - I) \,.\, I = O \tag{1}$$

Here the dot between the two factors stands for the so-called *scalar product*. By definition, if A and B are two vectors, their dot product is

$$A \,.\, B = A\, B \,\mathrm{Cos}\,(A, B) \tag{2}$$

Since Cos 90 deg. $= O$, the condition that two vectors are perpendicular to each other is

$$A \,.\, B = O \tag{3}$$

Eq. (1) is an application of this relationship to a circle and represents the vector equation of a circle of diameter D passing through the origin.

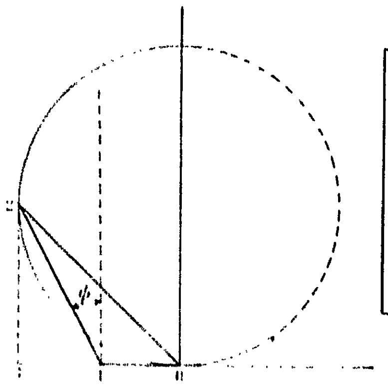

FIG. 1

I shall now show an application of this method to a very simple and well-known a-c. locus problem, namely that of a constant reactance x and a variable resistance r in series across a

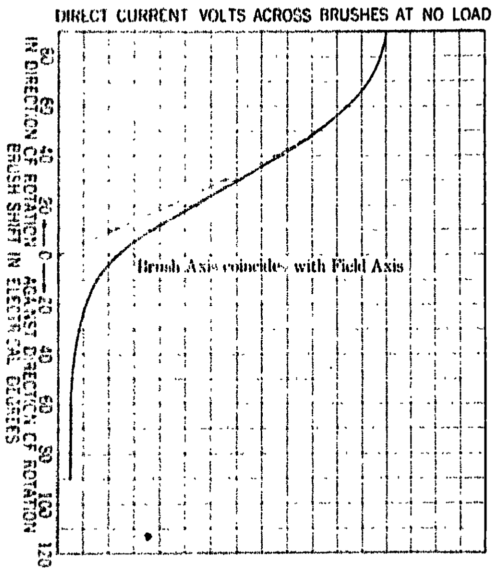

FIG. 2

source of constant sinusoidal voltage E. It is required to find the locus of the current I. We have

$$E = I\, r + x\,(j\, I) \tag{4}$$

where $j\,I$ is a vector numerically equal to I and leading it in phase by 90 deg. Since r is variable, and we want a locus, it is necessary to eliminate $I\,r$ from eq. (4). The general method used in vector analysis is to take a scalar product of both sides of eq. (4) with some vector perpendicular to the vector to be eliminated. The vector $I\,r$ is in phase with I; hence both sides must be multiplied by $(j\,I)$, because $(r\,I)\,.\,(j\,I) = O$. The result is

$$[E - x\,(j\,I)\,]\,.\,(j\,I) = O \tag{5}$$

or, after division by x,

$$[\,(E\; x) - (j\,I)\,]\,.\,(j\,I) = O \tag{6}$$

It will be seen that eq. (6) is of the form (1) so that the locus of $(j\,I)$ is a circle of diameter E/x. If desired, eq. (6) can be also written in terms of I instead of $j\,I$. It is only necessary to multiply the both factors on the left-hand side by $-j$, thus turning them by 90 deg. The result is

$$[\,(-j\;E/x) - I\,]\,.\,I = O \tag{7}$$

It is true that this particular problem can be just as readily solved by elementary geometry, but I purposely selected the simplest possible case to illustrate the general method.

V. A. Fynn: Mr. Kostko's paper is devoted to a very interesting attempt to develop a general theory of the "exciting" system of self-excited synchronous motors so as to secure a basis of comparison for the several already known types and for such others as further development work may disclose. The paper, however, also deals with the subject of synchronization and touches lightly on the starting conditions.

I have been actively interested in this field ever since 1905 and took out my first patent relating to synchronous induction motors in 1906 (See B. P. 11,298 of 1906). In the last few years I have gone over this ground with a fine-tooth comb in an attempt to discover a polyphase motor with controllable power factor which would be generally acceptable. During the process I too have analyzed this type of machine along very general lines. My experiences in this connection have led me to the conclusion that an exhaustive study of the "exciting" system is not sufficient, that the synchronizing torque is of at least equal importance in the case of self-excited, and of even greater importance in the case of separately excited, synchronous induction motors, and that the asynchronous performance of such machines is almost as vital if a proper basis for the comparison of various types is desired.

It has long been the practise to speak of the unidirectional ampere-turns on the secondary of a synchronous motor as "exciting" ampere-turns, Mr. Kostko does so in his paper, I have often done so myself, but the fact is that these ampere-turns do not always contain *real exciting* ampere-turns and do always carry something else. The term "excitation" conveys to one's mind a picture of the usually few ampere-turns necessary to produce the resultant motor magnetization and with this picture in mind one is very apt to form an entirely wrong conception of the dimensions and practical significance of the commutator of a synchronous induction motor and of the difficulties met with by the designer of such machines. The fact is that the unidirectional ampere-turns on the secondary of a synchronous motor are *always at least equal to the load ampere-turns*, sometimes to *load plus exciting* and mostly to *load plus over-exciting ampere-turns*. At a certain value of lagging power factor, the secondary of a synchronous motor carries exactly that number of ampere-turns as is carried by the secondary of a non-synchronous induction motor under like conditions. At such time all the exciting ampere-turns are carried by the primary, as is the case in non-synchronous induction motors. When a synchronous motor operates at unity power factor then its secondary carries the vectorial sum of load and exciting ampere-turns. For leading power factors its secondary carries load plus over-exciting ampere-turns. The result is that the commutator of a self-excited synchronous or synchronous induction motor carries working plus exciting or plus over-exciting current. Such a commutator must necessarily be large and if anything happens to it or to its cooperating circuits, the machine is put out of commission.

We ought not to speak of the secondary ampere-turns of a synchronous motor as "exciting" ampere-turns.

In the fifth paragraph of his paper Mr. Kostko says that synchronization is accomplished by the synchronous torque—strictly speaking, by a torque which later becomes the synchronous torque. This is true of all the earlier forms of synchronous or synchronous induction motors but is not necessarily true of all synchronous motors. Some of the several motors of this type which I have invented depart from this rule as I have shown in a paper read February 27th last before the Columbus Section of the A. I. E. E. and elsewhere.

In the same paragraph Mr. Kostko states that in separately excited synchronous motors the synchronizing torque is alternating. This used to be so but I have devised separately excited motors with strictly unidirectional and pulsating torques and others with even strictly constant synchronizing torques with quite a variety of synchronizing-torque configurations in between these limits to choose from, see "Engineering" February 20, 1925 and a paper presented to the Schenectady Section of the A. I. E. E. on March 27, 1925.

Just for the sake of historical accuracy it should be stated that contrary to Mr. Kostko's impression as voiced in his paragraph 6, the first self-compounding synchronous induction motor is apparently that of Burge, see B. P. 3227 of 1913, which has two secondary windings and *two* displaced sets of brushes.

I should like to stress my absolute agreement with Mr. Kostko's plea, paragraph 7, that a thorough theoretical investigation go hand-in-hand with experimental work and that haphazard experimenting be avoided. I have preached this doctrine for many years, also when connected with a company for which Mr. Kostko was working at the time, and I have successfully practised what I preached. In many cases, including all the synchronous induction motors I have invented, I was able to go even further and to work out the theory quite completely before making a single test, with the result that experimental development work was reduced to practically nothing.

I am bound to disagree with Mr. Kostko as to the opening phrase of his ninth paragraph. This statement of his explains why he has given such scant attention to the asynchronous features of the motors he has discussed as affected by the several arrangements of secondary windings and primary brushes he has referred to. My experience is that the effect of the "exciting" and synchronizing system on the asynchronous characteristics of the machine cannot be so lightly set aside.

The arrangement of secondary windings and primary brushes is now usually used to start, to synchronize and to operate the motor. If they are not so used additional windings are necessary which increase the cost and complicate the manipulations, if they are so used, then the secondary windings act as induction-motor secondaries at starting and their action is modified by the voltage appearing at the commutator brushes included in their circuits. In many cases this results in a considerable unbalancing of the several secondary circuits and a correspondingly poorer starting performance. To illustrate my point, refer to Mr. Kostko's Fig. 12. At the moment of starting, the brush voltage impressed on the secondary 2 leads the voltage generated in 2 by the synchronously revolving motor flux by 90 deg., whereas the brush voltage impressed on No. 1 lags by that amount behind the voltage generated in No. 1.

But of far more consequence is the influence of the configuration of the synchronizing torque on the asynchronous performance of the machine upon a torque demand which exceeds the maximum synchronous torque. As a specific example take a synchronous induction motor provided with the type of "excitation" shown in Fig. 10 and which was disclosed by me in 1916, see U. S. P. 1,337,648. Because of the fact that the unidirectional ampere-turns on the secondary of a synchronous motor are not "exciting" but really "load plus exciting" ampere-turns, also because these must be accommodated in a single-phase as against a polyphase winding as used in non-synchronous motors and finally because in addition to the winding carrying the unidirectional ampere-turns it is necessary to have another closed winding on the secondary to permit of the motor operating asynchronously, it is found that even by using more copper on the secondary than in the corresponding asynchronous motor the maximum synchronous torque can hardly be made to equal more than two-thirds of the maximum asynchronous torque. If the motor is to have the overload capacity which the material used permits of being developed asynchronously, then part of its overload must be taken care of asynchronously. In the case of a motor such as outlined in Fig. 10, the asynchronous overload capacity is not practically available because the alternating synchronizing torque with unequal positive and negative maxima which can be exhibited by such polyphase motors at subsynchronous speeds causes their speed to oscillate rapidly under asynchronous overload conditions. It is clear that only the roughest kind of work will permit of such an irregular motive power and such motors are accordingly so rated that their full-load torque equals about half their maximum synchronous and about one-third of their maximum asynchronous torque. This condition is another reason why such motors are very costly.

In prior publications I have shown how this very undesirable condition can be remedied, thus greatly increasing the weight efficiency and therefore reducing the cost of such machines and need not again go into this question here, but the condition just discussed does show the vital importance of the configuration of the synchronizing torque on the weight efficiency of synchronous induction motors and clearly suggests that it does not suffice simply to study their compounding characteristic if a true picture of the relative merits of different types is desired.

I should further like to point out that Mr. Kostko's assertion in paragraph 14, column two, on page 448, is true enough in so far as synchronizing and synchronous operation is concerned, but not true in regard to starting for the reason that if two displaced windings are used instead of one only and both are connected to the same brush set, the two component windings form a polyphase secondary and make it unnecessary to add a winding on this member which will be active at subsynchronous and inactive at synchronous speed.

That Mr. Kostko's assertion in paragraph 15 is true, so far as it goes, was demonstrated in my paper "Another New Self-Excited Synchronous Induction Motor."[4] It clearly appears from that paper that Mr. Kostko's proposition is not true when it comes to synchronization. Furthermore, for certain angular displacements there is a great practical difference between the two types. The single-brush-set type is so touchy for certain angular displacements as to be useless in practise, whereas quite steady corresponding operation can be had with the two-set type.

In the last paragraph of Part two, Mr. Kostko states that the pulsations of current and torque during the synchronizing period are unavoidable whether the axis of "excitation" is fixed or variable. This is true for the type with fixed but not true for that with variable position of the axis of "excitation." I have shown how such pulsations can be avoided in separately, as well as in self-excited, synchronous motors.

The motor dealt with under "example 1" is my 1906 motor; not only is the synchronizing torque in this machine "very nearly alternating" but it is actually so and its frequency is double the slip frequency as pointed out in detail in my paper "A New Self-Excited Synchronous Induction Motor."[5]

As to the motor discussed under "example 2," I gave the complete circle diagram for this machine in my contribution to the discussion of the papers presented at the 1925 Midwinter Convention and have shown that at light loads the primary current of this motor lags by nearly 90 deg. behind the terminal voltage,

4. A. I. E. E. TRANSACTIONS, 1925, p. 64.

5. A. I. E. E. TRANSACTIONS, 1924, p. 660.

that at a certain load this lag diminishes abruptly and is converted into a lead, after which the lead diminishes steadily with a further increase in load and finally again becomes a lag. It is therefore putting it very mildly to say that the power factor at light loads is not as good as can be expected in synchronous motors.

My investigation of this whole subject has revealed quite a number of interesting conditions not apparent from the Kostko analysis. Thus when using a phase-displaced system of secondary windings connected to a phase-displaced system of brushes on the primary, or more broadly, connected to a plurality of voltages which are phase-displaced when alternating, it is possible to cause the motor to operate synchronously over a wide range of loads and asynchronously at loads below, as well as at loads above, said range. It is further possible to cause the axis of the synchronous unidirectional magnetization on the secondary to travel in the one or the other direction when the axis of the resultant magnetization of the motor moves in a given direction as the load of the motor increases or decreases. This leads to some very interesting combinations to which I may refer in greater detail at some later date. One way to secure the change in question is to reverse the connections between one of the secondary windings and its brushes in Fig. 13.

On the whole, I must admit that my study of the synchronous induction motor has been somewhat disappointing. I feel reasonably certain that I have reached rock bottom, having devised and carefully analyzed some seven or eight different types and worked out a fairly complete general theory which agrees with the results of tests, but I have not found any self-excited synchronous induction motor which I can recommend as a general-purpose motor. My view is that many synchronous motors on any one system of distribution are undesirable; because of their rigid speed characteristic these machines require *instantaneous* response from the generating set and sudden changes in load become so many hammer blows on the system. The fact that self-excited motors require slip-rings as well as a commutator and that both of these are in constant use are undeniably practical disadvantages, particularly in view of the fact that the commutator carries load as well as exciting currents. My conclusion is that synchronous induction machines are much better suited for use as synchronous condensers than as motors. They are much superior to synchronous condensers with defined polar projections now in general use for the reason that no line disturbance can put them out of commission which, so often happens with the pronounced-pole type. Synchronous induction machines used as condensers automatically resume synchronism under any and all conditions and when so used, can be located in sheltered positions where the slip-rings and the commutator will have a chance of operating satisfactorily.

I believe that conditions are much more favorable in the case of larger, separately excited synchronous induction machines and such can no doubt be advantageously used as motors in a number of cases. But when it comes to a general-purpose motor I think that the solution will be found in a compensated non-synchronous machine.

J. K. Kostko: The inversion is undoubtedly the most powerful method of graphical study of circuits yet devised; it originated in this country (F. Bedell and A. C. Crehore, "Resonance in Transformer Circuits," *Physical Review*, Vol. II, 1894-1895, p. 451), but it is much better known and more used abroad. In a circuit containing no independent e. m. f. the current is proportional to the applied voltage; if, for a certain phase angle between the current and the voltage, the value of the former is I' for the voltage E' and I for the voltage E, then the lengths of the vectors $O\,E'$ and $O\,I$ representing E' and I are given by the relation $O\,E' \times O\,I = E\,I'$. If I' and E remain constant, $O\,E'$ describes the locus 1 of the voltage at constant current, while $O\,I$ describes the locus, 2, of the current at constant voltage; the foregoing relation immediately suggests the possibility of passing from one locus to the other by inversion (for details see *Electrical World*, Vol. 75, p. 724, 1920). It is usually much easier to construct the locus 1 than the locus 2, because, if we start from a known current, we can draw a vector diagram with correct linear and angular relations between the vectors. In practise it is seldom necessary to go through the process of inversion; the construction usually can be simplified by making use of the fact that the angle between two curves remains unchanged by the inversion. Thus, in Fig. 3 the line $A'\,X'$ is the constant current locus of a circuit consisting of the primary resistance r and a variable inductance. Its inverse is the circle 3, of diameter $\dfrac{E}{r}$. $A'\,X'$ and this circle are the loci of points at which the power from the line is consumed entirely in the resistance r. Therefore, at points common to the circle 3, and to the locus of the motor no power is transferred from the primary to the secondary. The circle, 3, is zero-power or zero-torque circle. It is usually possible to determine the angle between the line $A'\,X'$ and the constant current locus 1; it is also the angle between the final locus 2 and the circle 3. Since the latter is fully determined by the primary resistance, r, this angular relation is an important element determining the locus 2. For instance, in the polyphase induction motors the locus 2 is normal to the circle 3. In a single-phase induction motor it is very nearly normal to it (the exact angle can be calculated from design or test data). In a polyphase synchronous reaction motor circles 2 and 3 are also normal. In a synchronous motor of the type of Fig. 10 of the paper the angle between 2 and 3 is equal to the angle of brush displacement. If two points A and B are inverse of A' and B' respectively, and the constant of inversion with respect to the origin O is c, then $A\,B = A'B'\,\dfrac{c}{O\,A' \times O\,B'}$. This relation can be used in order to represent an element such as an e. m. f. by means of a segment in the diagram. The e. m. fs. E, E_1 and E_2 of the paper are represented in this way; other examples can be found in various publications of the writer.

Thus, by the use of various geometrical properties of inverse figures we obtain a complete graphical representation of the performance with its elements shown directly in the diagram. It is hardly necessary to insist on the advantages of such a representation, especially in the study of a new motor type, where calculations should be undertaken only after a clear idea as to the useful range of the design constants has been obtained from the study of the diagram.

A diagram in which the zero-torque circle 3 is used is the exact one, taking into account the primary resistance. The transition to the simplified diagram is easy. If r decreases, the diameter of 3 increases; for $r = O$ the circle 3 coincides with the axis of abscissas. The feeling against the exact diagram is probably due to the fact that the old methods of taking the primary resistance into account are extremely complicated in comparison with the inversion method making use of the circle 3. An article in 1921, TRANSACTIONS [6] shows how the problem of constructing the exact locus of a polyphase induction motor from test data is simplified by the use of this method.

Mr. Weichsel's remark as to the meaning of the equivalence is to the point, but a careful reader is not likely to make a mistake in this respect because the writer took good care to point out in the paper (page 11, first column) that the torque in the diagram comprises the friction and the loss in the exciting circuits; the net torque is, therefore, somewhat affected by the choice of the exciting system, but not in any definite way. By suitable choice of mechanical features, such as the weight of copper, any one of the two equivalent motors can be made either better or worse than the other; even in the same motor a change

6. A. I. E. E. TRANSACTIONS, 1921.

of the field copper (leaving the size of conductor unchanged) will affect the net torque without in any way affecting the current locus. The physical change from one exciting system to an equivalent one is affected by the structural features of the motor. No general rules can be given, but each case must be studied individually.

It would be of interest to "go over" my deduction of the current locus using Prof. Karapetoff's method; but the current locus alone is of little value to an engineer. If a comparison of the methods is intended, it would be of greater interest to take up the problem of the graphical study of the motor from the beginning and try to find a solution as general and complete as that obtained in the paper; in my opinion this is the only sensible and fair way of comparing the two methods. The solution of Prof. Karapetoff's example by the inversion method is as follows: let $O\,I'$ be the vector of the current I'; the constant current locus is a line parallel to $O\,I'$ and at a distance $x\,I'$ from it; the current locus at constant voltage E is the inverse of this line, *i. e.*, a circle passing through the origin O, tangent to $O\,I'$ and of diameter $\dfrac{E\,I'}{x\,I'} = \dfrac{E}{x}$.

In his discussion Mr. Fynn continuously refers to the features of his separately excited motor as contradicting my conclusions which are derived for the self-excited motor. My statements as to the latter type are not directly attacked, but expressions such as "true as far as it goes," "true enough" etc., are likely to cause some doubt in the minds of the readers. It is well to point out that there is nothing ambiguous or vague in these statements if applied to the motor type for which they have been developed. For that matter, they apply to Mr. Fynn's motor as well, but, for the present, I shall confine myself to the type studied in my paper, because the experience with this type shows that, with such complicated subjects, convincing arguments and a common ground for a profitable discussion can be found only in a rigorous and impersonal mathematical study; and, while I have done myself some work on this subject, it would clearly be out of the question to take it up now.

Mr. Fynn's remark that the study of the exciting system is not sufficient, is correct; it is for this reason that I developed in the paper not the theory of the exciting system, as he says, but the complete theory of the self-excited motor. The synchronous (and synchronizing) performance is determined by the constants a, b, α, β, r, x, X; the first four determine the exciting system and are investigated in detail; the last four determine the main a-c. winding. They are used in all vector diagrams for the construction of the current locus, but no further study of these elements is undertaken because they occur in many well-known motor types and are quite familiar to the readers.

Mr. Fynn's remark as to the large size of the commutator gives an impression that it is due to the amount of ampere-turns on the secondary. Such is not the case: it should be charged mainly against the self-starting feature of the motor, which involves a very low exciting voltage, as explained in the paper. Mechanically, the commutator must fit the size of the motor, but its output is only a few per cent of that of the motor. If we could use 150-250 volts for excitation, instead of 15-25, the commutator would be as small as structurally possible, regardless of the number of ampere-turns. The danger of sparking and circulating currents in a coil of many turns short-circuited in a strong field also militates against the choice of a high exciting voltage.

In my opinion Mr. Fynn attaches an exaggerated importance to the asynchronous features of the motor as compared to the synchronous performance. His remark as to the voltage appearing at the brushes at starting is true, but he overlooks the order of magnitude of the phenomenon. At starting we may have some 500 induced volts in a field winding, and some 20 volts across the brushes, of the same frequency and added vectorially. An unbalance which may be caused by these 20 volts in the two phases of the secondary is really a small matter, the more so because the winding of a self-excited motor is usually made stronger than that of the induction motor in the same frame, so that there is a margin for a slight reduction of the asynchronous torque. If this unimportant action of the brushes be disregarded (or simply avoided by disconnecting the brushes at starting) then the windings of the secondary should be designed (1) as a part of the exciting system, and (2) as a secondary of an induction motor. Plan (1) is extensively studied in the paper; but, as Mr. Fynn puts it, only a scant attention is given to plan (2), because it was not intended to take up here matters pertaining to the induction-motor design, important as it is.

That synchronization is accomplished by the synchronous torque is admitted by Mr. Fynn, at least for the motors studied in the paper; therefore, all parts of the paper dealing with the synchronous performance, *i. e.*, practically the entire paper, can be considered as dealing with the synchronizing torque. It is rather strange to read Mr. Fynn's admonition that "it does not suffice simply to study their compounding characteristics...." etc.

With reference to Mr. Fynn's remark about a motor with two displaced windings connected to the same brush set: I never said that the equivalence of the synchronous and synchronizing operation also means the equivalence of the starting features.

All the motors shown and described in Mr. Fynn's paper "Another New Self-Excited Synchronous Induction Motor" are fixed-axis motors, equivalent to the type of Fig. 10 of my paper, with respect to synchronizing as well as the synchronous operation. If the constants of a motor are changed, for instance by reconnecting field windings, as described in Mr. Fynn's paper, we have not one, but several distinct motors, and to each of them the principle of equivalence to the motor of Fig. 10 applies in full.

In the example 1, Fig. 6, the locus 2, Fig. 7, is normal to the circle of zero-torque 3, of radius $\dfrac{E}{2\,r}$; the torque at a point of the locus is measured by the distance of this point from the chord $D\,C$ (not shown). Due to the curvature of the circle 3 the positive maximum of the torque is somewhat less than the negative; hence the expression "nearly" alternating. Only if r is neglected, the circle 3 coincides with the axis of abscissas and the torque becomes truly alternating.

The variation of the lag of the current in example 2 can be followed in Fig. 9. In practise the motor would not be as bad as it appears, because, on account of losses, the no-load point will be nearer to the origin than D-C-K, and the transition to the lead will occur at a very light load.

The interesting conditions mentioned by Mr. Fynn can be found in the paper; the one which is really important is given quite a prominent place in the chapter on synchronizing. I refer to the motor which has minimum as well as a maximum torque at synchronism. The analytical conditions are given on the bottom of page 68. The current locus of such a motor has no common points with the zero-torque circle 3. If the constants are such that its radius is small or vanishes, as in examples 3 and 5, the pulsations of the torque and of the current are also small or vanish. The travel of various fluxes can readily be followed on the constant-current locus 1.

Notes on the Development of a New Type of Hornless Loud Speaker

BY CHESTER W. RICE[1]
Associate, A. I. E. E.

and

EDWARD W. KELLOGG[1]
Associate, A. I. E. E.

Synopsis.—*The paper describes a series of tests directed to the evolution of a loud speaker, free from resonance. Various types of sound source were tried. For the most part horns were avoided. Diaphragms, when employed, were either so light and stiff that their natural resonance was above the essential frequency range, or so flexible that their resonance was below the lowest important acoustic frequency. Best results were obtained with the latter type, and it is shown on theoretical grounds that a small diaphragm, the motion of which is controlled by inertia only, and located in an opening in a large flat wall, will give an output sound pressure proportional to the actuating force, independent of frequency. It should be possible to make an ideal sound reproducer on this principle. A practical loud speaker which approximately fulfills the above conditions has now been evolved. It consists of a flexibly-supported paper cone actuated by a coil in a magnetic field and provided with a baffle. As compared with ordinary loud speakers, this instrument radiates much more of the low tones and more of the very high frequencies which makes for clearer articulation.*

The extension of the range of response of the loud speaker to higher and lower frequencies, makes defects in the remainder of the system more noticeable, particularly roughness and blasting due to overworked amplifiers. It is, therefore, important that the amplifier used with the new loud speaker be designed to have ample capacity.

* * * * *

Initial Tests With Non-resonant Types

SEVERAL years ago tests were undertaken in the Research Laboratory of the General Electric Company, to ascertain whether or not it would be possible, by sacrificing sensitivity, if necessary, to produce a loud speaker free from the most objectionable of the distortion which characterizes loud speakers in general.[2]

Amplifiers and amplifier tubes had been developed to a point where there was no difficulty in obtaining voice currents of any required magnitude, practically free from distortion. Aperiodic microphones and condenser transmitters were in use in broadcasting station studios.[3] The availability of these comparatively new tools and the fact that in the matter of distortion the loud speaker was the weakest link in the chain of apparatus involved in transmission and reproduction of speech and music, appeared to justify a renewed attack on the problem. Even though it should be found that a large and expensive amplifying system was necessary, owing to sacrifice of sensitivity, it was felt that there would be many applications of a loud speaker of high quality. Happily in the later designs it was found that the anticipated sacrifice of sensitivity was not necessary.

The worst distortion in the ordinary loud speaker is due to horn-resonance and diaphragm-resonance. To eliminate the horn-resonance, it was proposed to abandon the horn. To avoid the diaphragm-resonance we might, for example, eliminate the diaphragm, by using a "talking arc;" or we might use diaphragms in which the resonance frequencies were above or below the working range.

One of the first undertakings was to build a resistance-capacity-coupled amplifier in which the final stage was a tube having an oscillator rating of 250-watts output. With a 1500-volt plate supply, this amplifier could deliver about 70 milliamperes of sine wave current at 200 volts, with practically no wave-form distortion, and it was possible to test some very insensitive devices. Among the things tried were:

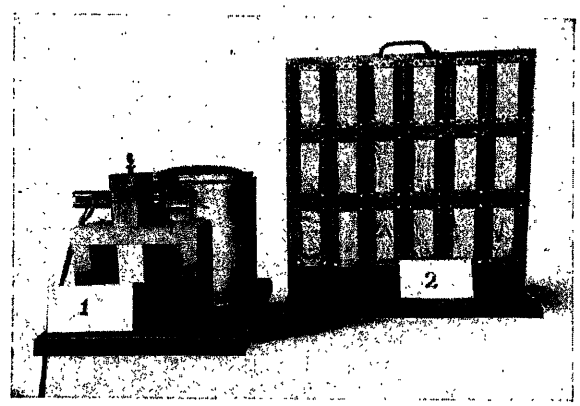

Fig. 1—Siren and Gold-Leaf Thermo Phone

1. A gold leaf thermophone with an area of about one-half square foot, shown in Fig. 1. The voice current superimposed on a direct current causes temperature fluctuations in the gold leaf. The adjacent air expands and contracts and produces sound waves.

2. Various designs of electrostatic loud speakers with large diaphragms: In these the diaphragm is a thin sheet of conducting material, actuated by the electrostatic attraction between it and an electrode placed close to it. Fig. 2 shows a model in which the electrodes were of felt, painted with graphite and separated by two sheets of varnished cambric.

3. A siren, shown in Fig. 1: Instead of moving a diaphragm to set up air waves, the voice currents are

2. A general discussion in the form of a symposium on the loud speaker problem is published in *Proceedings* of the Physical Society of London, Vol. 36, Parts 2 and 3, Feb. & Mar., 1924.

3. The construction and calibration of condenser transmitters are described by F. C. Wente in the *Physical Review*, July, 1917, and May, 1922. The theory of air damping as applied to the condenser transmitter is discussed by I. B. Crandall, *Phys. Rev.*, June, 1918.

Presented at the Spring Convention of the A. I. E. E., St. Louis, April 13-17, 1925.

made to operate a delicate throttle-valve which controlled the amount of air issuing from a jet. This principle is employed in the "Creed Stentorphone" evolved by Gaydon and manufactured by Creed of Croyden, England.

4. An agate cylinder machine, depending on varying the frictional force between a rotating drum of polished agate and a piece of metal attached to the diaphragm: This principle was first applied by Edison[4] using chalk cylinders, and later by Johnson and Rahbeck who used agate[5]. A modified form of frictional machine, called the "Frenophone," has recently appeared[6].

5. A talking arc.

6. Multiple unit area devices, made up of a large number of similar magnetic telephones, as shown in Fig. 3.

7. Combinations of several horn instruments, having different characteristics, so that each supplements the others. Fig. 4 shows a photograph of this arrangement.

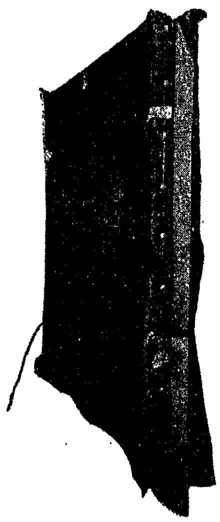

Fig. 2—Electrostatic Loud Speaker

8. The induction phone developed by Dr. C. W. Hewlett[7].

This is illustrated in Fig. 5. The diaphragm is a thin sheet of aluminum loosely supported between two pancake-type coils, wound with suitable venting spaces. Direct current is passed through the coils in such a direction as to give a radial field in the region of the diaphragm, and the voice current circuit is connected so that both coils act as primaries to induce currents in the diaphragm. The resulting force can be made to be almost uniform over the whole diaphragm.

9. Various designs of small diaphragm moving coil instruments.

Fig. 6 shows a number of instruments set up for comparison.

Of the possibilities, some were dropped after one or two experiments, while the more promising types were the subjects of considerable development. The electrostatic phone is capable of giving very fine quality reproduction, but owing to the low breakdown strength of air, only a small force can be applied to the diaphragm and a very large area is required to give a reasonable volume of sound.

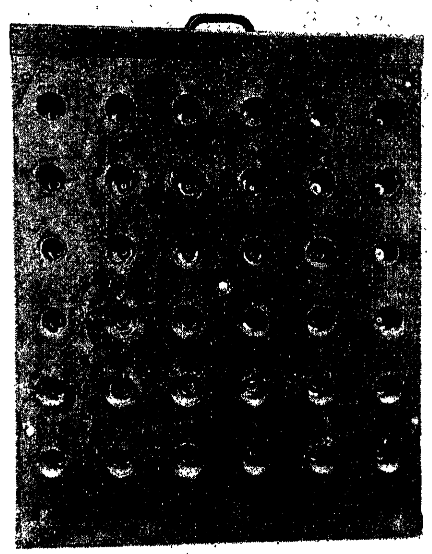

Fig. 3—Multiple-Unit Loud Speaker

Fig. 4—Triple-Horn Loud Speaker

Characteristics of Large Area Diaphragms

One of the first tests was an attempt to obtain the equivalent of a large area diaphragm by placing a number of small units close together. The panel is shown in Fig. 3. A single telephone receiver without a horn, gives entirely inadequate radiation of the low tones. The horn helps to bring out the low tones but introduces resonance. Placing a number of telephones in close proximity with their diaphragms moving in

phase also improves the radiation of lower tones without creating any resonance. The multiple unit instrument was a considerable improvement over a single unit with horn. But as the device was first built, the diaphragms themselves were resonant at about 1000 cycles. The next step was the substitution of telephones with diaphragms of steel, 0.0015 in. thick, stretched so tightly that their natural frequency was above 6000 cycles, or practically out of the voice range. When used as head-phones, these receivers gave very fine quality but as a loud speaker the multiple unit device gave undue prominence to the high frequency components of speech. Voices sounded thin and hard. Only after electrical compensation had been introduced by means of the circuit shown in Fig. 7A did the multiple unit loud speaker give a natural reproduction of voice. In other words, while the effect of the large area diaphragm as compared with a small diaphragm was in the right direction in helping the radiation of low tones, as had been anticipated by Rice in proposing this experiment, there was still an accentuation of the high frequencies when the multiple unit loud speaker was used without the compensating circuit.

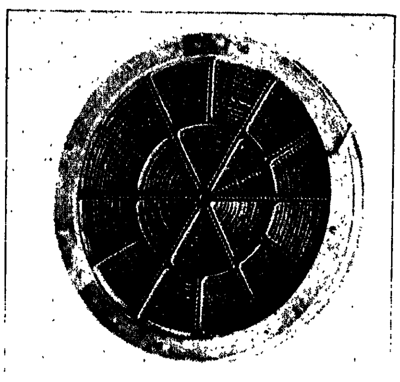

Fig. 5—Hewlett Induction Type Loud Speaker

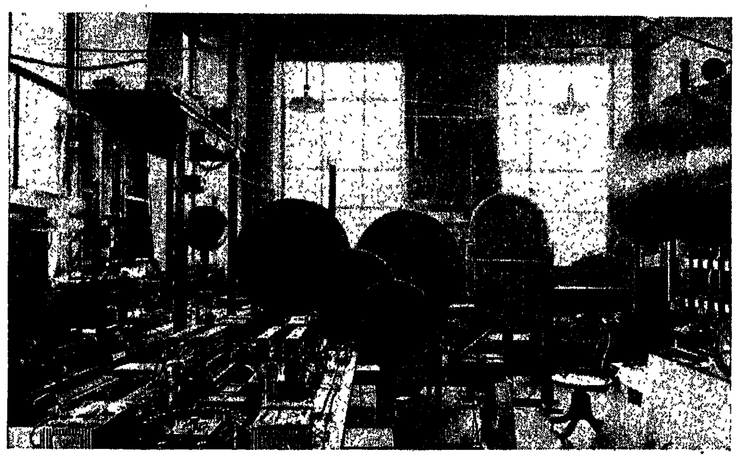

Fig. 6—Loud Speakers Assembled for Comparative Tests

Let us consider from a theoretical standpoint the difference between what makes a satisfactory headphone and what is required for a loud speaker. The ideal sound pick-up, or transmitter, would develop a voltage proportional to the pressure which the sound wave exerts on the diaphragm, whatever the frequency or wave shape. There are in use in broadcasting studios, special microphones and electrostatic transmitters which approximate this ideal characteristic very closely over a wide range of intensity and over a frequency range of from 30 to over 6000 cycles. Amplifiers can be constructed having almost any required amplification ratio, the output currents of which reproduce the input voltage wave with virtually no distortion. The perfect receiver, or loud speaker, must take these amplified voice currents and translate them into air pressures, exactly reversing the function of the pickup or transmitter. The transmitter being equally efficient for all frequencies in the working range, the telephone receiver or loud speaker must convert input current into sound pressure at the listener's ear with equal efficiency at all frequencies. Throughout the remainder of this paper, when a device is spoken of as giving sound radiation independent of frequency, it is to be understood that what is meant is that if a series of pure tones of equal power but varying pitch are produced in a damped room in front of a perfect transmitter with distortionless amplifier, and the output of the amplifier is fed to the loud speaker, the latter will radiate the series of tones with equal power.

In the case of the receiver held to the ear, there is a small cavity between the receiver diaphragm and the ear drum, and, assuming that there is no leakage of air, the pressure which the ear drum feels is proportional to the change in volume of the cavity caused by the deflections of the diaphragm. A diaphragm with natural frequency above the voice range, or, in other words, one in which elasticity and not inertia or damping controls the vibrations, gives a deflection proportional to the magnetic force, or practically proportional to the current through the coils, independent of frequency. Therefore, such a diaphragm gives a sound pressure in the ear proportional to the current supplied to the receiver, provided the receiver is held tight against the ear, and this characteristic is exactly what is wanted for a head telephone. What happens when such an elastic control diaphragm is operated in unconfined air? The simplest case is that of a large area diaphragm radiating plane waves. Here the pressure in the sound wave is proportional not to the deflection of the diaphragm, but to the maximum velocity which it attains, which, for pure tones or sine waves, is proportional to the maximum deflection multiplied by the frequency. Therefore, if we succeeded in obtaining the equivalent of a large area diaphragm by grouping together a number of telephones with tightly stretched

diaphragms, the device would still radiate the high frequencies in undue proportion. With the capacity shunt in the amplifier, as shown in Fig. 7A, this discrepancy is corrected.

Test of Small Inertia Diaphragm

At this point, Kellogg suggested using a coil-driven diaphragm with practically no elastic restoring force, so that at low frequencies very large amplitudes could be attained. In an ordinary telephone the stiffness of the

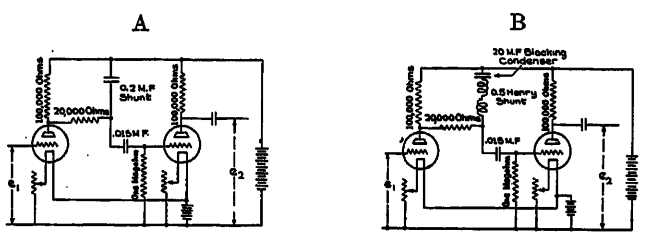

Fig. 7—Compensating Circuits

Type A gives $e_2 = e_1 \times \frac{1}{f} \times$ (Constant)

Type B gives $e_2 = e_1 \times f \times$ (Constant)

f = frequency

diaphragm is depended upon to prevent its sticking to the magnet poles and is, therefore, not suitable where an entire lack of restoring force is desired. On the other hand, the moving coil drive is eminently suited to this purpose, since no stabilizing force is required. Fig. 8 shows the construction of the first model built to try out the free diaphragm principle. Not only did this device produce more of the low tones than any previously tried, but it held up remarkably well for the very high notes, not showing any marked resonance. It did, however, have a rough quality in voice reproduction, which was corrected in the later designs.

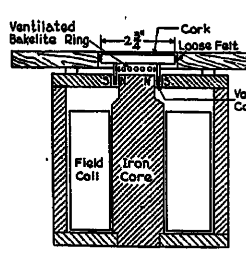

Fig. 8—First Model of Inertia Controlled Diaphragm Loud Speaker

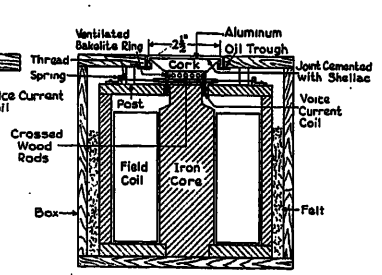

Fig. 9—Improved Design of Inertia Diaphragm, Loud Speaker

Trial of Triple Horn Loud Speaker

The multiple unit horn device, already mentioned and shown in Fig. 4, was first suggested and worked on in our group by Kellogg. It was an attractive possibility, especially in view of the sensitivity obtainable with horns, and the ease with which the balance between high and low tones could be adjusted. For the lower end of the scale, a Baldwin phone with a large exponential horn seemed to be the best combination of available apparatus, while some higher pitched phones with smaller horns took care of the middle and upper ranges. Experiments with this arrangement showed clearly that the three instruments supplemented each other, the combination sounding much better than any one alone, and the consciousness on the part of the listener of the presence of a horn was much less pronounced than in the case of a single horn device. The Baldwin phone would not give sufficiently low frequency output and after a number of attempts to build a suitably low-pitched phone, the conclusion was reached that the most satisfactory low-pitched phone would be one designed along the lines of the moving coil instrument already described. However, when this construction was adopted, no supplementary high pitched instruments were needed.

Improved Designs of Inertia Diaphragm Instruments

Fig. 9 shows the manner of construction of a moving coil instrument designed by Kellogg with a view to avoiding two of the possible causes of the rough quality which had characterized the machine shown in Fig. 8; namely, friction around the edges, and failure of the diaphragm to act as a true piston, or remain flat during vibrations. A maximum of rigidity, combined with light weight, was sought in the diaphragm design, an oil seal was provided around the edge, and the support consisted of four threads at right angles, held in slight tension, so that motion was very free in the axial direction, but practically no sidewise movements could take place. Vibration amplitudes as great as 1/32 inch were frequently observed on this diaphragm. The rough quality was practically eliminated in the new design. Provision was made for boxing in the instrument, and an interesting experience in this connection was that of placing the box over the back, which had the same general effect on sound quality as applying a short horn to the front of the diaphragm. Both helped to bring out the low tones and gave rise to some resonant effects. Bringing out the low tones was due principally to preventing circulation of air between the front and back of the diaphragm. The resonance was in the horn in one case, and in the box in the other. A peculiarity of devices employing very flexibly supported diaphragms is that resonant air chambers behind the diaphragm do about as much harm as resonant cavities in front of the diaphragm, the diaphragm usually taking part in the resonance. Attempts to damp the interior of the box with felt were not entirely successful.

The Use of a Baffle

A happy solution of the problem of preventing circulation was obtained by employing a flat baffle-board, at the suggestion of Rice, who was the first of the group to recognize the importance of the circulation factor in preventing the radiation of low tones. With the flat baffle, no air resonance occurs and both sides of the diaphragm give useful radiation, the total power radiated for a given diaphragm amplitude being nearly four

times as great as that radiated when the back of the diaphragm is enclosed.

Definition of Term "Inertia Controlled"

Subsequent experiments were devoted largely to the development of the free diaphragm type of sound reproducer, in which, throughout the essential frequency range, the electrical driving force is expended in accelerating the mass of the diaphragm. We shall speak of such diaphragms as "inertia controlled." A certain amount of elastic restoring force is unavoidable in the supporting system, and consequently the diaphragm must have a natural frequency. But if the natural frequency is below the important acoustic frequency range, the diaphragm may properly be described as inertia controlled. We have obtained best results with natural frequencies below about 70 cycles per second. Higher natural frequencies can be tolerated if the vibrations are well damped.

Theory for Large and Small Diaphragms

Diaphrams may be classified according to their mechanical properties as:

1. Inertia controlled
2. Damped or resistance controlled
3. Elastic controlled
4. Resonant
5. Diaphragms having wave action or phase differences between the different parts of the surface

Of these, the first three have simple relations between actuating force, frequency, and amplitude of motion, and would, therefore, appear to offer most promise of affcrding a sound source of constant efficiency. The resistance-controlled diaphragm, while difficult to obtain, is included in the list as representing a possible type and is of theoretical interest. It will be assumed in discussing the first three types of diaphragm that all parts of the surface move together, which means that either the diaphragm is small and rigid, or else the actuating force is applied to all parts. The wave action diaphragm is best represented by the large, shallow, paper cones which have been employed with considerable success. Familiar examples of this type are found in the Pathé and new Western Electric 540 AW loud speakers. Some other experiments along these lines were recently reported by Sutton.[8] Here the actuating force is applied at the center, or vertex, and flexural waves radiate toward the outer edge. If there is considerable energy loss so that these waves are attenuated rapidly, the net result is that at high frequencies a small area of the diaphragm near the vertex radiates sound, while at lower frequencies a larger area works. If the attenuation of the flexural waves is small, standing-wave conditions exist and there is a series of frequencies at which resonance occurs.

The relation between amplitude, frequency, and driving force, for diaphragms with pure elastic, resistance, or inertia control is as follows. If the diaphragm vibrates with simple harmonic motion at a frequency f cycles per second, and with an amplitude X centimeters, the deflection may be expressed by

$$x = X \sin 2 \pi f t = X \sin \omega t, \text{ centimeters} \qquad (1)$$

the velocity is

$$u = \frac{d x}{d t} = \omega X \cos \omega t\text{—centimeters per second} \qquad (2)$$

and the acceleration is

$$\alpha = \frac{d u}{d t} = \frac{d^2 x}{d t^2} = - \omega^2 X \sin \omega t \qquad (3)$$

centimeters per second, per second.

With elastic control, the deflection is proportional to the applied force; or to give the deflection shown in (1), we must apply a force

$$F \sin \omega t = K x = K X \sin \omega t \qquad (4)$$

in which F = maximum force in dynes, and K the diaphragm stiffness in dynes per centimeter.

From (4)

$$X = \frac{F}{K} \qquad (5)$$

or the amplitude is proportional to the maximum of the alternating force, independent of frequency.

With resistance control of motion the velocity is proportional to the instantaneous applied force, or to give the motion expressed in equation (2) we must apply a force

$$F \cos \omega t = R u = R \omega X \cos \omega t \qquad (6)$$

in which R is the resistance to motion in dynes per unit velocity.

From (6)

$$X = \frac{F}{\omega R} = \frac{F}{2 \pi f R} \qquad (7)$$

or the amplitude is proportional to the applied force divided by the frequency.

In the case of inertia control, the applied force is equal to the mass M times the acceleration. Hence to obtain the motion expressed in equations (1), (2) and (3) we must apply a force

$$- F \sin \omega t = M \alpha = - M \omega^2 X \sin \omega t \qquad (8)$$

or

$$X = \frac{F}{\omega^2 M} = \frac{F}{4 \pi^2 f^2 M} \qquad (9)$$

In this case the amplitude for a given driving force varies inversely as the square of the frequency.

There are two classes of diaphragms the sound radiation of which are simple functions of amplitude, frequency and diaphragm size.

a. Diaphragms large enough in comparison with the longest waves to give plane-wave radiation for all essential frequencies.

b. Diaphragms small enough in comparison with the shortest waves, to be treated as virtually point

8. *Wireless World and Radio Review*, Nov. 19, 1924.

sources for all essential frequencies, circulation of air between the front and back of the diaphragm being prevented by either a baffle or by enclosing the space on one side of the diaphragm.

The power in ergs per second[9], radiated from one side of the large diaphragm is

$$P = \frac{1}{2} \rho v S \omega^2 X^2 \tag{10}$$

in which

ρ = mean density of air in grams per c. c.

v = velocity of sound in air in cms. per sec.

S = area of diaphragm in sq. cm.

$\omega = 2 \pi f$

X = amplitude of diaphragm motion, assumed to be the same over the entire surface.

In the case of the small diaphragm, the power radiated from one side is[10]

$$P = \rho \frac{S^2 \omega^4 X^2}{2 \beta v} \tag{11}$$

in which β is the solid angle into which the radiation takes place, 4π for complete spherical waves, and 2π for hemispherical waves, or in other words, if a flat baffle is used. With a flat baffle, the radiation from both sides of the diaphragm is

$$P' = \rho \frac{S^2 \omega^4 X^2}{2 \pi v} \tag{12}$$

For these two types of diaphragm we can see from equations (**10**) and (**12**) what would have to be the relation between amplitude and frequency in order to have the sound output the same at all frequencies.

For the large diaphragm, equation (**10**) shows that P becomes independent of ω or of f if X varies as $\frac{1}{f}$, and equation (**7**) shows that applying a force, F, the same at all frequencies to a resistance controlled diaphragm, gives an amplitude which varies as $\frac{1}{f}$

If we have the means for making the force F a direct or inverse function of frequency, a large diaphragm with inertia or elastic control can be made to give the same output at low and high frequencies. For example, in the polarized electrostatic sound source, the force variation is proportional to the alternating voltage between electrodes. If the charging current supplied to the electrodes is fed through a resistance high compared with the capacity reactance of the device, then a constant voltage applied to the resistance and capacity in series will result in a voltage across the capacity inversely proportional to the frequency, and such a voltage will give constant sound radiation from a large area elastic control diaphragm. In like manner in the case of magnetically actuated diaphragms, in which the force is in general proportional to the current, if the inductive reactance of the windings is high compared with their resistance plus the plate resistance of the amplifier tube, the current through the windings will be proportional to the voltage applied to the grid of the tube, divided by the frequency. This will give the desired relation between force and frequency, for constant sound radiation from a large area elastically controlled diaphragm.

If we extend the consideration to the use of pick-up devices or transmitters having direct or inverse frequency characteristics, or include compensating circuits of the type shown in Fig. 7, there are many combinations which give a constant over-all efficiency. Of such combinations, those which throughout the system preserve the normal balance between high and low frequencies, have the advantage that a satisfactory ratio of useful to stray noises is more readily maintained, and the required amplifier capacity is less. We shall, therefore, assume that the goal is to produce a sound source which, when operated by the output of an amplifier tube, will give a sound wave pressure proportional to the voltage applied to the grid of the tube, the proportionality factor being independent of frequency. Such a sound source is the large diaphragm electrostatic unit, with resistance controlled diaphragm motion, and with capacity reactance high compared with the tube plate resistance. Another example is the large diaphragm electrostatic unit with elastic control of the diaphragm and with capacity reactance low compared with the tube plate resistance throughout the essential frequency range. Electromagnetically driven large area diaphragms, with elastic control of motion and inductive control of curent, or with resistance control of motion and resistance control of current, are also possibilities.

Turning to the case of the small diaphragm working with a baffle, equation (**12**) shows that for constant sound output $X^2 \omega^4$ must be constant, or the amplitude must vary inversely as the square of the frequency, and equation (**9**) shows that a constant driving force and inertia controlled motion gives just this required relation between frequency and amplitude. This relationship was pointed out by Kellogg who took especial interest in this type of device and designed all of the models employing small rigid diaphragms. The driving force independent of frequency is available in the form of a coil in a constant magnetic field and with enough resistance in the circuit compared with the reactance to make the current independent of frequency. There are obviously other combinations using small diaphragms, such as resistance control of motion and inductive control of current, which would give constant output, but the inertia controlled small diaphragm with resistance controlled current has all the advantages.

10. Rayleigh, Theory of Sound. Vol. II. Page 113.

Effect of Intermediate Diaphragm Size

Formulas for the sound radiation from a flat circular diaphragm situated in a flat wall or baffle of infinite extent have been developed by Rayleigh[11], all parts of the diaphragm being assumed to have the same motion. Fig. 10 shows the relative output at different frequencies of an inertia controlled diaphragm six inches in diameter, actuated by a vibratory force of variable frequency but constant magnitude. For wave lengths greater than about 1.5 feet, (46 cm.), the diaphragm may be treated as a small source, and the sound output is constant. At frequencies for which the wave length is less than the diameter of the diaphragm, the radiation practically follows the law expressed in equation (4) for large area diaphragms. Within this part of the frequency range inertia control gives too rapid a drop in amplitude as the frequency is increased, with the result that the power radiated is less at high frequency. There is, however, a compensating effect. At the same

Mass = 10 grams

time that the total radiation becomes less, the directivity increases, and the listener in front of the diaphragm receives a larger share of the total power radiated. The result is that with a diaphragm of this size, the listener, if stationed in front of the diaphragm, loses very little of the high frequency components. Even with larger diaphragms, very pleasing results have been obtained with inertia-controlled diaphragms, notably the Hewlett induction phone in which a 24-in. diaphragm has been employed with good effect. In this the tendency to give excessive radiation of low tones is reduced by the fact that no baffle is employed, and there is a diminution in diaphragm currents at low frequency due to imperfect transformer action. The directive properties of this large area diaphragm are very striking.

In order to radiate in accordance with equation (12) or as a small source, up to 5000 cycles, a diaphragm would have to be less than about 1 ½ inches in diameter, but since experiments indicate that much larger inertia-controlled diaphragms give good results, there is no justification for limiting the size to the value mentioned, particularly as sensitivity is gained from the adoption of larger sizes.

Requirements for True Piston Action

Since the inertia-controlled small diaphragm appeared, from both theoretical and experimental evidence, to offer the greatest promise of a practical solution of the loud speaker problem, subsequent experiments were devoted to finding the best form of device embodying this principle. The first models left much to be desired in the way of sensitivity and considerable room for improvement in quality. The condition that the diaphragm must move as a unit meant two alternatives; either the diaphragm must be very rigid for its weight and must be quite small, or the driving force must be applied uniformly over the entire diaphragm surface.

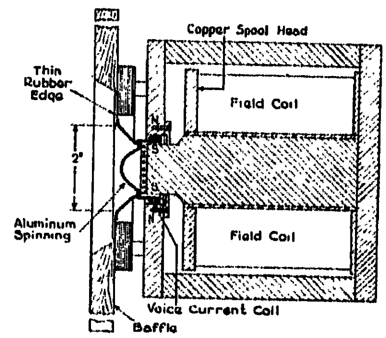

Fig. 11—Baffle-Type Rigid Diaphragm, Loud Speaker

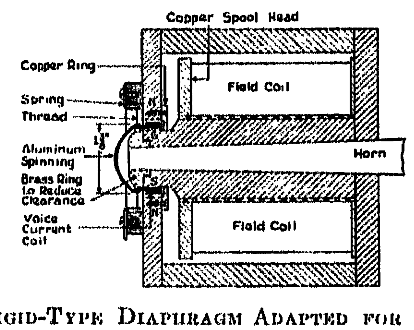

Fig. 12—Rigid-Type Diaphragm Adapted for Use with a Horn

Models with Rigid Diaphragms

Two of the most satisfactory forms of small rigid diaphragms are shown in Figs. 11 and 12. Of available materials, aluminum has as high a ratio of elastic modulus to density as any, combined with light weight. The oil seal of Fig. 4 was considered impractical for any but a laboratory model, and in place of it, either small clearance was depended upon to prevent leakage or a thin rubber membrane was used to bridge the gap between moving and stationary parts. Fig. 12 was de-

11. Theory of Sound. Vol. II. Pages 162-165.

signed for use with a horn[12]. The horn was four and one-half feet long with an exponential expansion from ½ inch to 30 inches diameter. Fig. 13 shows the same horn with the earlier model instrument illustrated in Fig. 9. Such a horn carries down to about 200 cycles satisfactorily and has no very strong resonances[13].

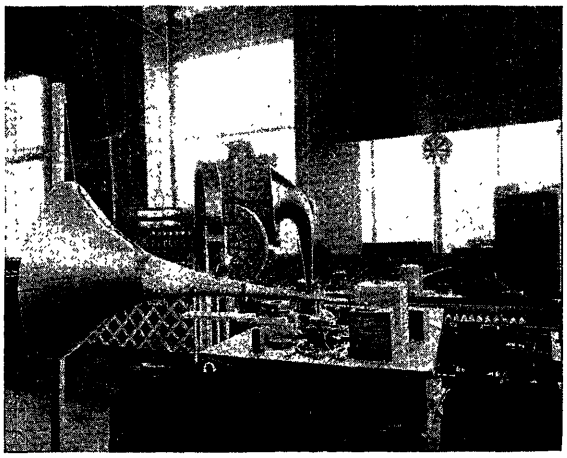

FIG. 13—RIGID-TYPE INERTIA-CONTROLLED DIAPHRAGM WITH EXPONENTIAL HORN

Resistance and not inertia control is the ideal diaphragm characteristic for an instrument employing a slow expanding exponential horn, and that pleasing results should be obtained with the free diaphragm must be ascribed to the fact that the diaphragm never attained the amplitudes at low frequencies corresponding to true inertia control, because of damping by the air column in the horn and strong electromagnetic damping characteristic of the moving coil drive. A

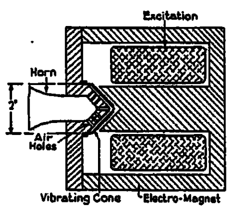

FIG. 14—COMMERCIAL GAUMONT LOUD SPEAKER

horn of adequate dimensions, however, is exceedingly bulky, and better results were subsequently obtained with flat baffles.

MODELS WITH DISTRIBUTED DRIVING FORCE

Of the devices in which the actuating force can be applied over the whole diaphragm area, thus making rigidity unnecessary, the electrostatic phone and the Hewlett induction phone have already been mentioned. In the latter, the air-gap length is the radius of the diaphragm, and a very strong magnetic field is practically out of the question. As a result the efficiency is low and the fine quality of which the instrument is capable is secured at the cost of a high power amplifier and considerable direct-current power for excitation. It is, therefore, not a household device, its field of application being rather in auditoriums.

Rice urged the probable value for the case of the small diaphragm instruments, of distributing the driving

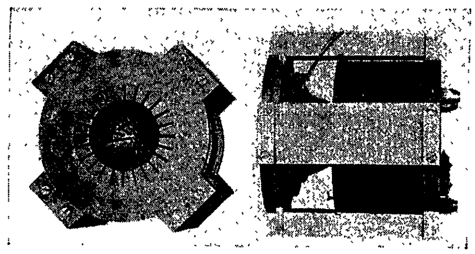

FIG. 15—GAUMONT TYPE LOUD SPEAKER ASSEMBLED

force over the entire diaphragm area, and believed that this could be done without sacrifice of field flux density. At this juncture a letter was received from Dr. W. R. Whitney describing a loud speaker which had been shown him in France by its inventor, Mr. Gaumont, and which fulfilled this condition.

Fig. 14 shows the construction of the commercial loud-speaker built by the Société des Etablissements Gaumont. The diaphragm is a cone of thin silk, to

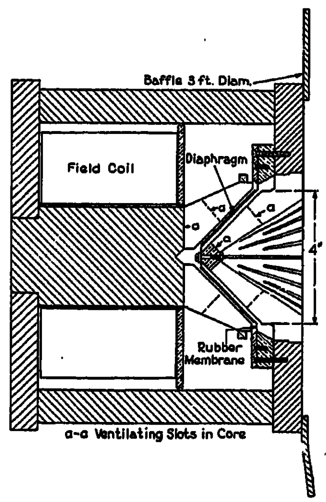

FIG. 16—MODIFIED DESIGN OF GAUMONT TYPE LOUD SPEAKER

which is cemented a single layer spiral of fine aluminum wire. An extremely light diaphragm is thus possible, making for sensitiveness and freedom from resonance. The reaction of the voice currents in the aluminum coil with the radial component of the magnetic field gives the useful driving force.

Figs. 15 and 16 show one of the Gaumont type loud speakers designed by Rice, for use with a baffle. The

12. A description is given in the *Wireless World* and *Radio Review* of Dec. 17, 1924, by Capt. H. T. Round, of a loud speaker resembling that shown in Fig. 12 in some respects.

13. "Function and Design of Horns for Loud Speakers" by C. R. Hanna and J. Slepian, JOUR. A. I. E. E., March, 1924. "The Performance and Theory of Loud Speaker Horns" by A. N. Goldsmith and J. P. Minton, *Proc.* I. R. E., Aug. 1924.

diaphragm support used in the commercial instrument shown in Fig. 14 does not afford sufficient flexibility. The substitution of a flat edge of thin rubber, as illustrated in Fig. 15, gave the necessary flexibility without which adequate radiation of low tones from a small diaphragm had been found impossible. Experiments also indicated that a considerably heavier diaphragm

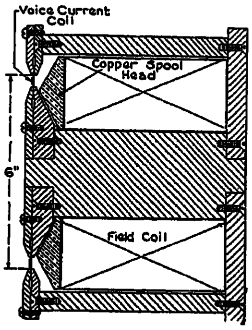

FIG. 17—CONSTRUCTION OF ANNULAR TYPE LOUD SPEAKER

than that employed in the commercial machine was required for good balance between high and low frequencies. The diaphragm which worked best was four inches in diameter and weighed 11 grams. It consisted of a single layer of copper wire embedded in rubber,

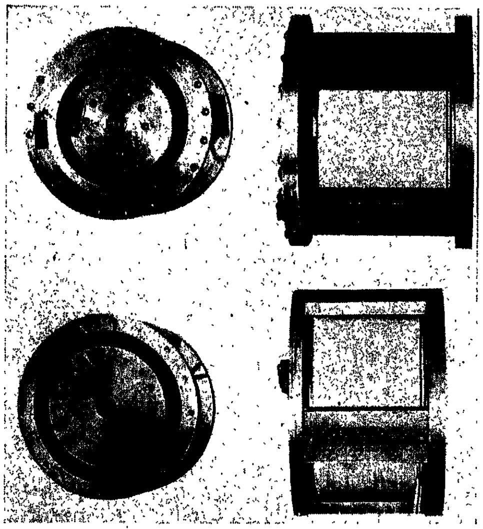

FIG. 18—VIEWS OF TWO ANNULAR TYPE INSTRUMENTS

which gave a soft, non-resonant structure. Adequate venting proved to be of utmost importance in this design in order that air reactions on the diaphragm might not affect its motion adversely and in order to let out the sound without muffling. A baffle 3 ft. in diameter was employed.

An annular diaphragm type of loud speaker having uniformly distributed driving force is shown in Figs.17, 18 and 19. This instrument which was designed by Rice presents no venting difficulties and gives the possibility of considerable diaphragm area. A thin rubber membrane spans the air-gap, and a single layer coil cemented to the membrane provides the driving force. The construction difficulties are much less and the total weight less than in the case of the conical diaphragm type. In the annular design, if the air-gap is kept short enough to give reasonable magnetic field strength; it becomes difficult to make the natural frequency of the diaphragm low enough to fall below the important acoustic range. Electrical correction by

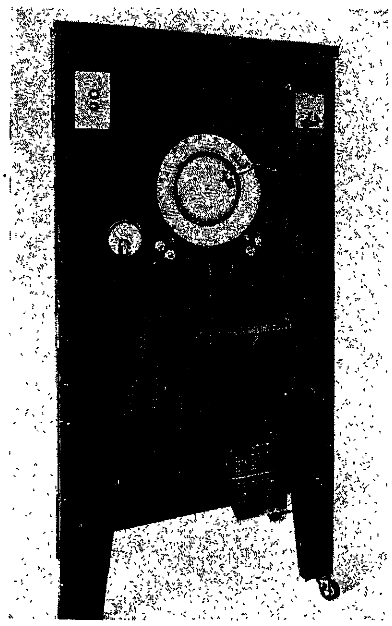

FIG. 19—ANNULAR TYPE LOUD SPEAKER ASSEMBLED IN CABINET WITH AMPLIFIER

means of a series-tuned shunt across the output of the amplifier eliminated the most objectionable results of the diaphragm resonance, and in this form the device was very satisfactory. A somewhat similar instrument used as a transmitter has recently been described by Round[14].

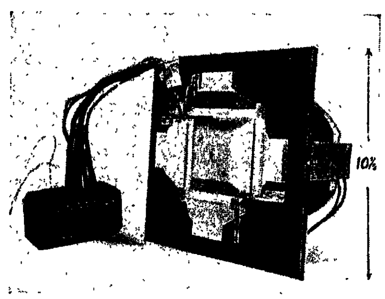

FIG. 20—ALUMINUM FOIL DIAPHRAGM LOUD SPEAKER WITH TRANSFORMER

Efforts to gain sensitivity by the use of extremely light diaphragms have always, in our experience, led to disappointment. The expected gain in sensitivity was not realized, and in most cases the light diaphragm devices were very high pitched; or in other words,

14. *Wireless World and Radio Review*, Nov. 26, 1924.

radiated too much high frequency sound compared with the low. This, for example, was the characteristic of the design shown in Fig. 20 in which a strip of aluminum foil[15] a half mil thick, by a half inch wide, carrying the voice current and vibrating in a gap between magnet poles served as diaphragm. Careful transformer design, very flexible mounting of the foil, and an adequate

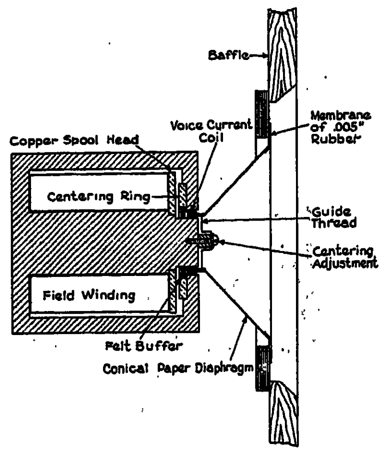

FIG. 21—CONSTRUCTION OF FREE EDGED, COIL-DRIVEN, CONICAL DIAPHRAGM LOUD SPEAKER

baffle made it appear that the result was not due to overlooking any of these factors. We must conclude either that unavoidable leakage was responsible for the failure to radiate the lower tones in due proportion,

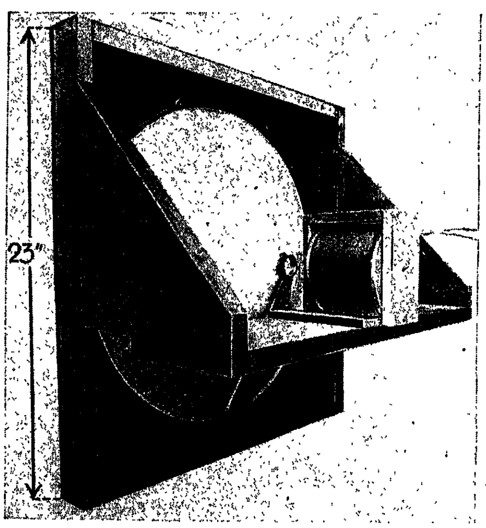

FIG. 22—LARGE FREE-EDGED PAPER CONE WITH COIL DRIVE

or else that air reactions, and electromagnetic damping play such important parts in the diaphragm motion compared with the inertia of the diaphragm itself, that the motion cannot be looked upon as inertia controlled, except in the upper frequency range.

Electromagnetic damping by the reaction of the driving coil with the magnetic field takes the form of a counter electromotive force which reduces the supplied current and driving force. The net result is the same as though the driving force had remained constant and a retarding force had been developed by a counter current generated by the motion of the coil. Thus "motional impedance" and electromagnetic damping are two aspects of the motion of the conductor in a magnetic field. Electromagnetic damping only becomes an important factor when the motional impedance becomes considerable compared with the other resistances and reactances in the circuit. Electromagnetic damping can be controlled in a measure by the ratio of transformation if a transformer is used. Making the load impedance high compared with the tube plate resistance gives maximum damping, while

making the load impedance low relative to resistance in the circuit minimizes the magnetic damping.

SEMI-RIGID DIAPHRAGMS

With the rigid type of diaphragm, a question to be settled experimentally was how large could the diaphragm be made before the quality of sound reproduction became impaired through failure of the diaphragm to act as a unit or plunger throughout the entire frequency range. A simple cone is an exceedingly rigid structure for its weight, particularly with respect to vibrations of the type which could be excited by a symmetrically applied force in the axial direction, such as is used in driving a conical diaphragm; or in other words, the cone is rigid with respect to vibrations like the opening and closing of an umbrella. With an angle of 45 deg. between the axis and wall of the cone, the rigidity is practically at its maximum. Paper cones of various sizes were tried with free or flexibly supported outer edges, using baffles to prevent circulation and

small coils as shown in Fig. 21 for drive. Diameters from 4 to 24 in. and angles from 45 deg. to 75 deg. were tried. These paper cones gave marked increase in

to have little effect on general sensitivity, but did somewhat alter the quality, diameters between four and eight inches giving the best results. The angle did not appear to be critical, but with very shallow cones speech sounded muffled, the high frequencies being lacking.

A rough calculation indicates that a 45 deg. paper cone 4 in. in diameter would begin to depart materially from rigid plunger action, at frequencies of between 3000 and 4000, while with larger diameter cones the change would take place at lower frequencies. The paper-cone diaphragms used in this series of tests must, therefore, be considered as acting substantially as

plungers for the lower frequencies with a gradual transition to wave action or progressive deflection at the higher frequencies. If there was any loss of quality due to the failure of the diaphragm to move as a whole at high frequencies, there was a compensating improvement as compared with the small diaphragm instruments, in a better radiation of the low tones, for the small diaphragms did not give

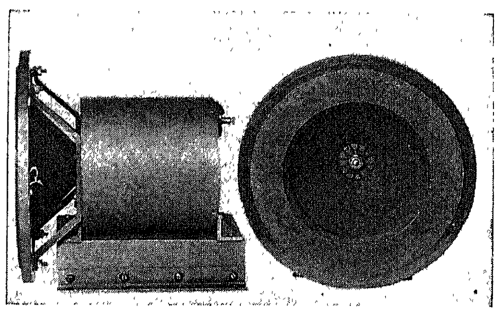

FIG. 27—FREE-EDGED, COIL-DRIVEN, CONICAL PAPER DIAPHRAGM LOUD SPEAKER UNIT

quite enough low frequency radiation. An extended series of tests was made to see whether a further improvement in quality could be obtained, making the

cone of various materials and different thicknesses and by employing stiffening members to reduce the tendency of the cone to break up into vibrations either of the kind with circular nodes or with radial nodes. Figs. 22 to 26 inclusive show some of the forms of diaphragm tried. Nothing better was found, however, than a simple 45-deg. cone of 0.007-in. to 0.010-in. paper, about six in. in diameter, with a flexible support around the outer edge consisting of a membrane of rubber 0.005 in. thick and ¼ in. wide, under very slight tension. Fig. 21 shows the general construction of diaphragm and field, and Figs. 27 and 28 show views of two models of the instrument with baffles omitted. Leaving the center of the cone open as indicated in Fig. 21 simplified construction and avoided the necessity of venting the space in front of the magnet core. A baffle, two feet square, appeared adequate. If the shortest air path between the front and back of the diaphragm is a quarter wave length or more there is no loss of radiation through circulation, although regions of interference between the two sound sources appear. An eight-foot wave length corresponds to a frequency of 135 cycles, and loss of output below this frequency may be attributed, in part, to circulation.

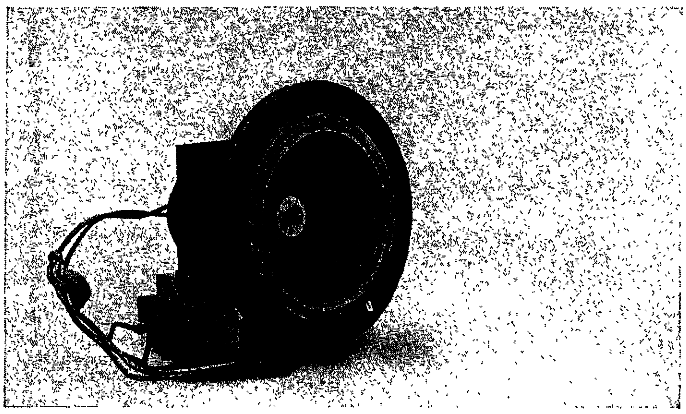

Fig. 28—Coil Driven Conical Paper Diaphragm, Loud Speaker Unit with Flexible Paper Edge

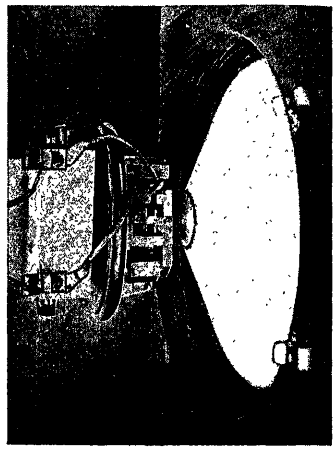

Fig. 29—Conical Paper Diaphragm with Free Outer Edge and Magneto Phone Drive

Summary of Conditions for Good Reproduction

The conclusion from these experiments was to the effect that the best practical solution of the loud speaker problem was a device combining the following features: *a conical diaphragm four inches or more in diameter with a baffle of the order of two feet square to prevent circulation and so supported and actuated that at its fundamental mode of vibration the diaphragm moves as a whole at a frequency preferably well below 100 cycles.*

The larger the diaphragm the less seriously will the baffle be missed if omitted. Thus, if the diaphragm were two feet in diameter, the effect of adding a baffle would be difficult to detect by ear. The use of the baffle gives latitude in the choice of diaphragm size. The baffle need not necessarily be flat, but if concave the solid angle included on the concave side should be at least as great as that in a cone with an angle of 45 deg. between wall and axis. With a smaller solid angle, resonance rapidly becomes noticeable and a change in general pitch level characteristic of horn action is brought about[16].

In order that the diaphragm may vibrate as a whole, the support at the outer edge must be very flexible compared with the diaphragm itself.

Comparison of Driving Systems

A low natural frequency means either a heavy diaphragm which would cost sensitivity, or else that the elastic restoring force supplied by the diaphragm supports plus any elastic restoring force in the driving mechanism must be small. Electromagnetic driving systems with moving iron armatures all require a certain amount of elastic restoring force to maintain stability. The required stiffness may be reduced by (1) lengthening the air-gaps, (2) working with weaker average magnetic field, (3) using a lever system which makes the diaphragm motion greater than the change in air-gap length; all of which mean a sacrifice of driving force. Fig. 29 shows a model employing a free edge cone with iron armature drive. By using a fairly large diaphragm and working close to the limit of stability it is possible to use this type of drive and obtain a low enough natural frequency and moderate sensitivity, but the moving coil drive has the following advantages: 1. The elastic restoring force may be made as low as desired without sacrifice of sensitivity. 2. Very large amplitudes can be allowed. (With a drive using variable length air-gaps, the change in gap length must always be small compared with the average length if distortion is to be avoided). 3. The relation between current and force is strictly linear and there-

16. "Effect of a Horn on the Pitch of a Loud Speaking Telephone," by E. W. Kellogg, *General Electric Review*, August, 1924.

fore distortion due to bends in the magnetization curves of iron is avoided in the moving coil drive. 4. If a strong magnetic field is provided the coil drive gives greater sensitivity than the iron armature drive. 5. No adjustment is upset if the weight of the diaphragm causes it to shift somewhat when the instrument is tilted. The disadvantages of the moving coil drive are the size and weight of the field magnet and the power required for excitation, but these disadvantages are outweighed by the advantages, in the opinion of the writers and their associates, particularly, when a special ampli-

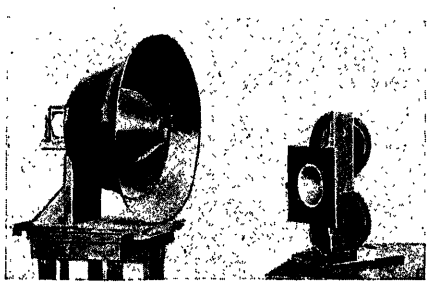

Fig. 30—Moving Coil Type Loud Speaker Unit with Permanent Magnet Field and Three-Pass Exponential Horn

fier is part of the loud speaker equipment. A loud speaker with moving coil drive and permanent magnet field is shown in Fig. 30.

Comparison of Free and Fixed Edge Cones

It may be of interest to compare the action of the flexibly supported conical diaphragm with that of one with comparatively rigid support. The latter has had extensive application in hornless loud speakers. If a vibrating force of constant strength, but variable frequency is applied at the vertex of the rigidly supported cone, there is small motion and little sound radiation at frequencies below the lowest resonance. Additional resonances occur at frequencies of the order of 3, 5, 7 times that of the fundamental. In order that low tones shall not be almost entirely lost in the output of such a device, it must be constructed so that the fundamental resonance occurs at a frequency low in the range of important sound. The diaphragm action may be said to be characterized by a series of resonances. The upper resonances are closer together on the musical scale, and this together with the greater damping makes the radiation more nearly uniform in this part of the range. The very high frequencies, however, are not adequately radiated when the cone is made very flat, or shallow compared with its diameter. The requirement of a low fundamental resonance calls for a shallow cone, unless the diameter is very large. The choice of angle is, therefore, a compromise.

The free-edged cone permits large amplitudes at low frequency, and as already pointed out the relation of amplitude to frequency is such as to maintain practically constant radiation. Since the radiation of the lower frequencies is not critical to either size or cone angle, these factors may be chosen entirely with reference to obtaining the best effects at high frequencies. Since the flexural waves which travel from the vertex toward the edge, are reflected as well by a free as by a fixed edge, only in opposite phase, standing wave conditions with circular nodes can occur with the free edge cone as well as with one having a fixed edge, and hence a series of resonances is possible. If the cone is steep, which means high velocity wave propagation, and small in diameter, the first resonance will occur at a high frequency, and the action characterized by a series of resonances will be confined to a minor part of the essential frequency range. Strong resonances in this region have not been observed, from which fact the conclusion must be drawn that damping in the diaphragm material and perhaps also in the material of the flexible edge is considerable.

The difference in the action of the diaphragms may be illustrated by the analogy of the behavior of two electrical transmission lines when an alternating voltage of variable frequency is applied. The free edged diaphragm is like a line short circuited at the end farthest from the generator, and the fixed edge diaphragm corresponds to an open circuited line. Current in the line is analagous to velocity of motion of the diaphragm. Large currents can be sent through the short-circuited line at low frequencies, the voltage and line inductance determining the current values. No resonance occurs until the frequency reaches a value which makes the line a half wave length long. Additional resonances occur at frequencies two, three, four, five, or more times that of the first. In the case of the open-circuited line little current flows until the first resonance is approached, at which the line is a quarter wave length long. The higher resonances are at frequencies three, five, and all odd multiples of the first. To make the

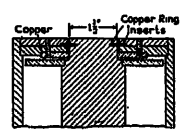

Fig. 31—Copper Ring Inserts to Reduce Impedance of Moving Coil

fundamental resonance occur at a low frequency, the line must be long, and constructed in such a way that the rate of wave propagation is slow.

Copper Rings to Reduce Impedance

In loud speakers employing a moving coil drive the radiation at high frequency can be increased, if desired, by a scheme due to Rice which consists in placing copper rings near the moving coil, so disposed that they form short-circuited secondaries and reduce the impedance of the coil at high frequency. In one coil tested the impedance at 4000 cycles was 57 ohms without the copper rings and 24 ohms with the rings in place. At 500 cycles the ohmic resistance of the coil was the princi-

pal factor, so that the rings had little effect. Fig. 31 shows the disposition of rings used for this purpose.

Special Amplifier

As was pointed out by Martin and Fletcher[17], voices and music do not sound natural unless reproduced at approximately the original level of intensity, even though the reproduction may be free from all wave form distortion. In order, therefore, that the full benefit of a high grade loud speaker may be realized, it is important that the amplifier which goes with it should have sufficient capacity to give a natural volume or intensity.

Fig. 32 shows the circuits of an amplifier which has proved satisfactory for household service. Two U V-216 kenetrons rectify 70 milliamperes at 550 volts. The field of the loud speaker serves as filter choke. In order that pulsations in the rectified current in the exciting coil may not cause changes in the air-gap flux and thereby produce hum and modulation of the sound output, the head of the spool on which the field coil is

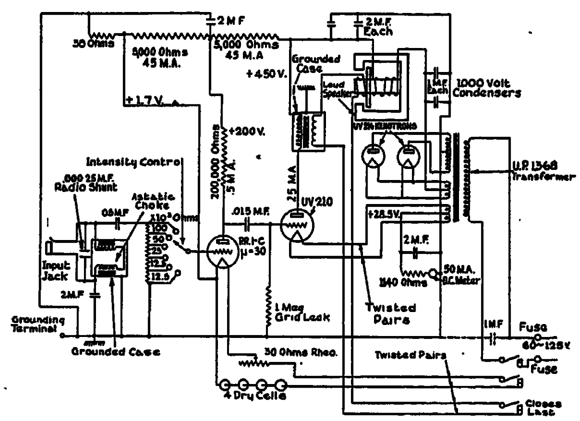

Fig. 32—Rectifier and Amplifier Circuit

wound is made of copper one-fourth inch thick. This expedient suggested by Kellogg steadies the flux so that there is almost no ripple. About 100 volts are dropped in the field coil, leaving 450 volts for the plate supply of the U V-210 radiotron which serves as the power tube. A bias of about 28 volts is required for the grid, and this bias is obtained by dropping 28 volts in a resistance so that the filament runs at a mean potential of + 28 volts with respect to the negative terminal of the rectifier. This makes the net plate voltage across the tube about 422, and the mean plate current is 25 milliamperes. Under these conditions an average U V-210 radiotron can send 10 milliamperes, r. m. s. value, of sine wave current through a 10,000 ohm load without appreciable wave distortion[18]. This represents about thirty times as much power as the same tube could put out with a plate supply of 120 volts.

Cabinet Set

Figs. 33 and 34 are views of a laboratory model of a cabinet set containing rectifier, amplifier and loud speaker. The front of the cabinet acts as baffle. To prevent air resonance in the box, the sides and back are vented by inserting panels of perforated brass. The ammeter shown in the picture is connected to read the plate current of the radiotron. Whenever the peak

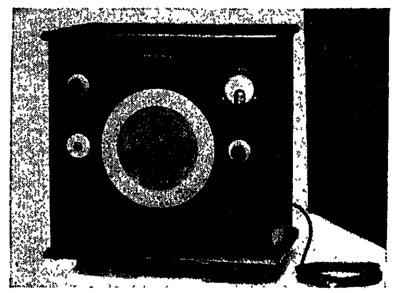

Fig. 33—Laboratory Model of Cabinet Set—Front View

values of the voltage applied to the grid of the tube exceed the value for which distortionless operation is possible the meter needle shows disturbance. If roughness commonly termed "blasting" is noticed in the reproduction, and if at the same time the meter needle kicks, the intensity of the input should be reduced. If the meter needle is steady, the fault is probably not in the amplifier.

Psychological Factors

Certain experiences connected with testing and demonstrating loud speakers of the type we have de-

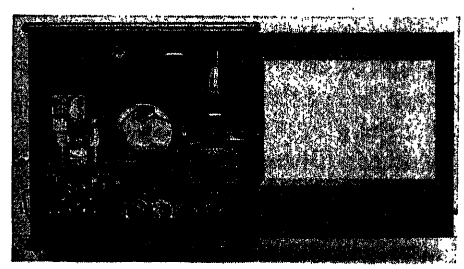

Fig. 34—Laboratory Model of Cabinet Set—Back View

scribed are of interest. The possession of an instrument in which distortion is minimized and whose response covers a wide frequency range, transfers the interest of the broadcast listener from "fishing" for distant stations to that of trying to find the best program among the near-by high grade broadcasting stations, and to enjoying the music or speeches themselves.

17. "High Quality Transmission in Reproduction of Speech and Music," by W. H. Martin and H. Fletcher. Journ. A. I. E. E., March, 1924.

"Physical Measurements of Audilion and their Bearings on the Theory of Hearing," by H. Fletcher. *Jour.* Franklin Inst., Sept., 1923.

18. Design of Distortionless Power Amplifiers, by E. W. Kellogg, A. I. E. E., 1925 Midwinter convention.

There are, on the other hand, conditions when the difference between the loud speaker with a wide frequency range, and one of the ordinary horn type which loses both very high and low frequencies, is not at all striking, and the latter may even sometimes be preferred. Measurements of sound intensity required for audibility[19] show that as intensity is reduced, the low tones will be lost first, since the threshold intensity for example of a 100-cycle tone is of the order of fifty times that for a 1000-cycle tone, intensity being expressed in sound wave pressure. As a result of this, when the reproduction as a whole is very faint, the instrument which produces the low tones does not sound materially different from one which does not, for even if reproduced in the correct relative intensity compared with the higher tones, the low tones are below audibility.

When a radio program is half smothered in static, it may sound better through a loud speaker whose response is mainly between 500 and 2000 cycles, than through one having a greater range. The energy in the incoming static is likely to be almost uniformly distributed over the audio frequency range, provided the receiving set is not responsible for distortion, whereas the range 500 to 2000 cycles includes the major part of the essential voice frequencies. Extending the range above and below would add to clearness and naturalness in the absence of interference, but with heavy static it may often bring in enough additional disturbance to more than offset the gain. Lack of clearness may be less irritating to the listener than disturbing noises. Hence the enjoyment of the wide range loud speaker is largely confined to strong stations or else to times of comparative freedom from static. A similar observation applies to roughness caused by "blasting" from overworked amplifiers or other causes. When any piece of acoustic apparatus is worked beyond the maximum amplitude for which the output bears a linear relation to the input, the resulting wave distortion takes the form of the production of overtones. The rough harsh sounds which result are much less noticeable with an instrument which cuts off the high frequencies. Therefore, if the improved articulation and greater detail in music, which are made possible by response to high frequencies, are to be a real advantage, we must avoid the faults just mentioned in the currents supplied to the loud speaker. The logical place to begin is the amplifier associated with the loud speaker. This must be carefully designed and have ample capacity so that there will be little temptation to overwork it. Few pieces of apparatus are so frequently worked beyond their proper capacity as loud speaker amplifiers. This is natural in view of the initial expense of an adequate amplifier, and the desire for volume of sound from the loud speaker. With the usual type of loud speaker a slight overworking of the amplifier is hardly noticed, and rather than provide greater amplifier power, users of loud speakers have compromised with low volume and some amplifier distortion, and either educated their ears to accept the result as good, or else lost interest.

19. Physical Measurements of Audition and their Bearing on the Theory of Hearing, by H. Fletcher, *Journ.* Franklin Inst., Oct. 1923, Bell System *Tech Jour.* Oct. 1923.

Another factor bears on the question of amplifier capacity. With distortion such as is usual in receiving sets and loud speakers the reproduction sounds best when weak, perhaps because the distortion is similar in some respects to the effects of distance. Use of such equipment results in one's forming the habit of enjoying faint music. With more nearly correct reproduction of the original music, enjoyment is increased by bringing the volume up to normal or the intensity to which one is accustomed when listening directly. In several instances it has been observed that when a loud speaker of the new type has been placed in the home of some one previously accustomed to a loud speaker of the usual construction, at first the listener preferred to keep the intensity very low, but after a few days we find him working with normal volume.

Output Measurements

Sound pressure measurements with constant input and variable frequency have been taken with two samples of the new type loud speaker, and these in general confirm the aural impressions that the instrument covers a wide frequency range without the great inequalities in output at different frequencies which characterizes loud speakers in general. Such measurements, however, are likely to be misleading unless extreme precautions are taken to avoid certain errors. Up to the time of writing the authors have not been able to obtain measurements under conditions with which they were completely satisfied, and it is, therefore, deemed best not to publish any of the output data so far obtained.

Acknowledgments

The writers wish to express their deep appreciation for the never failing interest and encouragement given by Dr. W. R. Whitney throughout the long investigation. We are also greatly indebted to our colleague, Dr. C. W. Hewlett, for many helpful suggestions and for the production of our first really high-grade loud speaker which was constantly used as a standard of comparison. We are further indebted to Mr. E. P. Lawsing for able assistance in the experimental work and to Mr. W. F. Winter in the mechanical construction.

Discussion

H. A. Frederick: In reading this paper one cannot but wish that some definite standard or method of rating might have been employed, so that the results of this investigation of many types of loud speakers might be placed quantitatively in definite positions on some scale of merit. Since the authors, as pointed out in the paper, have not as yet been able to obtain satisfactory quantitative measurements with their best designs, the readers are not in a position to judge the accomplishment.

While these measurements are not simple and are liable to be misleading, unless very carefully made, still the same comment applies to qualitative judgments by the ear alone.

In this work, the authors have primarily stressed the obtaining of a loud speaker giving high quality; that is, one which faithfully and without distortion reproduces the sound whose electrical counterpart has been fed to it. In striving for this result, it is difficult also to obtain efficiency. In the authors' analysis of the problem they have largely sacrificed considerations of efficiency. For example, the "inertia control" used in their design involves a diaphragm 90 deg. out of phase with its driving force or, in other words, low power factor. They have also neglected motional reactions of the mechanical system on the electrical as well as transition losses due to the connection of vibratory systems of different impedances. The analysis as a result is limited in its field of application. It is probable, on the other hand, that improvements to overcome such losses will be effected and that they will make possible loud speakers of high quality which will also be of materially higher efficiency than those now available.

Another phase of the loud-speaker problem which would seem to warrant consideration is the load capacity. This, of course, must be defined in terms of sound-power output. A loud speaker, to be satisfactory for certain very important classes of service, must be capable of giving out a very considerable amount of sound without having the relation between output and input depart from a linear characteristic. In rating the various types studied it would be of interest to know how they were found to compare on this score; also, it would be of interest to know what were the limits of output found for these most promising designs and whether magnetic or vibratory, namely, mechanical limitations were first encountered or whether heating of the coil limited its output.

In the favored design, the size of the baffle, of course, sets a lower frequency limit while the size of the cone and its rigidity set a higher frequency limit. It would be of interest to know where these two limiting frequencies were to be found.

Near the end of the paper, it is stated that the stiffness of a magnetic-type motor system can be decreased by weakening the polarizing magnetic system. As pointed out by Hanna, the polarizing field gives rise to what might be termed a negative stiffness since it acts in opposition to the mechanical stiffness of the system and, therefore, has the opposite effect to that stated.

The authors state that "if a strong magnetic field is provided, the coil drive gives greater sensitivity than the iron-armature drive." I would like to ask if they would explain a little more in detail just what is meant by sensitivity, and how this conclusion was reached. It would seem that the magnitude of the mechanical force and the mass, as well as the electrical impedance and current, would have to enter a satisfactory expression for sensitivity.

In the article appears the statement that "four times the power is radiated with the baffle as with the back enclosed." Is the conclusion based on theoretical grounds or was it determined entirely by observation?

The reference to the resistance-controlled type as being of only "theoretical interest" might perhaps appear to underestimate its importance since any loud speaker to have high efficiency must be largely resistance-controlled, the resistance coming from useful radiation of sound into the air.

B. F. McNamee: The loud speakers which have been on the market using a movable coil system are supplied (as I suppose this one is) with a field current, usually from a storage battery. I believe that such loud speakers have met with a certain amount of sales resistance, due to that fact. Especially where dry-cell tubes are popular, a source of field current is not very readily available. I would like to ask how permanent field magnets would work out in this case, or what other provision has been made.

V. E. Thelin: In endeavoring to get quality of tone, I have adapted a Western Electric unit to a talking machine which has a wooden tone arm, as well as a wooden horn, and I attribute the fact that the so-called horn effect had disappeared to a considerable extent, to this wooden construction. I compared this combination with a new speaker of the parchment-cone type, and an adaptor type unit of another manufacture. I noticed that the Western Electric unit and the parchment type speaker gave the same volume and tone quality and it was difficult to tell them apart when they were operating at the same time. The adaptor type, however, changed the quality considerably and on the low notes of the piano it was very mushy.

It seems to me that there is a large field for the amplifier unit demonstrated here today. With a unit of this kind, it, no doubt, would be possible to take a phonograph record, and using a needle which has practically no scratching, and, therefore, has perfect tone, but whose music is too soft to be heard in the horn of the talking machine, and amplify it to a considerable volume but still retain the perfect tone quality. In this way it would be possible to preserve the music of the present-day artists on the radio and hear this music many years to come.

I would like to ask Mr. Kellogg if the baffle need be of a certain kind of material for obtaining the best results.

R. S. Glasgow: The authors mention the Hewlett type of loud speaker in their paper and point out that one of its disadvantages is the long air-gap that the radial magnetic field has to traverse, with the result that considerable energy is required for excitation purposes.

I would like to know whether the quality of reproduction would be effected by the substitution of a thin iron diaphragm in place of the non-magnetic materials that are usually employed.

A. Nyman (by letter): The conclusion the authors have drawn from physical considerations is that the resistance control is the ideal for loud speakers; meaning, of course, by the resistance control any control which is proportional to the velocity of the movement of the sound-generating surface. From the ordinary physical consideration the loud speaker can be regarded as an ordinary electric motor with certain peculiar load conditions capable of giving resonance at certain frequencies, elastic control below that frequency, and inertia control above that frequency. It is quite evident that a motor of this type would operate most satisfactorily if the elastic control and the inertia control could be so small as to be negligible compared to the actual load output. Considering the loud speaker from this point of view, it is also evident that if a loud speaker can be designed with a large efficiency that the resistance control will naturally follow.

The problem therefore comes down to the design of a sound-producing structure of such a nature that the energy input from the electrical instrument is converted largely into sound energy and only a very small percentage into elastic or inertia energy. It is also evident that a large horn properly designed in such a way as not to have any permanent resonant characteristics would form an ideal load on the loud speaker, but involves an unwieldy mechanical structure. It has to be quite long before it is suitable. The attempts carried out by the experimenters, using large conical diaphragms apparently discloses the fact that it is difficult to construct a large conical diaphragm that will avoid irregular movements and local resonance difficulties.

In future, the development will be probably in this direction; that is, the construction of a mechanical structure for radiating sound in the space.

Even under the best conditions the energy that can be radiated into the air with an average loudness of sound is quite small. From this it follows that the restoring force, due to the elastic control should be small, and the inertia force should be also small. This condition naturally leads to a low-frequency structure, but consisting of light enough parts to be capable of responding to high-frequency currents. The writers of this

paper achieved this object by the construction of a moving-coil unit with a practically floating diaphragm, and a consequent natural frequency of around 100 cycles. It is, however, possible to achieve frequencies as low as this with the ordinary electromagnetic types of loud speakers, both the steel-diaphragm type and the moving-armature type.

In either of these types there are two forces opposing each other under normal operative conditions. These forces are the elastic forces in the diaphragm, and the magnetic pull of the magnets. Now, it is possible to adjust the relation between these two forces in such a way that the difference between them is quite small. The resulting natural frequency of the whole system is consequently also very small. This can be done without any sacrifice on the part of the strength of magnetization. As a matter of fact, it is necessary to choose a rather soft diaphram on the moving-iron type in order to achieve this magnetic balance.

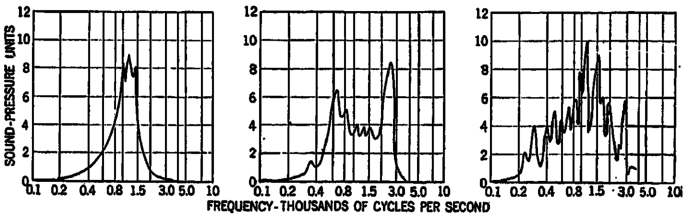

Fig. 1—For the Year 1921 Fig. 2—For the Year 1922 Fig. 3—For the Year 1923

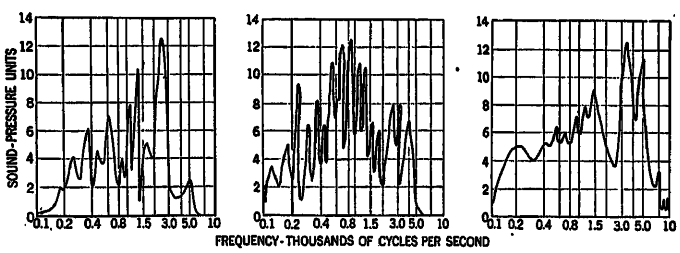
The sound-pressure measurements to which the writers refer at the end of the paper are undoubtedly still in a rather imperfect stage and can only afford comparative information on different types of loud speakers. It should be borne in mind, however, that under the best conditions the sound-pressure measurement will not give the complete information on a loud speaker. It is possible to choose a fairly resonant loud-speaker unit and a fairly resonant sound-diaphragm system, which in combination would give sound pressure measurements of almost constant value at different frequencies. However, this loud speaker will not necessarily give good musical or speech reproduction. There is a phenomenon which may be described as persistance of sound in all musical instruments; it has the same effect as the reverberation in large auditoriums, and is caused by the fact that resonance condition exists. This persistence causes the sound to continue radiating from the sound-distributing structure after the loud speaker has ceased to produce this sound. Of course, if the following note is of a different frequency from the persisting note, and possibly of a frequency causing a musical dissonance, the resulting sound would have a jarring effect in a musical composition. This phenomenon, which is not very well known, and as far as I know, has not been investigated by physical measurements, is however quite pronounced, and if precautions are taken to eliminate it, a considerable improvement in sound quality is possible.

J. P. Minton (communicated after adjournment): In a series of popular articles appearing during the past year in the *Wireless Age* I have pretty well covered the whole field of the ear, the voice and the loud speaker up to the present moment. As a result of this study and experimentation it is clear to me that up to the time, the loud speaker, in spite of improvements, has failed to give entirely satisfactory reproduction. Until the appearance of this new loud speaker, this device has been the weakest link in radio. In this respect radio has suffered in the past the same limitation that the phonograph has existed under. In phonograph reproduction the sound box and its associated horn were the weakest links. Recording was developed to an extent which made it possible to get into the record much more than the sound box and horn were able to give out. In a sense, radio reception has existed under the same impediment. However, radio originally was developed entirely for the transmission of intelligence and not for that of pleasure and entertainment. The requirements and sustaining forces in the two cases, therefore, were quite different. Accordingly, radio was developed to a high degree of perfection while the phonograph has not been so highly developed.

When radio broadcasting and reception came into existence, the already highly developed state of radio made possible the rapid growth of this new form of entertainment and education. The loud speaker had to be injected into this picture. Its use had previously been limited to certain fields of not very great importance. It had not received very serious consideration up to this point. Phonograph quality was quickly attained by use of horns of various sizes and shapes to which were attached units of the usual types. This stage was a temporary one, but it has existed for four or five years. In the meantime, a great deal of fundamental research was undertaken and now as a result of this work the loud speaker has been brought to a point where its performance is such as to make possible the reproduction of the original with an exactness astonishing to all of us.

As the authors have indicated the development has gone through a number of stages and in addition to their own excellent contribution to this work much credit for the gradual evolution of the loud speaker is due to many other workers in this and the allied fields of voice, ear and music analysis. Among the names of those who have contributed most from the fundamental point of view to this work will be found Rapleigh, Lamb, Webster, Stewart, Miller, Foley, from our universities and from our industrial research laboratories will be found such men, in addition to the present authors, as Hewlett, Slepian, Hanna, Fletcher, Wegel, Crandall, Maxfield, Goldsmith, Ringle, Wolff, Kranz and others.

From the scientific point of view it will be interesting to show a group of six curves which may represent the evolution of the loud speaker. The ordinates in these curves are proportional to sound pressures and the abscissas are frequencies divided by 1000. During the early stages (say 1921) of broadcasting, Curve 1 may represent an average loud speaker. Curve 2 may represent the state of the art in 1922. Curve 3 represents what was obtainable for 1923, Curves 4 and 5 for 1924 and Curve



Figs. 4—For the Year 1924 Fig. 5—For the Year 1924 Fig. 6—For the Year 1925

6 for 1925. These curves represent a steady progress in four or five directions. First, extension of the range of response to include both higher and lower frequencies. Second, uniformity of response, or the gradual elimination of the sharp peaks and depressions. Third, more nearly equal response at all frequencies. Fourth, reduction of non-linear distortion. Fifth, introduction of pure low-frequency response.

Curve 6 represents the performance of the new Rice-Kellogg loud speaker. The curve was taken close up to the loud speaker so that the characteristics of the vibrating system itself, actuated by a constant force, would be obtained. The loud speaker covers quite affectively a frequency range extending from 100 to

7500 and perhaps 10,000 cycles. The response is quite uniform compared with all other types of loud speakers and this new speaker gives an exceedingly small amount of non-linear response and therefore small distortion compared with all other loud speakers.

I wish to call attention to the fact that Curve 6 does not indicate complete agreement between the theory based on inertia action and the response at various frequencies. If the cone followed this simple theory then the response as measured by sound pressure should be constant at the various frequencies. Now, in this particular sample tested the response rises abruptly at 100 cycles; it also falls off abruptly above 6000 or 7000 cycles; there is also quite a marked depression in the region of 2000 cycles and a minor one at 4000 cycles. I am quite inclined to the view, therefore, that, in addition to the inertia-controlled motion which the authors seem to favor, there are also present to a marked extent flexural vibrations which, due to circular and diametral nodes of motion, corresponding to a plane membrane, produce the characteristics as indicated by the curve. We have studied these types of motion, for somewhat larger cones than the 6-in. one adopted by the authors, both theoretically and experimentally, and have found very curious nodes and interesting data which will prove of considerable practical value. At a later date we hope to have the opportunity to present these results.

E. W. Kellogg: Mr. Frederick has called attention to the fact that an inertia-controlled diaphragm implies a low-power-factor system, or one in which force and motion are nearly in quadrature, and therefore only a small fraction of the driving force is expended in the useful work of producing sound radiation. I have made a calculation which indicates that the efficiency of the loud speaker described in our paper is of the order of one per cent, which, it must be admitted is low, but compares very well with that of other loud speakers.

It may be of interest to review the possibilities of a sound reproducer in which the diaphragm motion is in phase with the driving force. Such a condition obtains when a diaphragm is in resonance, and efficiencies of 50 per cent or more are probably possible at a single frequency, using a resonant diaphragm. But when we impose the requirement of substantially constant efficiency over a frequency range of 100 to 5000 cycles, we must forego the benefits of resonance. The resistance-controlled diaphragm will have the correct radiation characteristic, 1—if it is large enough compared with the longest waves to give plane wave radiation, or 2—if it is used with a properly designed horn. For efficiency, the force which resists motion must be due to the air reaction on the diaphragm. In free space this air reaction is very small, and if it is to be large compared with diaphragm inertia or elastic forces, an extremely light and flexible diaphragm must be used. Such a diaphragm must be actuated by a uniformly applied force. Electrostatic loud speakers have been built with large-area diaphragms of very light material, and these have probably had quite high efficiency, if we define efficiency as the ratio of sound power output to electrical power input. But unfortunately we have to pay for the total volt-amperes supplied rather than simply for the electrical power, and the electrostatic loud speaker has a very low electrical power factor.

The case for the horn-type loud speaker has been discussed by Messrs. Hanna and Slepian[1]. By means of the horn the air reaction on the diaphragm can be increased to a point where it will effectively damp the motion of as stiff and heavy a diaphragm as is commonly employed in loud speakers. Thus a magnetically driven diaphragm may be used with resistance-controlled motion, or with a unity-power-factor relation between force and velocity. But a magnetic drive has good efficiency only when the motional impedance is a large part of the total impedance, or in other words, when as in the case of an electric motor, most of the impressed voltage is used in overcoming the counter electromotive force due to armature motion. A study of the motional impedance of magnetic telephones shows that only in the neighborhood of a resonance frequency is the motional impedance considerable compared with the resistance and inductive reactance, and if sufficient damping is introduced by the air reaction on the diaphragm to give substantially uniform response over a wide frequency range, the motional impedance becomes very small at all frequencies. This probably explains the fact that no horn-type loud speaker which we have tested shows any greater average efficiency than our inertia-controlled paper cone. I do not despair of considerably greater efficiencies being ultimately obtained in loud speakers, but from the standpoint of present progress in the art of sound reproduction, I do not believe that the adoption of inertia-controlled diaphragms can be construed as a step in the wrong direction.

Mr. Frederick raised the question of load capacity. The moving-coil drive has a distinct advantage over the iron-armature drive on this score. With the cabinet-set amplifier described in the paper, our loud speaker can easily reproduce vocal solos with the original sound volume, or can reproduce a piano selection as it would be played in a drawing room, though perhaps not with the maximum loudness that would be used in a large concert hall. The limit of loudness is set by distortion in the amplifier rather than in the loud speaker. In fact the latter will handle all the output which can be obtained without distortion from a U. V. 211 radiotron (50 watts oscillator rating) with a 1000-volt plate supply, or eight times the power obtainable from the cabinet-set amplifier.

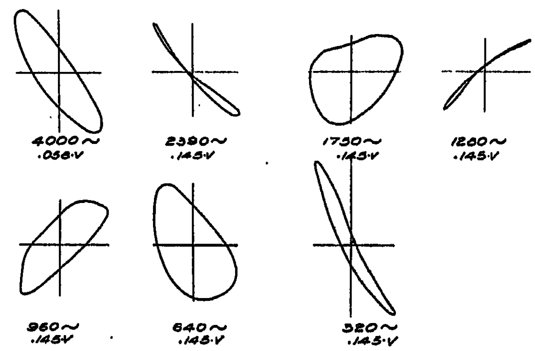


FIG. 7—BRAUN-TUBE RECORDS OF SOUND WAVES

In stating that working with a weak magnetic field makes possible a lower net restoring force in the case of an iron-armature driving element, we made the assumption also made by C. R. Hanna in his January 1925 I. R. E. paper, that the magnetic reduction of stiffness cannot be more than a certain fraction (say 50 per cent) of the spring stiffness.

In comparing two loud speakers, we have rated the one as more sensitive which would produce on the average more total sound output from a given vacuum-tube source, both instruments being equally fitted to the tube impedance. In saying that the moving coil gives greater sensitivity than the iron-armature drive, we are reporting our experience with these types of drive as applied to paper-cone diaphragms.

Mr. McNamee asks about the use of permanent magnets for the field. When the loud speaker is combined with an amplifier, the dynamic field is hardly a drawback since the field winding acts as a necessary filter choke. We have done some experimenting with permanent magnets, but have not, up to the present succeeded in obtaining an adequate field for a moving-coil instrument without a very heavy magnet system.

Mr. Thelin asked about the material of the baffle. It should

1. The Function and Design of Horns for Loud Speakers, by C. R. Hanna and J. Slepian, JOURNAL A. I. E. E., March 1924, page 250.

be stiff and heavy enough so that it will not readily be set in vibration by the air pressure. Wood, pressboard, and similar materials are satisfactory and convenient to use.

The question has been asked whether an iron diaphragm would increase the sensitivity of a Hewlett loud speaker. Dr. Hewlett found no gain from the use of iron, but instead, a distinct loss as compared with copper or aluminum. The increased flux density must be around, rather than in, the conductor in order to increase the force.

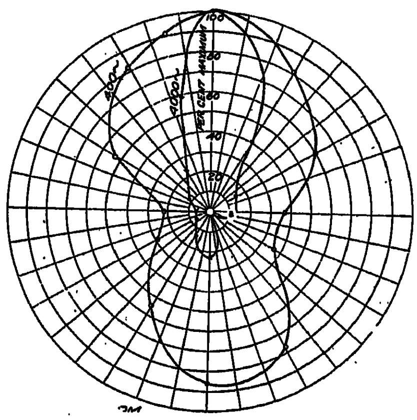

FIG. 8—SHOWING SOUND OUTPUT OF LOUD SPEAKER AT DIFFERENT POSITIONS

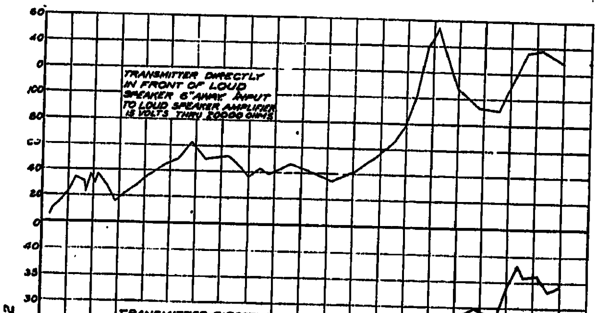

FIG. 9—CONDENSER TRANSMITTER 34 IN. FROM CENTER OF CABINET. HORIZONTAL DIRECTIVITY OF LABORATORY MODEL OF RICE-KELLOGG LOUD SPEAKER, PER CENT MAXIMUM SOUND PRESSURE VS. ANGLE.

I am submitting as part of the discussion some sound-pressure curves which we have recently obtained. The measuring arrangements were still in the developmental stage when these curves were taken, and a high degree of accuracy is not claimed. In fact in acoustic measurements so great are the difficulties encountered that a measurement that can be trusted to be within 50 per cent of the correct value might be regarded as highly satisfactory. In the present case a condenser transmitter, with amplifier, detector, and galvanometer, was used for measuring sound pressure. The amplifier, detector and galvanometer system was calibrated by introducing a measured low voltage in series with the condenser transmitter. The condenser transmitter was similar in construction to that described by F. C. Wente in the *Physical Review*, July 1917, and May 1922. A calibration of the condenser transmitter was made by actuating its diaphragm by means of a special, laminated-pole telephone magnet held 1/16 in. from the diaphragm, the force being assumed to be proportional to the current through the coils. This does not give an absolute calibration, but should show any radical departure from the shape of the curve given in the *Physical Review* article already mentioned.

In loud-speaker tests it is important to guard against the error of crediting sound radiated in harmonics to the fundamental frequency. For example, if an instrument is supplied with a 200-cycle alternating current, and it happens to be one hundred times more sensitive at 400 and 600 cycles, than at 200, then a very small percentage of harmonics in the supplied current, plus harmonics produced in the instrument itself may give rise to a much larger radiation of 400- and 600-cycle sound than of 200-cycle sound. If the sound-measuring apparatus measures total r. m. s. pressure independent of frequency, considerable sound pressure will be indicated, and this would naturally be assumed to be 200-cycle output pressure.

To make sure that no serious error arose from this source, a Braun-tube oscillograph was set up. Between one pair of plates, a voltage was impressed, proportional to the current supplied to the loud speaker while a voltage from the condenser-transmitter amplifier, proportional to the sound pressure, was impressed across the other pair of plates of the Braun tube. If both voltages are sine waves, the figure which appears on the screen is an ellipse or an inclined straight line. Harmonics in one of the voltages result in deformations of the figure. In the present measurements, the oscillograph figure was watched throughout the entire range of frequency, and tracings were made of all the figures which were seriously distorted. In no case was it found that the harmonics carried more than 25 per cent of the energy of the fundamental in the output sound wave. Several samples of Braun-tube figures are shown here in Fig. 7.

The next serious problem in the testing of loud speakers results from the fact that the curve of sound pressure vs. frequency, changes in shape with change of microphone position. Which of the many possible positions will give a curve best representing what listeners on the average will hear? It would seem logical to avoid the irregularities due to standing waves in the room, and give a curve in which the sound pressure shown is a measure of the total sound power output. An approximation to this is obtained by averaging the square of the sound pressure over a considerable space by moving the microphone rapidly to and fro during each reading. Facilities for moving the microphone or transmitter in this manner were not available in our case and as an alternative, several curves are shown in Fig. 8 for different transmitter positions. The high or low regions which are common to all three curves may be interpreted as indicating large or small output from the loud speaker, while the irregularities which are different in the different curves are principally room effects. It will be noticed that the curves taken with the transmitter directly in front of the loud speaker show a marked increase in sound pressure above 2300 cycles. The instrument, however, has rarely been criticised on listening tests as having too much high-frequency output. The curve taken with the transmitter to one side, does not show such an excess of high tones. Evidently then the high sound pressures recorded in the upper frequency range are due in part to the concentration of the sound in a forward beam. The curves of Fig. 9 were taken by moving the transmitter in a circle and recording the sound pressure every 30 deg. They show the

radiation at 4000 cycles to be sharply directed forward whereas at 400 cycles there is only a slight depression at the side due to interference between the waves from the front and back of the diaphragm. In total sound radiated, therefore, the excess of high frequencies is only slight. If high frequencies are lost in the transmitting or receiving systems, the listener prefers to take a place directly in front of the loud speaker, so as to get the full benefit of what is left, while if articulation is good, but there are roughnesses, or high-frequency disturbances present in the currents fed to the loud speaker, the listener will sit to one side.

It is probable that the frequency of 2300 cycles, where the forward projected sound begins to increase, marks the transition between the two modes of action of the cone. Below this frequency it acts as a unit or plunger while at higher frequencies there is wave action with some resonances. The depression in the region of 2300 cycles may correspond to the droop in the calculated curve in Fig. 10. This lends support to the belief that practical plunger action is maintained up to 2300 cycles. In the upper range, irregularities in the response may be expected not only from resonance in the cone, but also from the fact that the cone depth is appreciable compared with the sound wave length, and, therefore, the diaphragm no longer radiates like a flat plate.

The loss of output below 200 cycles is due to a decrease in the driving force. If the current through the moving coil is held constant the output sound pressure is practically the same at 80 as at 200 cycles, but in the curves shown here, it is the voltage supplied to the first stage of the amplifier which is maintained constant. The current through the moving coil then changes with changes in the coil impedance. This impedance rises from about 17 ohms at 200 cycles to over 80 ohms at 80 cycles and the consequent decrease in coil current results in reduced driving force and reduced sound output. The rise in impedance is due to the motion of the coil, which with inertia control becomes very large at low frequency.

Echo Suppressors for Long Telephone Circuits

BY A. B. CLARK[1]

Associate, A. I. E. E.

Synopsis.—*A device has been developed by the Bell System for suppressing "echo" effects which may be encountered under certain conditions in telephone circuits which are electrically very long. This device has been given the name "echo suppressor" and consists of relays in combination with vacuum tubes, which are operated by the voice currents so as to block the echoes without disturbing the main transmission.*

This paper gives a brief description of this device, together with a discussion of its possibilities and limitations. A number of echo suppressors have been operated on commercial telephone circuits for a considerable period so that their practicability has been demonstrated.

TABLE OF CONTENTS

INTRODUCTION

In designing telephone circuits which are electrically very long, an important problem is presented by the necessity of avoiding serious "echo" effects. Echo effects are caused by reflections of voice waves which take place whenever electrical irregularities are encountered in telephone circuits. The effects produced are very similar to echoes of sound waves. Some of the reflected waves return to the receiver of the talker's telephone so that if the effects are severe, he may hear an echo of his own words. Other reflected waves enter the receiver of the listener's telephone and, if severe, cause the listener to hear an echo following the directly received transmission.

Reflections of voice waves occur in all practical telephone circuits. It is only in telephone circuits of such length as to require a number of repeaters, however, that echo effects become serious. The fact that the circuits are electrically very long makes the time lag of the echoes appreciable. At the same time, the telephone repeaters overcome the high attenuation of these long circuits and, consequently, make the echoes louder. The seriousness of the effect is a function both of the time lag and the volume of the echoes relative to the direct transmission.

A brief discussion of these echo effects was given in a paper[3] presented before this Institute about two years ago, and in a later paper[4] some examples of their relative effects in practical telephone circuits were given. In these papers the importance of keeping electrical irregularities within proper limits was pointed out as was also the advantage gained by using circuits having a high velocity of propagation so that the lag of the echoes is reduced.

As a supplement to these methods, a device to which has been given the name "echo suppressor" was developed by the Bell System, along lines suggested by John Mills[5]. In all practical telephone circuits involving more than a single repeater there are points where the transmission in the two directions passes through two separate paths. At these points the direct transmission passes through one path while only reflected currents or echoes pass through the other. The echo suppressor is located at one of these points. In this device, the voice currents, with the help of vacuum tubes, are caused to actuate relays which cut off the echoes in the return path without disturbing the other path through which passes the main transmission.

This paper, after briefly reviewing the nature of echo effects in four-wire circuits, explains, in a general way, how an echo suppressor functions on such a circuit. The four-wire echo suppressor is then described together with some variations in its design for use under special conditions and with other circuits. This is followed by a discussion of the possibilities and limitations of echo suppressors, both on four-wire and other types of telephone circuits.

REVIEW OF NATURE OF ECHO EFFECTS IN FOUR-WIRE CIRCUIT

Fig. 1 illustrates the way echo currents may be set up and circulate in a four-wire circuit. In this figure, *a* shows a four-wire circuit in diagrammatic form. The squares at the extreme right and left are intended to represent the telephone sets used by two subscribers at the terminals *W* and *E*. The squares marked *N* represent electrical networks which simulate or balance, more or less perfectly, the impedances of the two telephone lines terminating in the instruments at *W* and *E*. In the four-wire circuit, the squares with arrows represent one-way repeaters. At each terminal the two separate one-way circuits comprising the four-wire circuit are joined together by means of the familiar balanced transformers. When *W* talks, the transmis-

sion passes directly to E over the upper pair of wires in the four-wire circuit, while, when E talks, the direct transmission passes over the lower pair of wires.

Below the diagram of the four-wire circuit is given another diagram, b, showing the path of the direct transmission as well as the paths of the echoes which are set up when W talks to E. The heavy line in the diagram represents the path of the direct transmission through the upper pair of wires in the four-wire circuit.

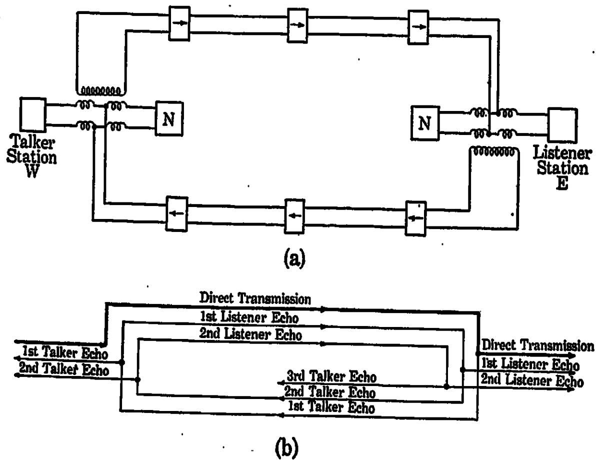

FIG. 1—ECHOES IN FOUR-WIRE CIRCUIT

In a practical four-wire circuit it might require, say, 0.05 second for the voice currents to make this journey. This would be the case if the four-wire circuit were 1000 miles (1600 km.) long in cable with extra-light loading—coils of 0.044 henry spaced 6000 feet (1.8 km.) apart. Cable circuits loaded in this way have a velocity of propagation of about 20,000 miles (32,000 km.) per second.

When the voice currents reach the distant end of the four-wire circuit, the larger part goes to the listener at E. If the balance between the line and network at the distant terminal is not perfect, however, a portion of the currents will travel back over the lower pair of wires toward W as an echo. This echo will, in the case assumed, reach the receiver of the telephone at station W, 0.1 second after the original voice wave is impressed on the line at that station. The path of this echo is labeled "1st Talker Echo." It is evident that if this echo is loud enough it may seriously distract the talker.

If the balance between the line and the network at Station W is also not perfect, part of this first echo will travel back over the upper pair of wires to Station E, the path of this echo being labeled "1st Listener Echo." The listener at E will hear this echo, if strong enough to be audible, 0.1 second after he hears the direct transmission. Evidently, if this echo is sufficiently loud as compared to the direct transmission, it will cause difficulty in understanding.

When the "1st Listener Echo" arrives at the end of the four-wire circuit, there is still another reflection of part of the current which occurs producing the "2nd Talker Echo."

This process is repeated, producing successive echoes which are received at both terminals W and E as indicated, the successive echoes getting weaker and weaker.

ACTION OF ECHO SUPPRESSOR ON FOUR-WIRE CIRCUIT

An echo suppressor will now be applied to the four-wire circuit and consideration given to its action and to its effect on the echoes. Fig. 2 shows a four-wire circuit which it will be assumed is exactly like the one shown in Fig. 1, with the exception that an echo suppressor has been applied to it. As before, the diagram a shows the four-wire circuit, while, below this, another diagram b shows the paths of the direct transmission and of the echo.

In Fig. 2a the echo suppressor is shown in very simple diagrammatic form. It will be described later in detail. For the present it is sufficient to explain that the echo suppressor consists of two similar high-impedance vacuum tube amplifier-detectors bridged across the two sides of the four-wire circuit, each amplifier-detector having associated with it a relay which operates whenever alternating voltage of sufficient strength is impressed across the input. The operation of either relay places a short circuit across the side of the four-wire circuit opposite to the one to which the input of its particular amplifier-detector is connected. This short circuit blocks the transmission flowing in one side of the four-wire circuit and, at the same time, renders the other amplifier-detector inoperative.

Normally, the contacts of the two relays are open,

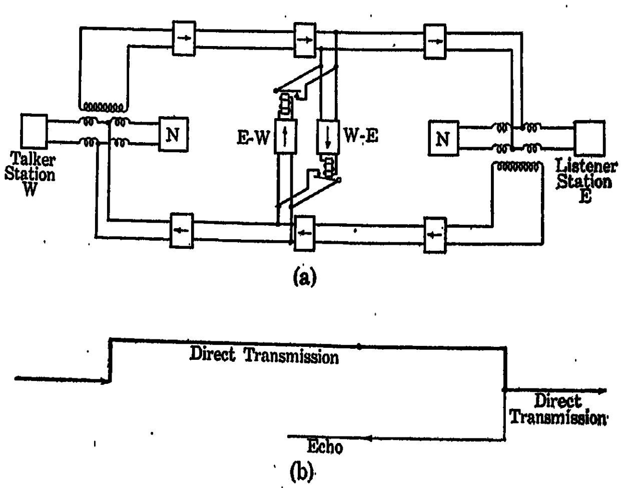

FIG. 2—ECHO SUPPRESSOR CUTTING OFF ECHO IN FOUR-WIRE CIRCUIT

so that talking may be done in either direction over the circuit. When W begins to talk, the condition illustrated in the figure is produced. W's voice currents, when they reach the middle of the circuit, cause the relay associated with amplifier-detector W-E to operate, thus placing a short circuit across the lower pair of wires in the four-wire circuit. The direct transmission from W to E is not affected at all, passing on to Station E where it is heard by the listener. The echo, which

starts back from Station E, travels toward Station W as far as the point where the echo suppressor is connected to the circuit. It is stopped there, however, by the short circuit which the echo suppressor has applied.

In the same way, when E talks, his voice currents actuate the amplifier-detector marked E-W and apply a short circuit to the upper pair of wires, thus preventing the passage of the echo current around the circuit.

The circuit shown in Fig. 2a is one of the more convenient for satisfying the fundamental operating conditions of an echo suppressor. These may be stated as follows: When no one is talking, free paths should exist for transmission in either direction and each suppressing relay should be ready to act at the passage of speech over the side of the circuit with which it is associated. When speech passes in one direction over the circuit the resulting operation of the corresponding half of the suppressor should not only interrupt the continuity of the opposite side of the circuit, but at the same time prevent the other half of the suppressor from functioning. The latter condition is desirable as otherwise the returning echo might have enough energy at times to operate the opposite part of the suppressor circuit and so interrupt the direct transmission. Outside of this restriction the selection of the points from which the echo suppressor input currents are derived and the points at which the relay control functions are applied is governed only by such considerations as economy of apparatus and convenience. In general, it is the more economical arrangement to have a single relay, which interrupts the path through which the echoes return, also remove the speech input from the suppressor by such a relative association of parts as shown in Fig. 2a.

It will be noticed that, as a finite time is needed for the switching operation, there is a possibility, if the two subscribers begin talking simultaneously, of both halves of the suppressor being operated together and remaining operated, with both sides of the circuit cut off, for a time equal to the release time of the relays. However, for the times of operation and release, which are found desirable from other considerations, it has been found that no apparent difficulty has been caused by this effect.

Because of the fact that an appreciable time is required for the voice currents to travel, it will be seen that exceedingly fast operation of the relays is not necessary. In the example given, if it is assumed that the echo suppressor is connected to the circuit at its midpoint, the echo requires 0.05 second to reach the point where the short circuit is applied, after the voice currents reach the input of the amplifier-detector. The echoes will be cut off by the relays, therefore, even if the latter require as long as 0.05 second for operation. If the echo suppressor is nearer to the end of the four-wire circuit this operating time would need to be somewhat shorter. In practical four-wire circuits it is seldom that an operating time shorter than about 0.02 second is required. It is an easy matter to secure this speed of operation with standard telephone relays.

The diagram also shows that, in order to completely cut off the echo, the echo suppressor relay must not open, after talk ceases, until the complete train of echoes has reached the point where the short circuit is applied. In the example given, the length of time required to reach the point where this relay applied the short circuit after the voice currents pass the input of the amplifier-detector is 0.05 second. It is seldom that this lag is greater than 0.1 second in practical four-wire circuits.

It is seen from the two above paragraphs that it is desirable for a four-wire echo suppressor to possess a moderately short operating time and a longer releasing time. How this is accomplished will be described in what follows.

Description of Four-Wire Echo Suppressor

In Fig. 3 is shown a circuit diagram of one-half of the echo suppressor, which is shown complete but in less detail in Fig. 2a. It consists of two vacuum tubes operating in tandem, the first functioning as an amplifier and the second as a combined amplifier and detector.

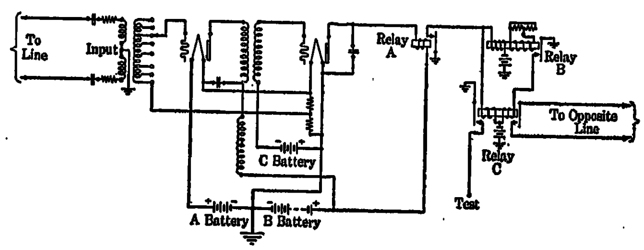

Fig. 3—Circuit Diagram of One-Half of a Four-Wire Echo Suppressor

As was shown in Fig. 2a the voltage impressed on this amplifier-detector combination is derived from speech currents passing over one side of the circuit, while the relay controlled by this combination short-circuits the other half of the circuit.

The voltage input to the amplifier tube is supplied through a transformer which is broadly tuned by series condensers to produce a circuit efficient at the more important voice frequencies but inefficient at other frequencies, particularly below 500 cycles per second. The circuit thus functions to minimize the effect of noise currents on the operation of the relays. Likewise, in the interstage transformer coupling, emphasis has been placed on securing the maximum voltage step-up to the detector grid in this same frequency region. To avoid any harmful reaction upon the transmission characteristics of the main circuit which might result from bridging on an input circuit whose impedance varies so greatly over the speech frequency range, this circuit is arranged to have a high impedance. The input transformer is also provided with a series of taps

on one of the windings, thus affording a simple means of varying the sensitivity of the device.

The detector tube is operated with a sufficiently large negative grid potential to reduce its space current to zero, or nearly so, when no input is applied to the circuit. Accordingly, relay A which is connected in the plate circuit is normally in a released condition. When

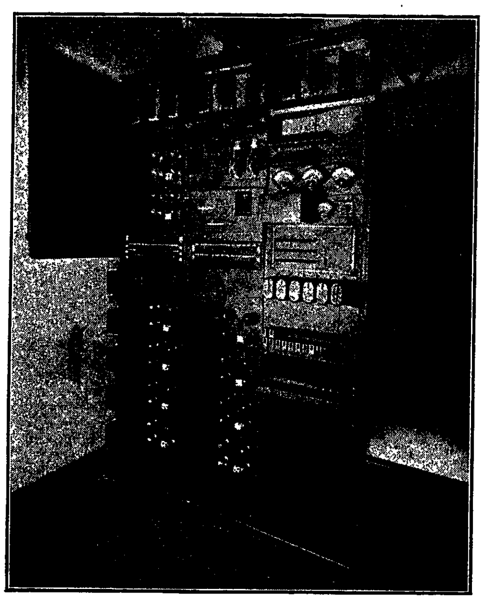

FIG. 4—INSTALLATION AT HARRISBURG, PA.

speech currents are applied to the circuit the voltage on the grid of this tube fluctuates. Those variations which make the grid more negative produce no effect but those which make it more positive allow pulses of current to pass through relay A, tending to operate it. A condenser is bridged from plate to filament of this tube, the purpose of which is to average these rectified half waves of applied speech so as to insure smooth and positive operation of the relay.

When speech is applied to the circuit the resulting operation of relay A does two things. It causes the operation of relay C by connecting a ground to one of its windings, and it likewise operates relay B. The operation of relay C short circuits the opposite line. The time required for the operation of relay C, in response to a sustained alternating e. m. f. suddenly applied to the input of the amplifier detector, is about 0.02 second. As pointed out above, operation in this length of time takes care of conditions in the large majority of cases encountered on four-wire circuits.

The function of relay B is to provide a delay in the release of relay C after speech has ceased to be applied to the suppressor circuit input and relay A has released. Its operation in response to that of A, it will be noticed, connects ground to a second winding on relay C which will then in turn remain operated as long as the relay B maintains this auxiliary current after the relay A has released. Relay B is made slow releasing by an auxiliary winding closed through a low resistance, and its time of release can be adjusted over a considerable range to meet different operating conditions by changing the value of this resistance. Differing adjustments are rarely called for in practise and these relays are normally set for a releasing time of 0.1 second.

A number of echo suppressors have been installed at Harrisburg, Pa., where they are now in service on a group of four-wire circuits. Fig. 4 is an illustration of this installation of four-wire echo suppressors. Fig. 5 shows a close-up view of an individual panel from the front. Both halves of the suppressor working on a single circuit are mounted together on one panel. The method of mounting and the type of equipment in the echo suppressors are in general quite like the standard for the four-wire circuits with which they operate. Although in Fig. 3 the battery supply circuits are shown individual to this set, in the actual installation common batteries are used. The four filaments of the tubes on one panel are operated in series from the 24-volt battery.

The operation and maintenance of these devices involve little that is different from standard repeater equipment. There is one test, however, which is employed in checking the times of functioning that perhaps deserves special mention. This test involves observing the time needed for the suppressor to go through any number of complete cycles of operation and release. To make this test, the short-circuiting contacts of relay C and the input of the suppressor circuit are connected together and to an oscillator as shown in Fig. 6. As soon as the oscillator is connected to the input, the relay train begins operating and the shorting contacts of relay C in turn cut off the applied voltage. This short circuit is maintained across the input for a time by the slowness of release of relay B as previously explained. When it finally releases and in turn

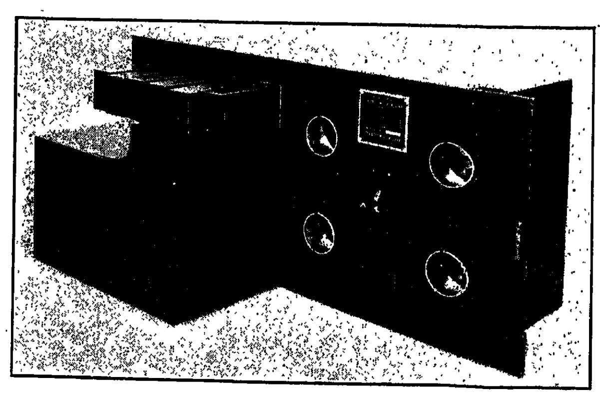

FIG. 5—FRONT VIEW OF ECHO-SUPPRESSOR PANEL

releases relay C, the suppressor again operates and the process is repeated over and over. At each repetition of the cycle the auxiliary contacts of relay C apply a ground to the test terminal which is connected to a counting device. With the aid of a stop-watch the number of cycles in any given time is readily determined and thus the time of a single cycle of operation.

This time is the sum of the time needed for relays A and C to make and the time needed for relays A, B and C to release. By observing the uniformity and smoothness of operation with which this cycle is carried out the tester can check the adjustment of all the relays. If relays A and C are properly adjusted so that their operation is positive and uniform, the operating time

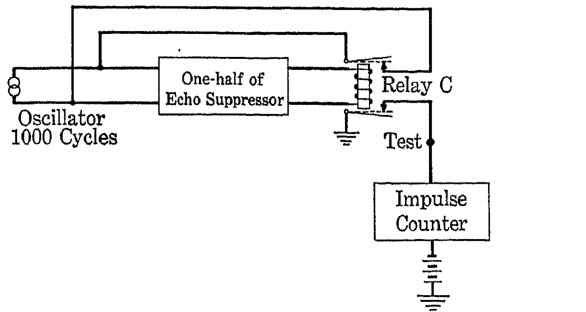

Fig. 6—Circuit for Testing Time of Operation and Release

will vary but slightly from the proper value of about 0.02 second. The test, therefore, gives a good measure of the longer release time which would normally be about 0.1 second.

Some General Considerations

As pointed out above, when an echo suppressor is applied to a telephone circuit, the telephone circuit remains operative in both directions when it is in the normal condition, *i. e.*, when no one is talking. It is only when talking is done over the circuit that the path for transmitting in the reverse direction, which is then useless so far as talking is concerned but which is harmful because it furnishes a path for the echoes, is blocked. The advantages gained by this arrangement are: (1) there is no possibility of cutting off the first part of words owing to the fact that the transmission path actually carrying the speech is unaffected by the switching operations; and (2) if the relays should fail to operate because the voice currents happen to be very weak, the listener at the distant end would still hear the speaker although both he and the talker might also hear some echoes. Weak speech does not, in general, give rise to such serious echoes as does strong speech. Therefore, when the voice currents happen to be so weak that they fail to operate the suppressor, the echoes produced may not be serious.

Now, in order to obtain these advantages it is necessary to face the possibility of "singing," since when no one is talking, the paths for transmission in both directions remain in their normal operative condition. It is evident that if the repeater gains are raised high enough, singing will begin exactly as it would if the circuit contained no echo suppressor. If singing starts in a circuit containing an echo suppressor, the circulating currents will build up until they become strong enough to cause operation of the relay associated with one half or the other of the echo suppressor so that one of the transmission paths will be blocked. This will temporarily stop the singing. It will commence again, however, as soon as the relay falls back to its normal condition. Thus, a chattering condition is produced which, in general, would not be tolerated.

In order to overcome the limitations which may be set on a circuit by the possibility of singing, it is necessary to go back to the old idea of a voice-controlled system in which the transmission is blocked when no one is talking. It is not necessary, however, to block both of the transmission paths since if one path only is blocked, singing evidently cannot occur.

Fig. 7 shows one of the possible arrangements of a voice-operated system in which singing is prevented. It will be seen that this arrangement includes an echo suppressor to which an additional relay D has been added, which keeps the upper transmission path blocked when the circuit is normal, *i. e.*, when no one is talking. Singing is, therefore, not possible when the circuit is normal.

Now, when talking is done at Station W the voice current waves, on arrival at the middle of the circuit, cause operation of the two relays associated with the amplifier-detector W-E. An appreciable length of time is required, of course, to operate relay D. To avoid the possibility of cutting off the initial parts of words during the time before relay D operates, it is desirable to delay the main transmission. What has been called a "delay network" has, therefore, been included as shown in the figure. This delay network may, of course, assume various forms, one of which might be an artificial loaded line or low pass filter. By including such a delay network, the voice currents can be retarded long enough to give the contacts of relay D time to clear the path before the voice currents reach the point in the circuit where the transmission has been blocked.

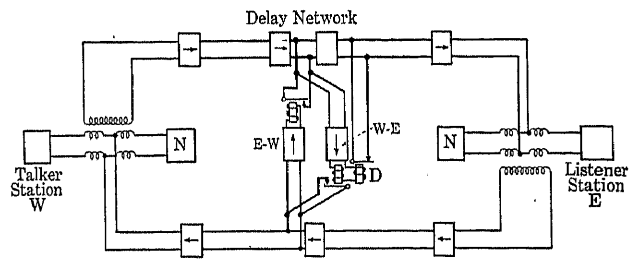

Fig. 7—Four-Wire Circuit with Voice-Operated Device Arranged to Suppress Echoes and Singing

In addition to clearing a path for the main transmission in the direction from W to E, the transmission path from E to W is blocked by the operation of the other relay associated with amplifier-detector W-E. The circuit, therefore, has no chance to sing when in the condition for talking from W to E.

When talking is done at Station E, the relay associated with amplifier-detector E-W is operated. This

prevents the echo returning from Station W from operating the relays associated with amplifier-detector W-E. For talking in this direction, therefore, the upper transmission path remains blocked. There is, therefore, no chance for singing, as was also the case for the other conditions.

By adding the delay network, one of the disadvantages of voice-controlled relay systems which keep transmission normally blocked is overcome in large part. This is the clipping off of the first parts of words, the possibility of which was mentioned above.

There remains, however, an important disadvantage in the fact that it is necessary that the voice currents never fail to operate relay D. If they did fail to operate this relay, the listener at Station E would hear nothing. It is necessary, therefore, that the amplifier-detector-relay system W-E be sensitive enough so that the voice currents which traverse the upper path in the four-wire circuit will never fail to cause operation of its relays.

On the other hand, noise currents which traverse the upper path in the four-wire circuit must never cause operation of the relays associated with the amplifier-detector W-E. Such false operation would, of course, prevent transmission over the lower pair of wires from Station E to W and would, therefore, render the four-wire circuit inoperative.

To overcome the singing limitation, it is thus seen that it has been necessary to produce a device which requires greater sensitivity and is, therefore, more seriously affected by noise currents than is a simple echo suppressor. This is in addition to the further complications involved.

Now, in applying simple echo suppressors to long telephone circuits, it is in general not the possibility of singing, but rather, the necessity of avoiding false operation of the relays by noise currents that constitutes the most serious limitation. This is discussed in more detail in what follows. For the present, it is sufficient to note that in the case of most long-distance telephone circuits the method of avoiding singing, which has been described, appears to offer possibilities of limited application only.

Echo Suppressors Applied to Other Types of Telephone Circuits

It will, of course, be understood that in practise a normal commercial telephone circuit is always two-wire at the two ends where connection is made to the subscribers' instruments. The rest of the circuit may be entirely four-wire or it may be all two-wire, or a combination of both. The application of echo suppressors to circuits which are not all four-wire will now be considered.

One important practical case is that where a four-wire circuit is sandwiched in between two two-wire circuits. Such a case is illustrated in Figs. 8 and 9. Fig. 8 shows conditions without an echo suppressor while Fig. 9 shows conditions with an echo suppressor. In both figures, a diagram of the circuit itself is shown in the upper part a, while in the lower part b are shown the paths of the direct transmission and echoes. These transmission paths illustrate the condition when talking is being done from Station W to Station E. In both figures, for simplicity, the first echoes affecting the talker and listener only are shown, echoes of these echoes being ordinarily of little importance.

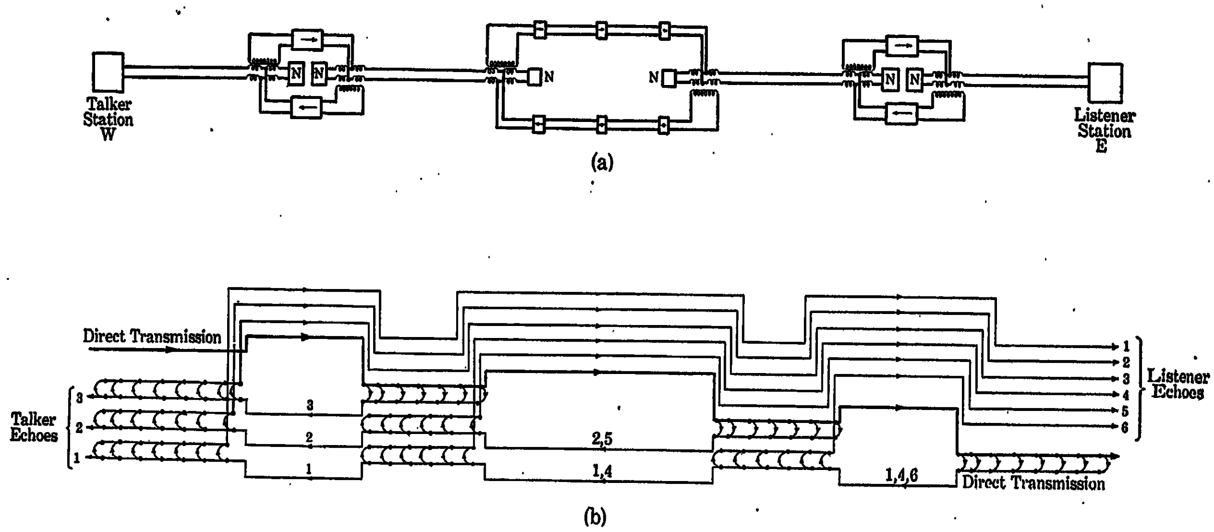

Fig. 8—Echoes in Combination Two-Wire and Four-Wire Circuit

It will be observed in Fig. 8b, which represents the condition of affairs when no echo suppressor is used, that the listener hears echoes coming from as many as six different paths. The talker hears echoes from three paths. Now compare this with Fig. 9b which represents the condition of affairs when an echo suppressor is employed. It will be observed that all of the echoes which return through the four-wire circuit have been suppressed. Echoes from only two paths now reach the listener, while echoes from only one path now reach the talker. Furthermore, the echoes affecting both talker and listener, which remain when the echo suppressor is

employed, are those whose paths are comparatively short. The echoes whose paths are the longest have been cut off by the action of the echo suppressor. These echoes which travel over the long paths have the greatest lags and are usually most serious. Consequently, cutting these echoes off makes a material improvement possible even though the echoes whose paths are short remain.

In order that an echo suppressor may operate satisfactorily on a circuit, such as the one shown in Fig. 9a, it is necessary that the time required for operation of the relays be short enough so that, if there are any serious echoes returning over short paths, the relays will operate before these reach the suppressor. After operation, the suppressor relays must remain operated until the echoes whose paths are the longest have been suppressed.

In the case of telephone circuits worked entirely on a two-wire basis, echoes may also constitute an important limitation when the circuits are electrically long. On such circuits it is also generally true that the most serious echoes are those whose paths are the longest, namely, those which travel back and forth between points at or near the ends of the circuit. The application of an echo suppressor to one of the repeaters in a two-wire circuit, therefore, offers possible advantages.

If it is imagined that the four-wire circuit shown in Fig. 9a is shortened so that the whole four-wire circuit is located at one point, the two-wire condition would be represented. The time lags which were introduced by the lines comprising the four-wire circuit are now absent. It is possible, however, to introduce delay networks into the two sides of the two-wire repeater to which the echo suppressor has been applied, so as to make it effectively a four-wire circuit, although the two ends are not geographically separated. This would evidently allow the four-wire echo suppressor which has already been described to be applied without modification.

By using somewhat higher speed relays and switching systems, however, it has been found possible in tests which have been made, to obtain satisfactory operation on an all two-wire circuit without introducing devices to produce time lags. This is possible because the important echoes in a two-wire circuit generally lag enough to allow time for relays to operate. Only a few of the echoes return to the suppressor with very small time lags. Some of these can be allowed to pass without causing appreciable impairment, provided they are not strong enough to cause false operation of the relays which block the main transmission path.

Possibilities and Limitations of Echo Suppressors

The curves in Fig. 10 show how, when no echo suppressors are employed, the echo effects limit the extent to which the over-all loss of a circuit may be lowered by the application of repeaters.[6] The curves in this figure apply to four-wire circuits of various lengths (without echo suppressors) used to handle terminal business, *i. e.*, connections to subscribers not involving the use of other toll lines in tandem with the four-wire circuit. It is assumed that simple compromise networks giving only a rough degree of simulation of the impedances of the terminal circuits are used. The curves, which are based on experimental data, indicate roughly how the over-all volume efficiency must be limited to keep echo effects small enough so that they are not considered disturbing when ordinary telephone conversations are carried on.

Consider, for example, what are the limitations for

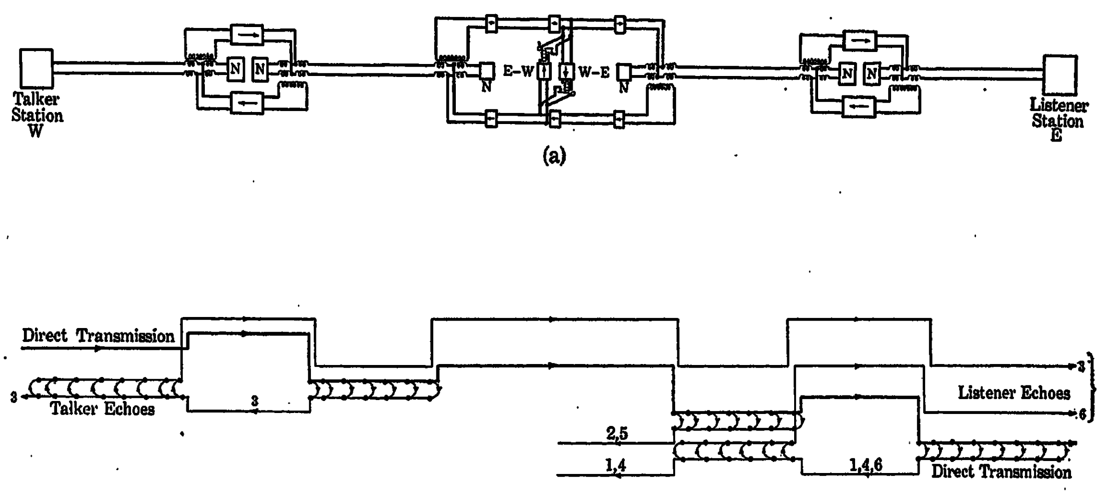

FIG. 9—ECHO SUPPRESSOR CUTTING OFF ECHOES IN COMBINATION TWO-WIRE AND FOUR-WIRE CIRCUIT
(a) Combination two-wire and four-wire circuit with echo suppressors
(b) Paths of direct transmission and echoes

6. The ordinates on this figure are in terms of the new "transmission unit" abbreviated "TU," which is defined in a paper entitled "The Transmission Unit, etc." by W. H. Martin, JOURNAL of the A. I. E. E., June 1924. Also in the article entitled "The Transmission Unit" by R. V. L. Hartley, *Electrical Communication*, July 1924.

a circuit 1500 miles (2400 km.) long, with extra light loading. One of the curves which is marked "Talker" shows that in order to keep the echoes which affect the talker sufficiently low, requires that the over-all loss in the circuit be made no lower than about 14 TU.[7] The other curve marked "Listener" shows that keeping the echoes which affect the listener within proper limits is a less severe limitation, requiring only that the net loss be made no less than about 7 TU. Singing of a circuit such as this would not ordinarily begin until the loss was reduced to zero or even, perhaps, made less than zero, *i. e.*, an over-all gain.

If an echo suppressor were applied to a circuit such as the above, a maximum improvement of the order of 14 TU might be looked for. As a matter of fact, results as good as this have been obtained in tests.

In order to obtain a result as good as this requires, of course, that the echo suppressor be given a sensitive enough adjustment so as to cut off substantially all of the echoes, even when the voice currents are weak. When given such a sensitive adjustment, there will, of course, be a tendency for noise currents to produce false operation. In certain cases, avoiding such false operation may require that the sensitivity of the echo suppressor be reduced to the point where weak voice currents fail to operate the relays. In such cases, results as good as the above will not be obtainable.

In practise, little or no trouble from false operation due to noise within the cable facilities, comprising a four-wire circuit, is experienced. When the connections to the terminals of the four-wire circuit are short, therefore, so that, on these terminal connections, the noise currents are comparatively weak and the voice currents large, it is possible to realize in practise the full theoretical possibilities from an echo suppressor. In other words, it is possible to work a four-wire circuit under these conditions at a very low loss, or even an over-all gain.

When the lines connecting the subscribers with the terminals of the four-wire circuit are long, so that the voice currents may be weaker and, perhaps, the noise currents may also be stronger, results as good as this may not be obtainable. However, even in this case, a material improvement can usually be effected by the echo suppressor.

For the condition in which a four-wire circuit is switched to a variety of different circuits at the terminals, it was shown in Fig. 10 that the requirement that echoes should not disturb the talker is more severe, so far as limiting the minimum loss is concerned, than the requirement that echoes should not affect the listener's transmission. It will, of course, be obvious that talkers connected to either terminal of the four-wire circuit through connections involving small transmission losses will hear louder echoes than will talkers connected through circuits having larger losses. In other words, the minimum net loss of a four-wire circuit used in this way is limited by the requirement that the talkers connected through low losses should not receive too much echo. Now, of course, the relays in the echo suppressor will respond most readily to these talkers. Satisfactory operation of the relays for these talkers will, therefore, be secured even though the echo suppressors be given such an adjustment that the relays will not respond to the voice currents from talkers connected to the circuit through a higher loss. Cutting

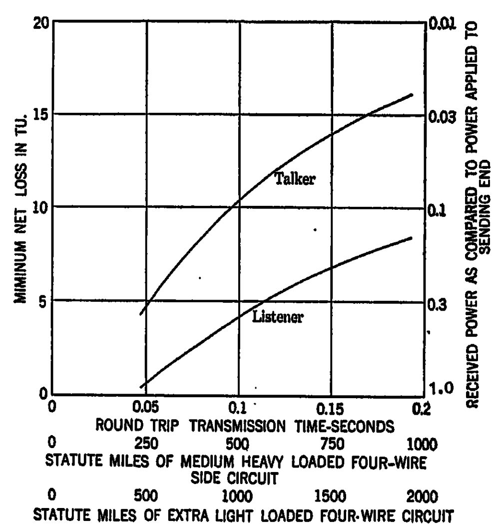

FIG. 10—ECHO LIMITATIONS ON LOSS OF A FOUR-WIRE CIRCUIT

off the talker echoes in the case of the connections involving low losses, therefore, makes it possible to materially lower the loss introduced by the four-wire circuit even though other echoes are not cut off.

In the curves of Fig. 10 it is seen that for a 1500-mile (2400 km.) extra-light loaded circuit the possible improvement which may be secured by cutting off the talker echoes from low loss connections may be as much as 7 TU even though echoes from other connections are not cut off.

In general, for combinations of four-wire and two-wire circuits and for circuits which are all two-wire as well, talker echoes are also more serious than listener echoes provided that the impedance irregularities at intermediate points in the circuit are small, as is usually the case with high grade circuits. Consequently, echo suppressors make it possible to effect improvement in many cases even if the line noise which is present requires reduction of the sensitivity of the echo sup-

7. Due to transmission variations of the different parts comprising long telephone circuits such as these, the over-all loss varies to a certain extent with time. In practise, adjustments of circuits in the Bell System Plant are made often enough to keep the variations within about $\pm$ 2 or 3 TU. The working net loss must, of course, be made high enough so that echo difficulties will not be encountered when the variations combine in such a way as to give the over-all, or net loss, its minimum value. For example, in the case of the 1500-mile (2400 km.) circuit above, if it is assumed that the circuit is limited by echoes to a 14 TU minimum net loss and that it is maintained within limits of variation of $\pm$ 3 TU, the working net loss would be 17 $\pm$ 3 TU.

pressors to the point where weak voice currents fail to operate the relays. If the line noise requirement does not enter as a limitation, a greater improvement is, of course, possible as is also the case with all four-wire circuits.

Conclusion

The echo suppressor, which has been described, offers attractive possibilities in supplementing other methods for obtaining satisfactory transmission over long two-way telephone circuits.

The application of an echo suppressor to a telephone circuit requires no changes in the circuit itself, the echo suppressor being merely attached to the circuit at some convenient point.

For any particular type of circuit, the advantages to be gained by using echo suppressors increase with length. For a given circuit length the advantages to be gained are greater with low-speed than with higher-speed circuits.

Echo suppressors offer the greatest possibility of usefulness on cable circuits, owing to the inherent low-speed and quietness of such circuits. Generally speaking, the application of echo suppressors to cable circuits offers possibilities of effecting savings by allowing the use of heavier weight, lower-speed loadings in place of lighter weight, higher speed loadings, as well as the imposition of less severe requirements as to impedance uniformity of the circuits.

Discussion

S. P. Shackelton: When any device, which differs as fundamentally from the existing order of things as the echo suppressor is introduced into a working system there will arise problems as to its practical application. To a very large extent these problems have been met in the installation at Harrisburg which is referred to in the paper. It may be profitable to review somewhat the experience obtained in that installation.

It will be realized that the proper association of an echo suppressor with a telephone circuit is essential for satisfactory operation. This involves not merely obtaining the correct circuit connections in the office where the suppressor is located but also in securing a suitable circuit layout for the entire length of the telephone circuit. While considerable latitude is possible in the geographical location of the suppressor, still the time intervals introduced by the relays require that it be located at some distance from the ends of the circuit. The introduction of telephone repeaters a number of years ago imposed somewhat similar restrictions as to circuit-layout changes. These factors all tend to eliminate temporary circuit-layout changes and to confine the changes to those authorized after consideration of complete circuit requirements. This is particularly true on toll cable where the need for emergency changes is less frequent than with open-wire lines.

A consideration of the operating conditions to which echo suppressors are subjected suggests certain differences between the relay requirements and those usually met by telephone relays. As a rule relays are given specified adjustments, either mechanical or electrical or both, and then are expected to function in the circuit with a certain margin between the adjusted condition and the normal working condition. In the echo suppressor no such margin is possible, the relay simply operating on voice currents of sufficient magnitude and failing to operate on weaker ones. The margin here required is not possible in the usual sense by means of relay adjustment and hence the provision is made for varying the sensitivity by means of different connections to the input transformer. It will probably not be possible to adjust all circuits for the same sensitivity owing to the different conditions of noise and energy level encountered. Also the margins may differ widely. In fact, there may be no margin in the usual sense, the suppressor being adjusted to operate only on the relatively strong voice currents.

No unusual maintenance requirements are introduced by the use of echo suppressors in the plant. The conditions just outlined call for somewhat different treatment, however, than is usually followed. The paper outlines the operation of a testing circuit for checking the relay adjustment. Such a circuit indicates the combined effect of all the time intervals introduced by the different relays in normal operation modified by the action of the amplifier rectifier in short circuiting its input. Even with the use of such a testing circuit it is necessary to give the individual relays their proper adjustments. Also some experience is necessary in the use of the testing circuit to interpret its results. Provision is made for reading the current in relay *A* Fig. 3, in normal operation and at the same time it is possible to monitor on the suppressor. In this way a check on the operation can be obtained. This is particularly desirable as the relay *A* is subject to severe operating conditions and requires closer maintenance than would be the case for direct-current operation. It is to be noted that the entire operation of the circuit is dependant on relay *A*.

In usual telephone practise, even with the simplest circuits, whenever relays are involved, it is customary before putting a circuit in operation to check the relay adjustment by means of a current flow and give the prescribed current-flow adjustment for those relays. An interesting incident in connection with the installation at Harrisburg, might be brought out. The suppressors were all assembled completely in the Western Electric Company laboratory, tested out and shipped to Harrisburg. In shipment, relays cannot be expected to maintain their adjustment. The men who put the suppressors into service at Harrisburg had had no previous instructions as to relay adjustments, and yet in spite of that fact when they completed the installation, they put one of the suppressors on a telephone circuit which was set up for trial without any check whatsoever on the adjustment, and it worked along very nicely. This would bear out our assumption that in spite of the fact that maintenance conditions may be somewhat different, they are not any more severe than any normal circuit operation.

H. S. Foland: In connection with echo suppressors for long telephone circuits, it occurs to me that some additional discussion of the trial installation at Harrisburg may be of interest.

The paper mentions this installation and shows a picture of the apparatus as installed. Harrisburg was selected as a suitable location for a trial installation of this apparatus for several reasons:

First: There were four-wire cable circuits between New York and Pittsburgh, so loaded that any material extension of them should result in noticeable echo effects. These circuits were of course, provided primarily for New York-Pittsburgh circuits.

Second: It was possible to extend these circuits from Pittsburgh by means of several different types of facilities to points sufficiently distant to produce the desired echo effects.

Third: Harrisburg is suitably located between New York and Pittsburgh to provide the time interval required for the apparatus to function and to permit the operation of the circuits to be observed from the New York end.

Fourth: Harrisburg is a repeater point on these cable circuits, (approximately at the center of the New York-Pittsburgh section) and thus a suitable point for an echo-suppressor installation.

Ten 19-gage, medium heavy loaded four-wire cable circuits between New York and Pittsburgh were taken and the Pittsburgh terminals extended to a number of distant points over a variety of types of facilities:

Four circuits were extended to Chicago by means of four-carrier telephone channels;

One circuit was extended to Chicago by means of an open- wire circuit;

One circuit was extended to Cincinnati by means of an open-wire circuit;

Three circuits were extended to Cleveland by means of cable facilities between Pittsburgh and Cleveland, in part four-wire and in part two-wire;

One circuit was extended to Detroit by means of an open-wire circuit to a point near Toledo and from that point to Detroit in a two-wire cable circuit in the Toledo-Detroit Cable.

It will be appreciated, I believe, that this was a rather comprehensive selection of facilities on which to institute a trial and that the results obtained from these several combinations might reasonably be taken as indicative of the performance of the echo suppressors.

These circuits were then equipped with the echo suppressors at Harrisburg and a close supervision maintained of their performance, both from the standpoint of equipment trouble and from the standpoint of the effects of the echo suppressors on the operation of the circuits. The data collected have indicated that these echo suppressors function in an effective manner and that they have not been subject to an abnormal amount of trouble.

The paper points out that this apparatus operates so as to short circuit the return transmission path. This was an interesting feature from an operating standpoint, since the thought naturally occurs that such an arrangement would give the speaker right of way over the circuit and that the listener at the opposite end of the circuit would be compelled to wait until the speaker had finished or at least had made an appreciable pause before it would be possible to interrupt him. A very considerable number of conversations were carefully observed to determine if there was any indication of this effect, and it was established that the users of these circuits carried on conversations in a perfectly normal manner, interrupting one another in apparently the same manner as on circuits not so equipped. This result may be explained, of course, by the very short intervals of time involved in the operation of this equipment.

From an operating and maintenance standpoint, there was something disturbing in the thought of giving service dependent upon the operation of relay equipment a considerable distance from the speaker and actuated by the speaker's voice, but experience with the Harrisburg installation has indicated that the echo suppressor is a practical device, both effective and reliable in its operation.

A. B. Clark: I do not want to leave the impression that echo suppressors are vitally needed on all cable circuits. As a matter of fact, there are in service today types of cable circuit capable of giving a good grade of commercial telephone transmission for distances of at least 1000 mi. without any echo suppressors at all. However, it is possible that in certain cases echo suppressors may allow the desired transmission results to be secured more cheaply.

The echo suppressors which have been installed at Harrisburg and have already been referred to are working on types of cable circuit which were designed for use up to moderate distances only. When the echo suppressors were placed on these circuits, the circuits were intentionally pushed beyond the limits for which they were originally designed. If the "long-distance type of cable circuit" were available, it would be possible, for the circuit lengths involved in this case, to dispense with the echo suppressors at Harrisburg.

Frequency Multiplication
Principles and Practical Applications of Ferro-Magnetic Methods

BY N. LINDENBLAD[1] and W. W. BROWN[2]
Non-member Non-member

INTRODUCTION

MANY of the principles involved in the multiplication of frequencies by the use of highly saturated iron cores have been established by early investigators in the field of radio engineering. A number of articles on the subject have been published by various investigators, although very little information about the performance of frequency multipliers under load conditions was found.

Frequency multipliers were investigated in connection with the development of the 200-kw. Alexanderson radio system; however, it was found entirely feasible to build 200-kw. alternators which would generate directly the frequencies required. During these and other investigations, frequency multipliers were used to generate a wide range of frequencies in a study of transmission phenomena, and very satisfactory performance of the multipliers was obtained. Simplified circuits were developed and communication established between Schenectady, New York, and New York City with very small amounts of power. Both telegraphy and telephony were used.

This paper describes some of the results to date of a joint investigation by the Radio Corporation of America and the General Electric Company, and is intended to present, in a condensed form, physical conceptions of the operation of iron-cored frequency multipliers. The main object of the investigation is to determine the possibilities of increasing the usefulness of the 200-kw. Alexanderson alternators. Results, to date, include a number of improvements in the design of frequency multipliers and arrangement of circuits, and indicate that frequency multipliers may be used advantageously with 200-kw. alternators to meet special requirements. Indications are that frequency multipliers could also be used in industrial applications where relatively large amounts of power at relatively high frequencies are required.

PRINCIPLES OF SINUSOIDAL AND SHOCK EXCITATION

Any periodic curve is the resultant of a number of sinusoidal curves of various amplitudes and frequencies, and these can be separated by mathematical treatments in accordance with the well-known Fourier's theorem. The periodic fluctuations of the distorted magnetic field in frequency multipliers has thus been studied, affording a basis of incomparable value in such work.

In practical work, with iron-cored frequency multipliers, a distinct line may be drawn between two methods of excitation,—the sinusoidal and the shock methods. Considered theoretically, the former represents a condition in which the resultant flux curve consists, in its elements, of only two sine curves, the fundamental and the harmonic desired. The resultant flux curve obtained when using the shock excitation method may be resolved into a greater number of elementary waves.

The sinusoidal method is more and more nearly approached as the desired harmonic is supplied with new energy during the greater part of the duration of its period. In the well-known case of doubling the frequency of the fundamental by means of a double unit arrangement, the sinusoidal method is predominant. The arrangement consists of two separate multipliers, each saturated to the correct degree by direct current and connected in such a way that a distortion of the magnetic flux takes place alternately in each unit for each half-cycle of the fundamental. The magnitudes of direct current and alternating current can be so chosen that the voltage induced by the distorted field is sinusoidal and is the second harmonic of the fundamental frequency.

As the art of the ferro-magnetic method advanced, it was found by various investigators that higher efficiencies could be obtained by the shock excitation method; that is, instead of obtaining an induced e. m. f. of sinusoidal character by the sinusoidal method, it is better to force the device to its maximum efficiency by shock excitation. The output of a given multiplier, when shock excited, has been found in nearly all cases to be larger than when adjusted to induce a sinusoidal e. m. f.

1. Radio Corporation of America, New York, N. Y.
2. General Electric Co., Schenectady, N. Y.

Presented at the Spring Convention of the A. I. E. E., at St. Louis, Mo., April 13-17, 1925.

It was found that, when doubling a fundamental frequency, the difference between the two methods from an efficiency and output standpoint was not very great. However, as the multiplication ratio was increased, the efficiency of the sinusoidal method dropped very rapidly. When using the sinusoidal method at higher multiplication ratios, a number of

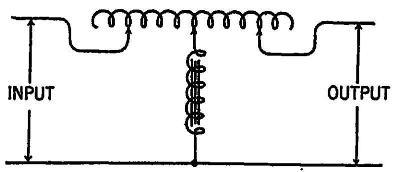

Fig. 1—Frequency-Multiplier Circuit

units are required, combined in cascade, and the over-all efficiency is the product of the efficiencies of the individual stages. On the other hand, when using the shock excitation method, the desired multiplication is accomplished in one stage, and, though the efficiency of this one stage may be lower than the efficiency of one of the stages in cascade, the over-all efficiency will usually be higher.

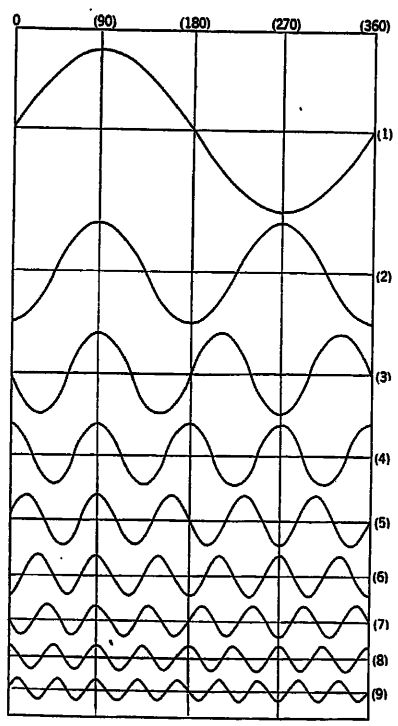

Fig. 2—Phase Relations Between a Fundamental Wave and Various Harmonics

When using the shock excitation method, the energy is supplied to the harmonic during a relatively shorter time period and assumes a transient character. This introduces two problems which become more difficult to solve as the multiplication ratio is increased.

The first problem was manifest in the inability to load the system. The fundamental frequency circuit would not oscillate unless the kv-a. of the circuit was made relatively large, since using relatively low kv-a. in the circuit, little energy is stored and the disturbance at the time of the energy transfer to the harmonic circuit is too great. Also by employing a circuit of reasonably large kv-a., when working with transient impulses, a cushion effect is obtained across the multiplier to allow the induced voltage peaks to develop. This is accomplished by the resonant circuits connected to the multiplier being series circuits of relatively high inductive reactance. A series-tuned circuit has an infinitely high reactance to transients, whereas a

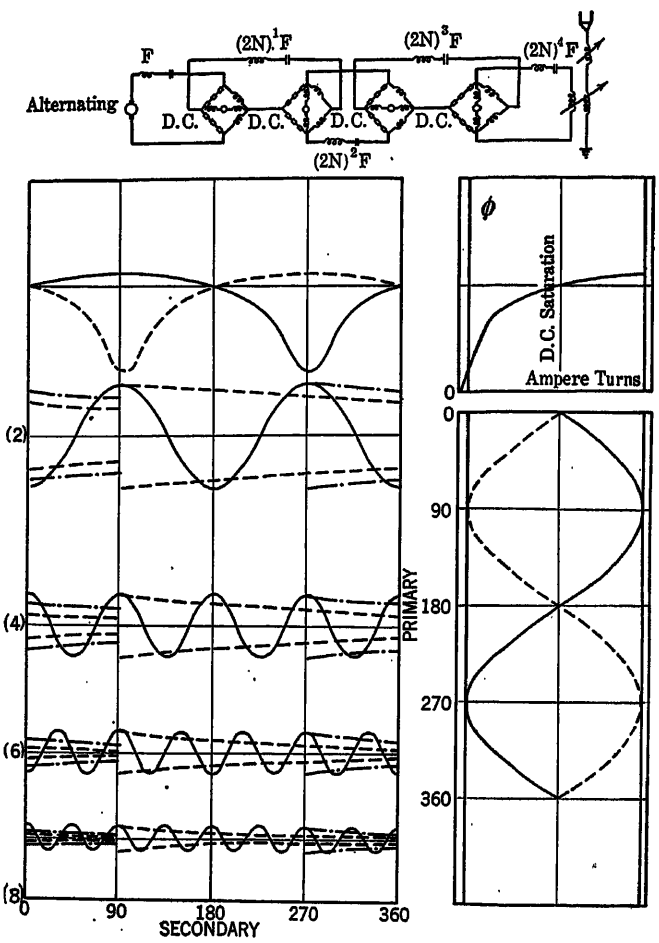

Fig. 3—Half-Cycle Excitation Multistage Arrangements of Frequency Multipliers for the Production of Even Harmonics

parallel-tuned circuit has zero reactance to transients. The reactance in the resonant circuit also prevents the fundamental or some undesirable harmonic that may accidently develop from entering the output circuit. In the case of doubling the frequency, the reactance required to separate the two frequencies needs to be larger than would be required by any of the reasons previously given. To avoid an unduly large reactance for this case a circuit was developed by E. F. W. Alexanderson, which is shown in Fig. 1. The circuit consists of an auto-transformer arrangement, utilized in such a way that the section from one end of the coil

to its intermediate tap comprises the inductance in the resonant circuit for the fundamental frequency. The remaining portion of the coil from the intermediate tap to the opposite end comprises the inductance of the resonant output circuit. The intermediate tap of the coil to which the multiplier is connected is chosen so that the voltage induced in one section from the other section neutralizes the voltage impressed on the intermediate tap from the multiplier. For circuits arranged for higher multiplication ratios, this arrangement ceases to function on account of the pronounced transient character of the energy transfer. This

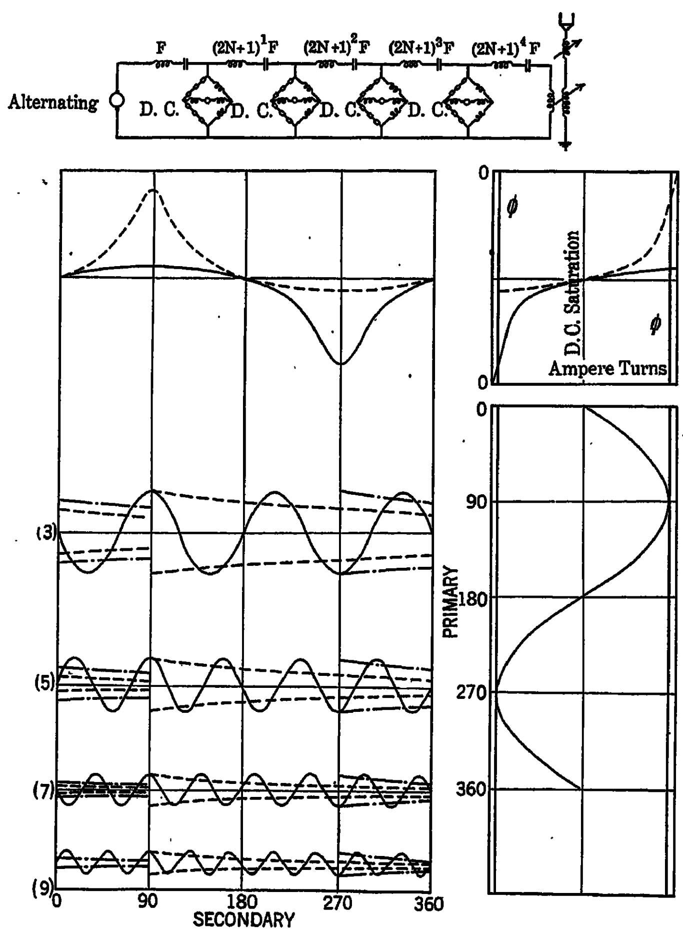

FIG. 4—HALF-CYCLE EXCITATION MULTISTAGE ARRANGEMENT OF FREQUENCY MULTIPLIERS FOR PRODUCTION OF ODD HARMONICS

circuit is not required for higher multiplication ratios, as the difference between the input and output frequencies is so great that ample separation is afforded through simple tuning.

The other problem introduced by the shock excitation method, which increases in difficulty with increased multiplication ratios, is the damping effect in the output circuit. Difficulties due to this phenomenon were first encountered in a transmission test on a wave length of 3200 meters (94,000 cycles) which involved quadrupling a fundamental frequency of 23,500 cycles. The test was very successful in all respects, except that it was difficult to obtain a clear note at the receiving station. The reasons were that the oscillations were damped and declined as a logarithmical function, thus giving a signal not as clear as obtained from a wave of constant amplitude. Side frequencies were also partly responsible for the impurity of the note. These side frequencies constitute a quite serious problem in radio applications, as they are the results of characteristics inherent in the circuit. If a circuit has more than one degree of freedom, the oscillations, when left without a continous guiding e. m. f., degenerate into oscillations corresponding to the various degrees of freedom of the circuit. The conditions are generally not improved by loosening the coupling between the circuits, as this merely tends to bring the various degrees of freedom closer together. It was therefore realized that, in order to improve the arrangement so as to give it real commercial value, the method of energy feed must be greatly improved.

As has been pointed out, the side frequencies and the damping effect were the results of too infrequent energy impulses. Some improvement could be obtained by means of a relatively large energy storage or tank circuit, but such an arrangement would consume relatively large amounts of power. A much better way would be to increase the number of impulses and thereby provide a more frequently occurring guiding voltage for the oscillations.

CIRCUIT IMPROVEMENTS FOR SHOCK EXCITATION

If the multiplication ratio is not too high, it is sufficient to obtain one impulse from each half-cycle of the fundamental. The connection arrangements to obtain the correct phase combinations of the harmonics are indicated in Figs. 2, 3, and 4. It should be noted that the circuits and relations differ for odd and even harmonics. When working with higher multiplication ratios, the one impulse from each half-cycle of the fundamental is not sufficient. One arrangement by which a greater number of energy impulses can be supplied to the harmonic is by the use of polyphase power supply. A similar arrangement has been suggested by Mr. Dornig[3], who also offered a method of combining a harmonic of one fundamental frequency with a harmonic from a different fundamental frequency. The use of polyphase or equivalent excitation is vital in circuits to transfer large amounts of power, as the reactive circuits can be reduced considerably and perhaps eliminated entirely if there is an energy impulse for each half cycle of the harmonic.

ADVANTAGES OF "DIP" METHOD

Regarding the methods of exciting the multiplier and utilizing the bend of the magnetic curve in the most efficient manner, it has been found advantageous

3. Contribution to Frequency Transformation by Means of Iron Core Inductance, *Elektrotechnische Zeitschrift*, Vol. 45, No. 42, October 18, 1924, pp. 1107-1108.

to employ direct-current excitation regardless of whether the harmonic is an odd or an even multiple of the fundamental. While it is true that odd harmonics can be produced without saturating the multiplier with direct current, a considerable increase in efficiency is obtained by using direct-current excitation. The reason is that when using direct-current excitation a much smaller alternating component can be used and a large portion of the iron losses eliminated. This is easy to realize by reference to a *H-B* curve of iron. When the iron is already saturated with direct current to a point above the bend of the curve, only so much alternating current need be superimposed to produce a "dip" in the flux intensity. The dimensions of this "dip" are determined by the harmonic desired. Thus the iron loss only occurs at the same time as the "dip" in the flux. During the rest of the time, the iron is fully saturated and the losses relatively small. On the other hand, when no direct current is used, a much larger amplitude of alternating current is required to reach the desired point of flux deformation. Besides, the iron is being worked in an unsaturated state the greater part of the cycle, which results in considerably higher iron losses. The only apparent advantage of the multiplier without direct current for producing odd harmonics is that, by using a single multiplier unit, an impulse is transferred from each half-cycle of the fundamental, whereas, when direct current is used, two multiplier units are required arranged in such a way that the phases of the impulses are correctly combined. However, this latter arrangement adds very little complication to a system.

Advantages of Short Magnetic Path

Theoretical considerations of the design of frequency multipliers indicated a decided increase in efficiency should be obtained by making the diameter of the core relatively small. The reason is that the inducing power of a magnetic field is due to the cross-section of the field, but not to the length of the path. Substantially the same results are therefore obtained with smaller amounts of iron and the correspondingly smaller core loss. In substantiation of this theory, a circuit containing a multiplier having a magnetic circuit 25 in. in length, see Fig. 5, was found to have an efficiency of 66 per cent when doubling. The same circuit, but containing a multiplier having a magnetic circuit 12 in. long, had an efficiency of 78 per cent. Similar effects have been observed by other investigators, but apparently the principles have not been investigated to determine the limits.

To investigate the possibilities of further improvement in this direction, a series of sample units have been made up in which the length of the magnetic circuit ranges from three inches to 3/8 inch. Measurements made on the unit having the shortest magnetic circuit indicated that a stage was reached at which the copper and iron losses approached equality, thus indicating that optimum dimensions had been reached. In this particular case, in quadrupling a fundamental frequency of 23,500 cycles, an efficiency of 90 per cent was obtained. These dimensions are, of course, dependent upon the application of the device and the materials used. Fig. 6 shows a sample multiplier with multiple-turn conductor around the core, and Fig. 7 shows a sample with single-turn conductor. The single-turn conductor is necessitated by the extremely small dimensions of the core.

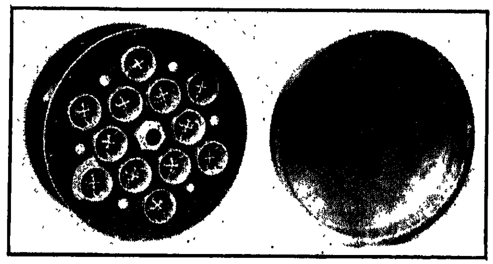

Fig. 6—Frequency Multiplier *F M*-9 (Bottom View With Base Pan Removed

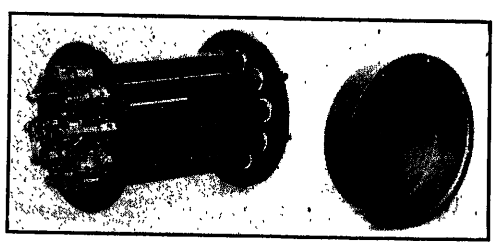

Fig. 7—Frequency Multiplier *F M*-10. 50-kw. Oil Pan Removed and One Section of Core Partly Withdrawn to Show Construction

Core Material

The efficiency and general performance of an iron-cored frequency multiplier is dependent, to a great extent, upon the characteristics of the iron used. In order to make direct comparisons of different grades of iron, samples were prepared in the form of a toroid having the same length of path, same amount of iron,

and with winding of the same conductor and the same number of turns. These samples were immersed in oil for tests. The tests consisted of measuring—

1. The impedance of the various samples at 20,000 cycles which indicates mainly the *B-H* characteristic of the iron.

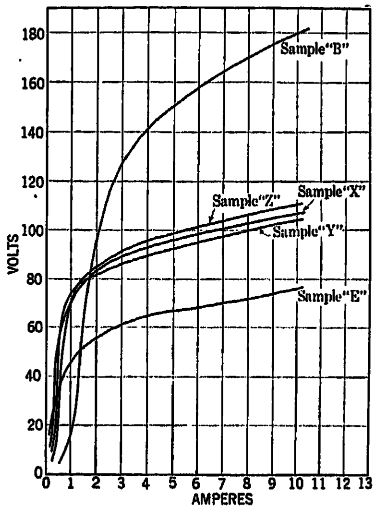

FIG. 8—20,000-CYCLE SATURATION CURVES OF IRON SAMPLES FOR FREQUENCY MULTIPLIERS

2. Measuring the temperature rise of the samples at various values of volt-amperes at 20,000 cycles.

The results of these tests are shown in Figs. 8 and 9. Conclusions from these tests, substantiated by results from other tests in which various grades of iron were used in frequency multiplier circuits, are as follows: The iron which has high *B* for a given *H* above the knee

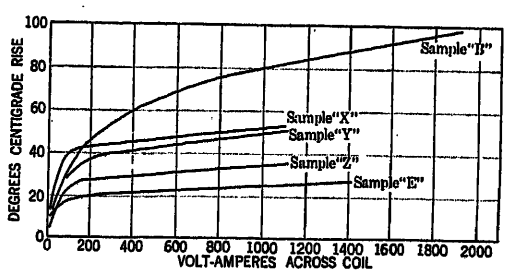

FIG. 9—20,000-CYCLE CHARACTERISTICS OF IRON SAMPLES FOR FREQUENCY MULTIPLIERS

of the curve stores more energy at operating adjustment than the iron which has a lower *B* for a given *H*. Stable operation is obtained with iron having a high *B-H* relation. The iron which has a relatively low *B* for a given *H*, while more efficient in operation, has a tendency to be unstable, due apparently to the relatively small amounts of energy stored. A compromise between stability and efficiency is indicated as a most desirable grade, from a practical standpoint.

The intermediate curves in Fig. 8 show the characteristics of an iron which apparently would be best suited. Another advantage of this iron is the relatively sharp bend in the *B-H* curve which should enable the transfer of a greater proportion of the stored energy of the fundamental frequency to the harmonic frequency circuit. This is particularly true in circuits which operate on a principle of shock excitation.

METHODS OF MEASURING EFFICIENCY

Losses in frequency multipliers are being measured by electrical and calorimeter methods. The results obtained by the two methods are in close agreement and are considered sufficiently accurate for practical purposes.

RADIO APPLICATION

The radio application of frequency multipliers provides a means to greatly increase the usefulness of high-power alternators. A 20-kw. frequency-multiplier installation is being made at the Radio Corporation's transatlantic station at Marion, Mass. This 20-kw. set will be supplied with power from eight armature coils out of a total of sixty-four coils from either of two 200-kw. Alexanderson alternators. This small part of the total capacity of an alternator will reduce the power from the main circuit only 12½ per cent, but will provide a separate transmitter for marine service. This 20-kw. transmitter will multiply a frequency of approximately 25,000 cycles five times in one stage. This set will include the best-known features in accordance with the principles outlined herein.

INDUSTRIAL APPLICATIONS

The industrial application of frequency multipliers appears to be where relatively large amounts of power are required at moderate frequencies. In the design of salient-pole alternators for relatively high frequencies and for relatively large powers, a nominal limit is between 500 and 1000 cycles. Alternators to develop frequencies appreciably higher than this nominal limit are usually of the inductive type, and, being in a special class, are costly to build and have relatively low efficiencies. It appears entirely feasible to use a 500-cycle salient-pole alternator, and, by the use of iron-cored frequency multipliers, produce relatively high frequencies in sufficient power capacities for many industrial applications.

Discussion

E. W. Kellogg: Mr. Brown spoke of getting a wave of 500 cycles and make it into a 1000-cycle wave with 90 per cent efficiency. The story is not complete until we know just what it does to the efficiency of the generator supplying the original wave.

W. Rogers: I should like to ask what use has been made of this principle in multiplying the ordinary ringing frequency which is 16 cycles to 133 cycles for use on composite ringers on telephone circuits.

S. P. Shackleton: I think the answer is that there has been no practical use made of it, and the principal reason is, I believe,

that the frequencies are so low that, to get very great efficiency it would require apparatus which would cost more than other apparatus available for generating 133 cycles.

For a number of years we did use the fundamental ringing frequency of 16 cycles or 20 cycles, whichever it happened to be, to operate an interrupter to produce the higher frequency. That, however, was none too efficient, and recently that has been superseded almost entirely either by a motor-generator set or by an improved type of interrupter operating from direct current.

W. Rogers: I do not suppose that this is a matter of much importance to the telephone companies, but it is of some importance to the railroads. The telephone company is in a position to use the methods described by Mr. Shackleton, because of their larger installations and because of the fact that their long-distance circuits are numerous and centralized. However, on the railroad, we have composite circuits which terminate at points where these things are not available. One of our greatest troubles is with our composite ringers. Most of us are still using the old interrupter, operated from d-c. or 16-cycle ringing current, and it has been suggested, and I believe demonstrated, that it is possible to take two, or, perhaps, three 47A repeating coils and, by saturating the cores of one of them and connecting them in a certain manner, change 16-cycle ringing current to approximately 133 cycles.

S. P. Shackleton: The only case of which I know where the higher frequency, 133 cycles, has been obtained by frequency changers of that type has been in Philadelphia, where our men became very much interested in that problem. They had working for several years, composite ringers supplied by means of such a device. I looked over the layout there and do not remember all the details of it, but I am very sure that if the frequency changer was made commercially available it would cost more than the interrupter which we are now using on our telephone circuits.

W. W. Brown: In reply to Mr. Kellogg's question regarding the efficiency of the power supply for frequency multipliers load: It is possible to adjust the frequency-multiplier circuits so that the load is approximately at unity power factor. This is entirely feasible in radio-frequency circuits, but uneconomical in relatively low-frequency circuits on account of the large kv-a. of the condensers required. Multiphase power supply appears to be the solution for the relatively low-frequency circuits.

Another probable radio application of frequency multipliers will be in connection with necessary changes to increase the possible rate of sending by long waves. In order to improve the efficiency of long-wave antennas, the resistance has been decreased to a remarkably low value. The effect of lowering the resistance is to lengthen the time constant of the antenna. A low time constant of such an antenna tends to cause distortion of signals at high rates of sending. By using a higher frequency, the time constant of a given antenna is shortened, which permits higher rates of sending. The application then will be in multiplying the entire output from a large alternator for high-speed transmission.

N. Lindenblad: In answer to Mr. Kellogg's question, the primary source is not affected as feed-back effects are prevented either by means of tuning or the Alexanderson neutralizing transformer.

In answer to Mr. Roger's question, it must be understood that frequencies obtained by the multiplication method referred to are only whole multiples of the fundamental frequency, not fractional multiples.

I agree with Mr. Shackleton regarding the probable high cost of the frequency changer for increasing the frequency of 16 cycles to 133 cycles, unless the demand for such a device is large enough to justify the cost of the development work.

Electric Propulsion of Ships

BY H. FRANKLIN HARVEY, Jr.[1]
Associate, A. I. E. E.

AND

W. E. THAU[2]
Member, A. I. E. E.

Synopsis.*—This paper deals with the electric propulsion of practically all classes of vessels. The several types of electric drive are treated, in general, with special emphasis on Diesel-electric drive, as it is believed that this type of electric drive will be of most general interest, particularly to the inland section of our country, since it is especially applicable to the smaller size vessels, such as are used on rivers and lakes, to vessels in the coastwise trade and to the usual size of ocean freighter.*

All types of propelling equipment, however, will be referred to for the purpose of comparing the advantages of electric drive with other methods of ship propulsion and to show the natural advantages of each particular system.

It is the intent of this paper to provide data valuable in the selection of the proper type of drive for each application, which must necessarily be determined by the character of the vessel and the service it is to render. Each type referred to has a particular field in which it is best suited.

The authors desire to give credit to the Westinghouse and General Electric Companies for much of the data and material for cuts included in this paper.

Introduction

EVEN a comparatively small ship represents a considerable investment. Capital being traditionally conservative and as ship owners have to consider the lives of passengers and crew as well as property, it follows that the established systems of mechanical transmission will be preferred until it has been established to the entire satisfaction of owners and operators that the electric drive possesses elements of safety, reliability and economy superior to any other type which may be considered.

The object of this paper is to show that electric drive, when compared with any other system, has outstanding qualities of safety and reliability and that the economy is superior except where special conditions favor one of the older types. Electric drive is, of course, still in its infancy and it is to be expected that a longer period of development will still farther extend its field of application.

As will be noted in the bibliography, several papers have already been written on different phases of this subject, but in this paper it is proposed to cover the entire subject in general.

The use of electricity for ship propulsion is no longer an experiment. H. L. Hibbard's paper on *The History of Electricity on Shipboard,* refers, in general, to several installations, all of which have been most successful. The superiority of this type of drive has been apparent for some time and the constituent parts have been well established; but not until comparatively recent years has it been practically applied.

The United States Navy, realizing the advantage of electrical drive, decided to give it a comparative trial with that of reciprocating engines and geared turbines. The success of the electric method of propulsion in the U. S. collier *Jupiter,* (now the aeroplane carrier *Langley*), as compared with that of the engine-driven *Cyclops* and the geared turbine-driven *Neptune* was instrumental in inspiring the U. S. Navy to adopt it for all subsequent capital ships, the first of which was the U. S. S. *New Mexico.*

The justification of the turbine-electric system of propulsion for ships is that it affords a transmission efficiency very nearly equal to that obtainable with gears of suitable speed reduction for economical turbines and propellers, and that it accomplishes this result by a simpler and more flexible means.

The justification of the Diesel-electric system for propulsion of ships is that it affords the fuel economy of the Diesel engine with the added advantages of smaller and simpler engines, flexibility, reliability and superb maneuvering qualities.

Reciprocating Engine Drive

For many years the reciprocating engine has been a virtually completed development, possible improvements being mere matters of detail. In many cases and especially in the larger installations, it is objectionable, due to its weight and space factors. However, this type of drive is reliable and thoroughly understood by operating engineers. It will probably be used indefinitely for ship drives as there are certain types of ships in which it would be inexpedient to apply other methods of propulsion, due to definite economic reasons.

The cost of fuel does not permit the general use of reciprocating engines in land stations, and this same objection exists on board ship.

Turbine Direct Drive

The first radical change in steamship propulsion was brought about by the introduction of the direct-connected turbine. This type of drive, however, is admittedly imperfect because the most efficient, lightest and simplest turbine is essentially a machine of a definite high speed, while the most efficient propeller is a low-speed device, so that the efficiency of both must be sacrificed in compromising the speed. The great majority of direct-connected turbine-driven ships now in operation have turbine speeds entirely too low for

1. Electrical Engineer, Newport News Shipbuilding and Dry Dock Company.

2. Marine Engineer, Westinghouse Electric and Manufacturing Company.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925.

good economy, with consequent efficiency little better than that of reciprocating engines, whereas, ordinarily, a turbine may be considered appreciably more efficient than a reciprocating engine, due to simple rotation and a much higher ratio of steam expansion. This disadvantage undoubtedly retarded the introduction of turbines for propulsion of ships before the use of gears. Nevertheless, this method of propulsion has been installed in some very fast passenger vessels as well as warships and destroyers. The *Mauretania* is a striking example of compromise in speed necessary, as the propeller and turbine speed is 188 rev. per min., whereas the most economical speed for the turbine would be 1400 rev. per min. and for the propeller, about 150 rev. per min. High-speed turbines of equal capacity in daily use are about 80 per cent efficient, while the *Mauretania* turbines are only 62.75 per cent efficient. This objectionable feature was principally instrumental in the introduction of mechanical reduction gears for ships.

As the turbine is not reversible, it is necessary either to provide reversing wheels in the main unit or a complete separate reversing turbine. A reversing element, when running ahead, introduces losses as great as 1½ per cent, and, being relatively small and inefficient, provides less backing power than that of reciprocating engines. The friction loss of the reversing turbine in the ahead direction is several times that in the astern direction. There is also a grave possibility of dangerously heating the reversing wheels if the vacuum drops. These causes have contributed to many turbine failures.

Turbines with reversing elements must necessarily be designed with larger clearances, thus lowering their efficiences; and the larger diameter necessitates larger radial clearances. Also the losses in the large connecting piping of cross-compound turbines are very appreciable. Separate reversing turbines complicate the control and add to the weight, space and cost. At its best, therefore, this method of drive provides rather poor maneuvering qualities and slow stopping, requiring, in some cases, as long as forty seconds to stop the screws when going full speed ahead.

The direct-connected turbine is further handicapped by its inability to utilize high superheat.

Therefore, the direct-connected turbine, although attractive in its apparent simplicity, has probably progressed as far as can be expected, and cannot be regarded as a satisfactory general method of propulsion.

Turbine Gear Drive

Many of the objectionable features of direct-turbine drive have been overcome by the introduction of mechanical reduction gears. They permit both the turbines and propeller to be designed for their most efficient speeds. Reduction gears are especially applicable to destroyers and light cruisers where the high-speed light turbine and relatively low-speed propellers are desired. Here the weight factor is most important and probably more than offsets the advantages of electric drive in such installations. Gear drive machinery for low-speed cargo vessels is, in general, lighter and the transmission efficiency is probably better than that of electric drive. However, when considering losses in the reversing element, extra oiling requirements, packing losses, extra steam losses due to larger clearances, the transmission efficiency is reduced very nearly to that of turbine electric drive.

The rubbing contacts of gears is of utmost concern and, to be safe, the gears must be liberally designed. With either the turbine direct or gear drive with more than one screw, the disabling of one unit means dragging a propeller. Furthermore, reduced speed conditions introduce inefficient operation as all prime movers must run at lower than designed speeds. Sudden application of load and vibration are hard on gears as is also misalinement due to springing of the hull or inaccurate workmanship. In many cases the noise of gears has been objectionable, especially on passenger ships. Life of gears has been uncertain and there have been many disappointments. However, with proper design and improved methods of manufacture, these troubles are being overcome. Considering the numerous installations, the most of which have proven satisfactory, and the relatively small percentage of failures to this type of drive is due considerable credit. Some cargo ships have run as much as 300,000 miles with the gears still in good condition.

Like the reciprocating-engine drive, gear drive will undoubtedly be used indefinitely as the application of electric drive in certain classes of vessels appears, at the present time, unwarranted.

Diesel Direct Drive

Following the development of the steam turbine came that of the Diesel engine, with its high fuel economy and attendant advantages.

A large percentage of European cargo carriers are equipped with direct-connected Diesel engines, and this type of propulsion is gaining rapid headway in this country. In addition to the many American Diesel driven ships already in commission the Shipping Board has decided to equip eighteen vessels of our Merchant Marine with direct-connected Diesel engines. This type of engine, however, has its limitations in capacity although the size of units is steadily increasing. With the larger sizes the space factor is of great concern as engines rooms must be made larger to accommodate them. Twin screw direct drive has been frequently used in order to provide two units for increasing reliability and permit the higher propeller speeds required by the engines, and also to have the engine come within the present limit in capacities. In many such cases the use of one propeller would permit a much better design.

Reversing difficulties with the Diesel engine, while now not as serious as in the earlier designs, are appreciable as the design is more complicated and extra precaution is necessary with most makes of engines,

always to have available high-pressure air. When maneuvering, this feature is of appreciable concern. The most economical speed of the Diesel engine is much closer to that of the propeller than is the case with the steam turbine, but the difference is great enough to cause considerable losses. These losses are, however, not sufficient to warrant the use of gears with Diesel engine drive.

Electric Propulsion General

While the development of the horizontal steam turbine and the Diesel engine opened new eras in ship propulsion, it remained to develop some speed-reducing connecting link between these prime movers and the propellers that would allow both to be designed and run at their most efficient speeds. The mechanical reduction gear provided a very logical connecting link; however, the advent of the electric drive introduced a fully reliable system with inherent advantages. The following enumerated points, substantiating this statement, are by no means theoretical, but, on the contrary, are the results of actual observations taken over a considerable period of time and with different types of ships. Such reasons are responsible for the rapid increase in the number of electrically propelled ships.

Reliability. The universal use and the indisputable success of electrical apparatus on land is sufficient testimony in behalf of its reliability. Its application to ship propulsion presents no serious difficulty, as the deleterious affect of salt and moisture have long been recognized and are easily surmounted by proper insulation of the windings and other precautions.

Electrically propelled ships now in service have demonstrated their unquestionable reliability and ability to withstand the most rigorous climatic and sea conditions.

The electrical transmission of power from the prime mover to the propeller provides the simplest, most elastic, most flexible and probably the most reliable method of speed reduction.

Economy. When considering fuel, water, lubricants and supplies in economy turbine electric drive compares very favorably with geared turbine drive and greatly exceeds that of reciprocating engine drive.

The fuel economy of the Diesel direct or the Diesel-electric drive is admittedly very much better than that of other types of drives, and on an overall comparison there appears to be little difference between these two types, as the flexibility and intangible advantages of Diesel electric make up for the expected better fuel economy of the limited Diesel direct drive.

While turbine electric drive is apparently less economical than geared turbine drive at full power in the ships which operate at several speeds, there are decidedly superior economic results at reduced power, especially on twin or multiple screw vessels having two or more main generators, as all propellers may be operated from one generator. Also, efficiency of electrical machinery does not change with age.

Commander S. M. Robinson has pointed out that the fuel consumption of the U. S. S. *Idaho* and *Mississippi*, (direct-connected turbine drive), depending on the speed, is from 20 to 47.8 per cent more than the U. S. S. *New Mexico* and at full power is 32 per cent more. Subsequent electrically driven battleships are showing better economy than the *New Mexico.*

Weight. The total machinery weight with electric drive is much lighter than with reciprocating engine drive, but is usually slightly heavier than geared turbine installations, although on certain classes of ships it may be lighter. This is particularly true for Diesel-electric drive. This depends somewhat on the arrangement, design and foundations in the engine room. Weight is an important item, as it directly affects cargo space and displacement. In analyzing comparative weights, a fair allowance must be made for the excess weight incident to overload capacity of electrical apparatus, factor of safety and flexibility of reserve.

Space. The position of the main generator with respect to the propelling motor is not essential. Therefore, a more convenient arrangement is possible than with any non-electric type of drive.

Of course, the Diesel electric shows up most favorably in space requirement due to the absence of boilers and the use of smaller fuel tanks.

With turbine-electric drive the condensers can be located directly under the turbines thereby saving floor space. However, in most cases, turbine electric drive requires more space than geared-turbine drive, although in many cases the flexibility of location with electric machinery permits a more advantageous utilization of space and requires a smaller engine room. The number of propellers and beam of ship have a direct bearing on this feature. In the case of the 7000-ton U. S. collier *Jupiter* the weight of the electric propelling machinery is 156 tons, whereas for her sister geared turbine drive ship *Neptune*, the weight is 150 tons. For 3000-ton freighters with certain makes of double reduction gears the weight is 9 tons less than turbine electric drive, but the saving in shafting by locating the motor aft makes the electric drive lighter.

Cost. The initial cost of the propulsion equipment has a direct effect upon the earning power of the ship because of interest, depreciation and insurance charges and, therefore, is an important item.

The features entering a definite comparison in cost of the various systems are somewhat difficult to determine, but on the basis of equal performance in regard to propeller torque and speed and considering all items relative to the propelling equipment, the costs of electric-drive systems do not appreciably exceed the cost of other types of drive.

When considering that the electric drives, especially the Diesel type with its smaller engines, permit more

or less standardization of prime movers and generators, resulting in a better production and stocking basis, the cost item gives them somewhat of a preference. The cost of the propulsion machinery alone is, however, not the only important factor, as advantages of the electric drives in the saving of piping, shafting, shaft alleys, oiling systems, maintenance, etc., will more than offset the extra cost of electric machinery in many cases where other systems, on the first analysis, appear preferable.

Operation. Ordinarily, as there are no large valves to operate, only one man is required to handle the control. The motor requires little attention and even if located in a separate compartment does not require an extra man. The fear of inability to obtain proper personnel for the operation of electrically driven ships was in the beginning an anticipated obstacle, but since the *Jupiter*, *Kamoi*, *J. H. Senior*, *Poughkeepsie*, *Golden Gate* ferry, *New Mexico* and many other similar ships have been successfully operated with no trouble from this source, this objection no longer exists. It is not necessary that the operator have any more theoretical knowledge of the electrical machinery on shipboard than on land, but simply must know its operating characteristics and general care. In many cases the operators of electric drive ships have had little experience with electrical machinery and principally due to simple control they have had no trouble in properly handling it.

The Westinghouse and General Electric companies have conducted special training schools for such operators and other similar schools will undoubtedly be arranged if found necessary.

The same doubt arose concerning operators for turbine driven ships, but there has been no trouble in providing an adequate supply of them. This is also true of electric locomotives and in practically all cases the operators are so enthusiastic they would hestitate to return to the steam drive.

The omission of the boilers in the case of Diesel-electric drive correspondingly reduces the operating force with an appreciable saving in expense, especially at sea.

Electrically driven vessels will naturally attract competent engineers who will take the best care of the machinery and thus tend to realize better efficiencies. First hand knowledge of the facts will convince the doubtful ones of the value of the electric drive.

Maintenance. Electrical machinery does not wear as does other machinery, and with the absence of wearing parts, except in bearings, there is little to get out of order. Furthermore, the maintenance would naturally be less than for other forms of drive for the reason that load conditions and control operations are less severe on the machinery and propeller. As a matter of fact, the years of experience with electrically driven vessels have proved that the cost of upkeep is surprisingly small.

Performance. The inherent characteristics of electrical machines are particularly well suited to ship propulsion. Their operating characteristics are the same in either direction of rotation, and consequently, except when peculiar conditions make it undesirable to utilize this feature, afford full torque and power for reversal. The reversing provision with geared turbine drive is only from 40 to 60 per cent of the ahead power and although this is claimed to be sufficient for ordinary conditions, emergency cases frequently warrant full power astern. This is particularly true of high-speed ships. An electric drive ship can be stopped in considerably less time than a geared turbine ship. This is not due wholly to the lesser backing power of the latter, but to the inefficiency of the reversing element of the geared turbine which incidentally causes an enormous draft on the boilers, greatly reducing the steam pressure.

The ability of the electric machinery to absorb and dissipate the power delivered by the propeller is of considerable value. Furthermore, the control of the propeller with electric drive is speedier than with any other type of drive. Analysis shows that reversing at full speed is easily accomplished and does not place harmful requirements upon the electrical machinery. These characteristics make electric propulsion ideal for difficult driving, stopping and maneuvering.

Efficient Speed Reduction. Electric drive lends itself to any desired reduction between the high-speed turbine and the low-speed propeller and both may be designed to operate at a speed corresponding to their highest efficiency. While the speed reduction ratio for Diesel electric is not so great as with turbine electric drive, it permits the use of standard speed engines and the best propeller speeds. With two generating units, one will propel the vessel at approximately three-quarters speed with practically no sacrifice in economy. With direct drive, a disabled unit would necessitate an idle propeller.

Electric drive affords means of reversal by a simple change in electrical connections without changing the direction of rotation of the prime mover and any desired reversing torque, up to full torque or more, can be obtained without affecting the efficiency of the equipment in the forward direction.

Both the turbine and Diesel-electric systems are capable of developing large overload torque at reduced speed and installations to date have proved this feature to be sufficient to meet all emergencies.

Measurement of Power. Accurate and constant knowledge of the power output is always obtainable from meters on the control board. In this manner the power requirements under varying operating conditions may be ascertained and studied. Also by recording electrical meters the total power on any trip or selected part of a trip may be obtained. This data with a record of fuel consumption affords simple means of calculating economy. Further, especially with two or more screws, it permits the detection of:

a. Excessive friction in thrusts, propeller shaft bearings or stern tube bearings.

b. Incorrect machinery or wrong pitch of propeller and bent or broken propeller blades,

c. Poor steering or improper rudder action due to mechanical troubles or wave movements on account of storm or wind conditions.

With no other type of drive can such defects as above noted be quickly detected and proper remedies expeditiously applied.

High Pressure and High Temperature. As the turbines used in connection with electric drive have but one direction of rotation they readily accommodate themselves to high pressure and high temperature steam and may, therefore, take advantage of these two very important economic measures.

Flexibility of Machinery. With a plurality of generating units, the failure of one will not disable the vessel. Simply by switching, any number of the generators may be made to supply power to all motors or any may be disconnected with little handicap to the remainder of the outfit. Furthermore, if reduced speed is desired for economy, part of the generators may not be run, thus permitting the active ones to operate economically near their rated and most efficient output. This would not be true with direct-connected units, as they must all operate at the reduced and consequently uneconomical loads. This feature is particularly desirable for ferry-boats and constitutes a reserve power factor; also for long cruising periods, it is of great importance in its affect upon fuel storage. It has a decided advantage in connection with battleships. Furthermore, the plurality of engine sets makes it unnecessary to carry on board as many spare parts as with direct-drive installations.

Main Generators Supply Auxiliaries. A very outstanding feature common to many turbine electric and most Diesel-electric driven ships is the ability to use the main propulsion generators for supplying power to axuliaries used in port. The power required for handling motor-operated cargo machinery is practically always considerably more than that required for the electric auxiliaries used at sea. Therefore in the non-electric-drive ships, the electric plant must necessarily be of sufficient size to provide for port conditions. This, of course, results in appreciable idle generating capacity at sea, or otherwise the sacrifice of motor-operated port auxiliaries. As Diesel-driven ships ordinarily have electric cargo machinery and as the cost of Diesel-driven generators is considerably more than for steam engine or turbine-driven generators this feature becomes quite important. These advantages have constituted a prominent factor in deciding for electric drive in several installations.

Location of Machinery. Electric drive permits the turbines to be most conveniently located, especially with reference to the boilers reducing the steam piping to a minimum, with consequent saving in weight, steam leakage and condensation. The motors may be located near the propellers thus reducing the long and expensive shafts, shaft alley and shaft bearings.

In case of battle craft, the units may be located in the safest place, constituting important naval advantages. With any electric-drive ship the fact that the large and bulky engines or turbines do not have to be in line with the propeller shafts gives great advantage in distributing the machinery and more economically arranging them in the machinery space.

Again electric drive affords a much cleaner engine room than can be obtained with most other types of drive.

Absence of Vibration and Noise. Electrical machinery operates without vibration and practically without noise. These features are highly desirable for all classes and especially passenger vessels.

No Racing of Propellers. As the prime movers for generators have efficient governors, the tendency of the propellers to race in heavy weather is eliminated. Although it is not the present practise, this feature can also be obtained by other types of drives, providing governors are used on the propelling units. In the case of direct and geared turbine drives it is customary to install only speed limit governors.

TURBINE-ELECTRIC DRIVE

With turbine-electric drive alternating current appears most satisfactory, as the generator is inherently suitable for direct-connection to the economical high speed turbine. D-c. turbine-electric installations have, however, been successfully used in ferry-boats, but this system is not suited for very high powers because geared turbines must be used. Also, the use of alternating-current permits high voltages with less current and consequently smaller interconnecting cables.

The electrical machinery is practically the same as used in land installations, except that it is specially treated to withstand marine conditions of moisture and salt. Unlike land installations, however, no power other than that for propulsion is required of the generators and, therefore, their speed and control may be varied to suit the desired combination with the motors. With high-speed turbines and improved electrical apparatus a good transmission efficiency can be obtained. This efficiency compares very favorably with double reduction gears when considering the losses in the reversing turbine, extra shaft bearings, etc.

When starting a turbine electric-drive vessel with a-c. machinery the turbine speed is reduced and excess generator excitation applied for pulling the motor in step, after which the speed of both generator and motor increases together.

Although the use of direct-current power is not so popular with turbine electric drive as alternating-current power, the installation in the ferry-boats of the San Francisco-Oakland Terminal Railways is of considerable interest.

The propulsion machinery consists of a three stage condensing 1100-kw., 3600-rev. per min. horizontal Curtis steam turbine, connected through reduction gears to a d-c. generator rated at 1000 kw., 500 volts, 900 rev. per min., supplying power to two double armature motors rated at 1200 h. p., 500 volts, 100/125 rev. per min. One motor is coupled to the forward propeller and the other motor to the aft propeller.

A 75-kw., 115-volt, 900 rev. per min. exciter is mounted on the end of the generator shaft and supplies excitation current to the generator and motor fields, and control current for operating the contactor solenoids and relays on the control panel.

The propelling machinery is controlled from the engine room. By means of a controlling rheostat, the shunt-field current of the generator can be varied to obtain different propeller speeds or reversed to change from ahead to astern movement, or vice versa. This rheostat also controls the operation of the two main-line contactors and the two contactors, which shunt the speeding-up section of the motor-field resistor. The motor operating as the astern or driving motor has full resistance in its field circuit, while the forward motor has sufficient of its field resistance short-circuited to produce a speed just above the drag speed of the propeller. The two armatures of each motor are connected in series, while the two motors are connected in parallel and in series with the main generator.

Overload protection is provided by means of line relays opening contactors in the motor circuits. In case the overload relays function, it is necessary to move the controller to the "off" position to reset them.

For the purpose of supplying auxiliary power for lighting and various other needs of the ship, two 35-kw., 125-volt, steam-turbine d-c. generator sets are installed.

Both the induction and the synchronous type motors are being used with complete success.

Induction Motors. To date, three general types used are:

a. Form-wound with external resistance

b. Form-wound with an additional high-resistance squirrel-cage winding for starting and maneuvering.

c. Double squirrel-cage winding, one high resistance for starting and maneuvering.

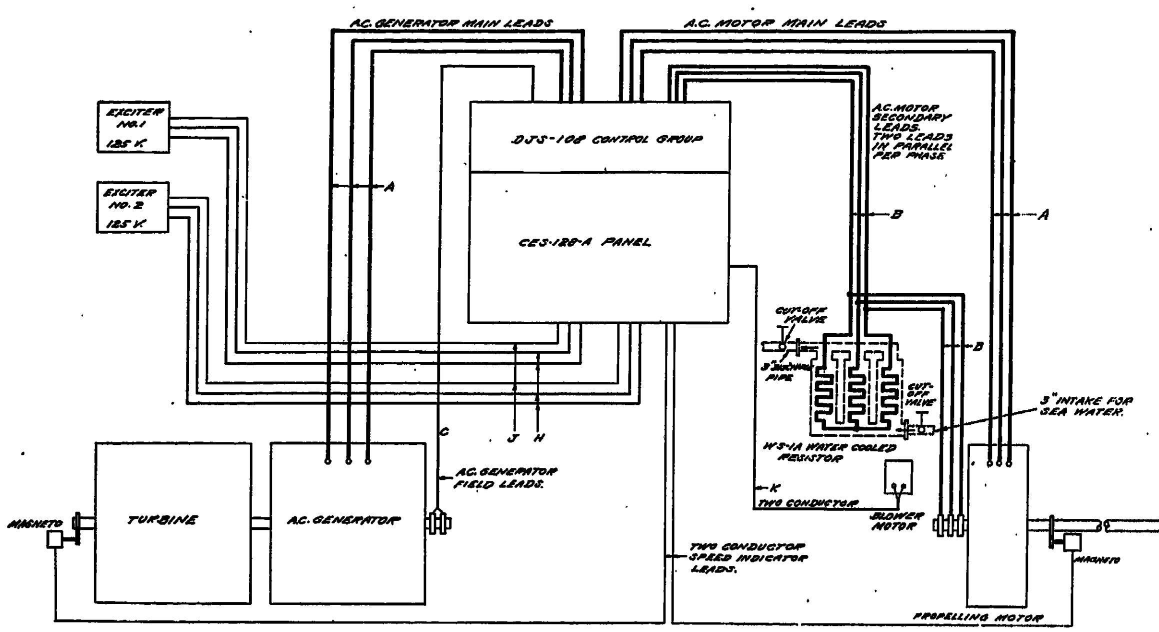

FIG. 1—CABLE CONNECTIONS FOR SINGLE SCREW BOAT PROPELLED BY INDUCTION MOTOR

	Cables	Size	Outside Diam.	Spec.

By providing the motors with pole-changing windings, an additional means is afforded for a different speed ratio between the generator and propeller, thus utilizing, in a most economical manner, the full output of one generator at reduced propeller speeds. This feature, to date, has been used only on battleships

where an economical cruising condition is of great importance.

The concatenation of motors, principally where two per shaft are used, is another way of obtaining a further speed ratio between generators and propellers. This method was contemplated on some of the battle cruisers which were cancelled by the Limitation of Arms Conference.

Typical merchant ship installations with induction induction motor, which is directly connected to the propeller shaft. The reduction ratio between the turbine and shaft speed is 30:1.

The propelling motor has a motor-driven blower, while the generator is self-ventilated. The air from both generator and motor is led away through ducts.

Two separate 125-volt exciters supply current for generator field excitation and the motor-driven blower. For operating the motor, in conjunction with the

motors will be found in the Shipping Board vessels *Eclipse, Invincible, Archer, Independence* and *Victorious.* The propelling machinery for each of these vessels consists of an eight-stage, 3000 rev. per min., horizontal steam turbine direct-connected to a 2300-volt, two-pole, three-phase, a-c. generator, supplying a 3000-h.p., 2300-volt, 100-rev. per min., three-phase, 60-pole turbine generator, a control equipment is installed consisting of a water-cooled resistor and a combined control group and control panel.

The motor is started, stopped and reversed by means of the high- and low-voltage contactors of the control group. In starting from rest or reversing normally, the water-cooled resistor is inserted in the motor form

wound rotor circuit. When the motor is nearly up to speed in either direction, the resistor is short-circuited.

The motor speed is varied by varying the generator frequency which is accomplished by changing the turbine speed. The turbine main hydraulic operated governor will regulate its speed from 20 per cent to 110 per cent.

The *Eclipse* was the first electrically driven merchant ship to circumnavigate the globe. She made the trip of 29,763 miles at an average speed of 10.3 knots, making twenty ports without one stop at sea.

Synchronous Motors. For ship propulsion, synchronous motors are provided with a high-resistance squirrel-cage winding, (amortisseur), embedded in the pole face of the d-c. field poles. This winding is used for starting and maneuvering and where thus far applied, provides sufficient torque for all conditions.

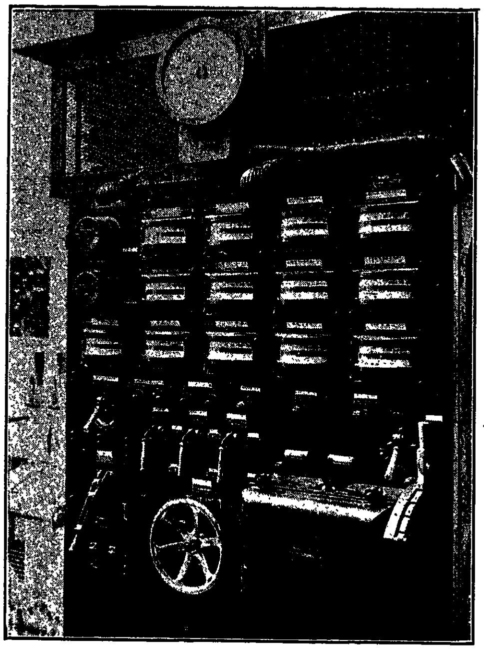

FIG. 3—PROPULSION CONTROL AND PANEL BOARD, JAPANESE NAVY FUEL SHIP *Kamoi*

After being brought up to speed as an induction motor, direct-current field is applied and the motor then runs in synchronism.

The Japanese fuel oil vessel *Kamoi* is a typical installation of synchronous-motor drive. The propulsion machinery consists of a 10-stage, 2400-rev. per min., horizontal Curtis turbine direct-connected to a 6250-kw., 2300-volt, 40-cycle, three-phase a-c. generator supplying power to two 3125-kw., 4000-s. h. p., 2300-volt, 120-rev. per min., three-phase synchoronous motors direct-connected to the propeller shafts.

The motors are open type and have motor-driven exhaust fans for ventilation; the generator is enclosed and self-ventilating. The air from both the generator and motors is led away through ducts. Temperature detecting equipments are provided for the generator and motors.

Two 400-kw., 112/225-volt, 5000/1100-rev. per min. turbine driven, three-wire exciter sets supply the necessary excitation current for the fields of the generator and motors and also power for the blower motors and ships auxiliaries. In addition, a 625 kw., 750-volt, 1100 rev. per min., a-c. generator is placed in line with the outboard exciter and in case of emergency can be coupled to the exciter shaft and used to supply line current to the propelling motors sufficient to bring the ship into port at a speed of about seven knots.

The control equipment consisting of two control groups and a control panel is installed for operating the motors in connection with the main turbine generator or auxiliary a-c. generator.

The motor is started, stopped and reversed by means of levers on the control panel, which electrically operate the line and field contactors in the proper sequence for the desired operating condition. These contactors can also be closed manually by means of levers at the side of the control panel.

In starting from rest, double field current is applied to the generator and the motors are operated as induction motors until nearly up to speed, at which time current is supplied to their d-c. fields, when the motors operate as synchronous motors. The generator field current is then reduced to normal. In reversing, the main operating lever is moved to the "off" position, the reversing lever set to the astern position and the main lever advanced as when starting ahead from rest. The motors are thus operated as induction motors bringing the propeller to rest and starting in the reverse direction until nearly up to speed, when d-c. field is applied for operation as synchronous motors.

The motor and propeller speed is varied by changing the generator frequency, which is accomplished by changing the turbine speed by means of its hydraulic operating governor mechanism.

The motor can be operated continuously at about 50 rev. per. min., in either direction as an induction motor, if necessary.

The Coast Guard Cutters *Modoc*, and others, also have synchronous motor equipments and similar control to that of the *Kamoi*, although they have a slightly different maneuvering arrangement. The *San Benito*, for which the propelling machinery was supplied by the British Thompson Houston Company, is also a good example of synchronous motor drive.

DIESEL-ELECTRIC DRIVE

The inherent advantages of this system indicate remarkable possibilities in the development of ship propelling machinery. The several ships now equipped with machinery of this type have shown most creditable performance and have lived up to every expectation. Although this method is relatively new, the constituent parts have been well established.

Diesel Engines. Any reliable make of engine which operates at a reasonably high rotative speed may be used. Engines for electric drive need not exceed established safe piston speeds for continuous operation. By using several cylinders of short stroke and small bore the heat stresses common to large cylinder slow speed engines are minimized and the result should be an engine of less maintenance and simpler construction. As the engine always starts under no load and runs in thus, in some cases, more than offsetting the added weight of the electrical machinery and resulting in an overall machinery weight probably less than for certain other types of drive.

The field of application of the Diesel engine to ship propulsion is greatly enlarged by electric drive, as several available units may be used in one installation whereas direct drive is somewhat limited by the present limit in sizes of most makes.

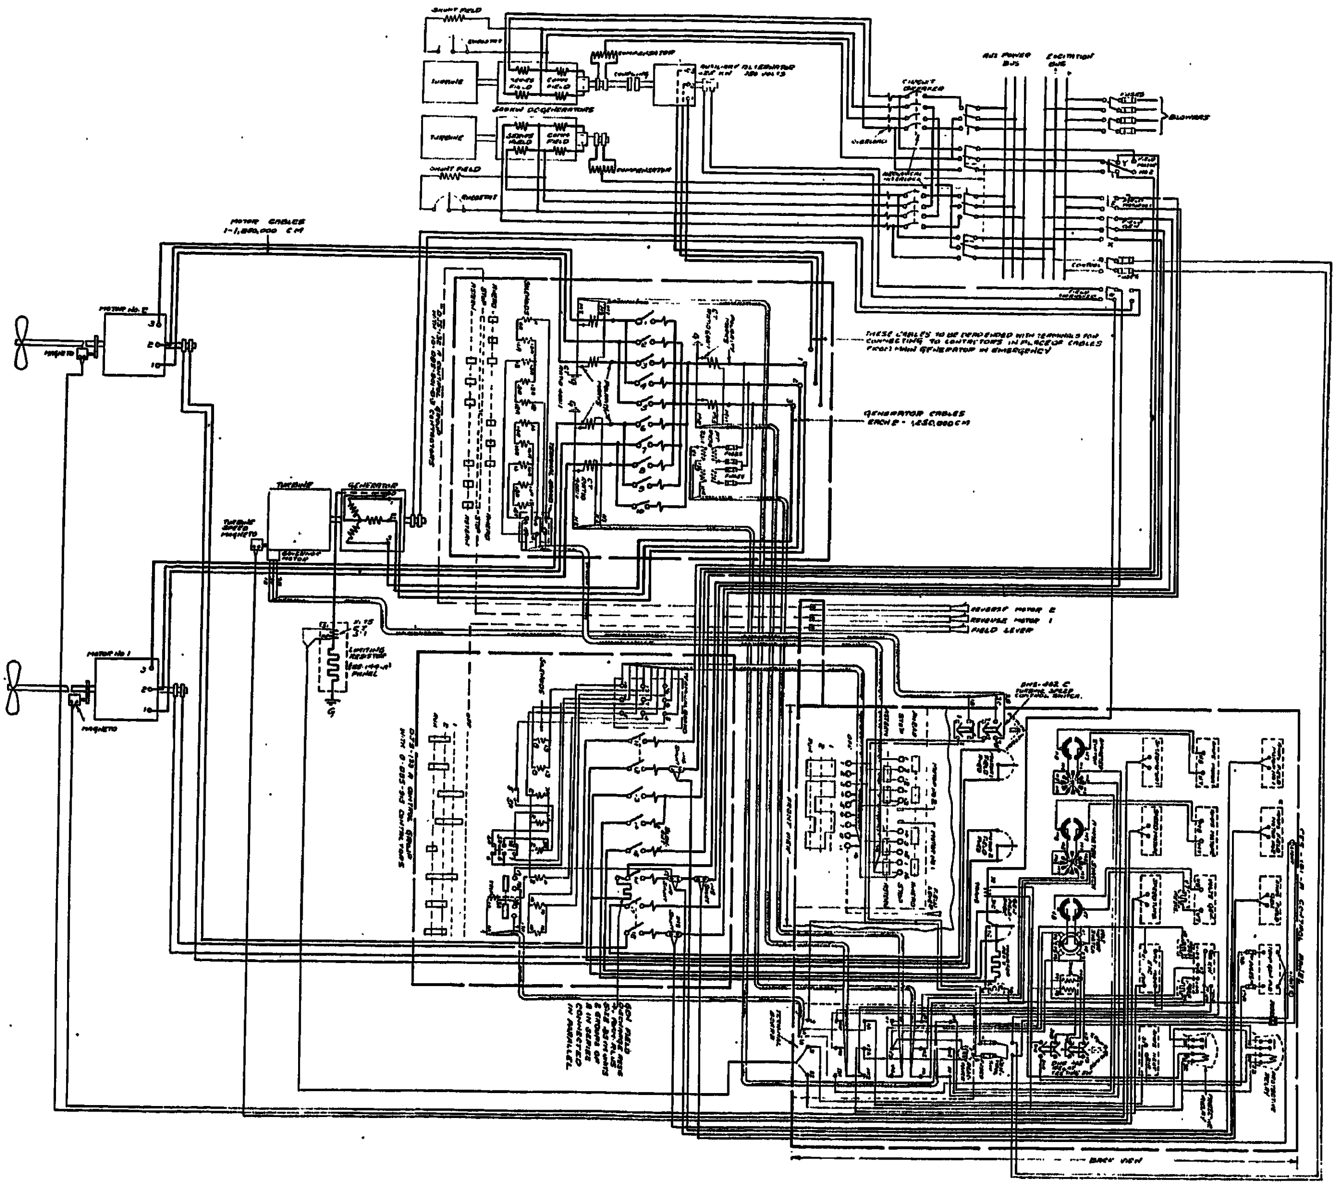

FIG. 4—CONNECTIONS FOR JAPANESE NAVY FUEL OIL SHIP *Kamoi*

the same direction and at constant speed, the design is further simplified by the omission of the reversing gear; also the large supply of high-pressure maneuvering air is reduced to a minimum. If desired, only one air-starting is necessary, as the remaining engines may be started by their connected generators running as motors supplied by power from the first generator.

In permitting high rotative speed engines, Diesel-electric drive rapidly reduces the weight per b. h. p.,

Selection of Power. Direct-current machinery is preferable as it permits of the generators being connected in series. Parallel connection of d-c. generators is practicable, but requires close governing and sacrifices other desired features of series operation.

While a-c. machinery could be used, especially with one generator and one motor, it is objectionable in that the propeller speed must be varied by changing the engine speed. Furthermore, an installation with

more than one generator would require parallel operation and close governing.

Therefore, the direct-current system described is, decidedly simpler, more flexible and more reliable, affording more refined control and providing greater power in case of casualty to a generating unit.

Control. With the d-c. system, motor speed and maneuvering may be controlled by armature rheostatic means. However, this method is wasteful during maneuvering and speed changes and necessitates a complicated controller.

The Ward Leonard System of voltage control is by far the most satisfactory and has been used in practically all installations to date. With this system, both the generators and motors are usually of the shunt type, but in some cases have differential field windings and are separately excited preferably from the same source. The exciters may be direct-connected to the main units, or separate. Also, excitation current may be taken from the auxiliary set, as two sources of excitation should be supplied. The generators and motors may or may not have forced ventilation depending upon the speed and size and the desirability to keep size of machines to a minimum.

The motor fields are excited with constant potential and always in the same direction. The generator field excitation is varied to suit the motor speed and direction. The motor speed under this condition varies in direct proportion to the voltage applied to the motor terminals and may be reversed by reversing the generator excitation; consequently it is only required to vary the generator fields from full excitation in one direction to full excitation in the opposite direction to maneuver from full speed ahead to full speed astern.

With the series connection of generators, like speeds for all engines is unnecessary as a variation simply produces a proportionate difference in the load carried by the generators, provided they are equally excited and have identical performance characteristics. Since it is necessary to handle only the comparatively low generator field excitation currents, for complete control ahead or astern the Ward Leonard system is obviously much simpler and less expensive than the armature rheostatic control. Such simplicity has a further direct affect upon the maintenance of the equipment.

The control board contains suitable switches, instruments, meters, protective relays, circuit breakers, etc., and a special reversing field rheostat and a remote control mechanism for operating the propulsion generator rheostat. This mechanism has an inherent time element for limiting the speed of operation for the safety of the electrical machinery. Such a speed limit, however, does not handicap the operation of the ship as only about five seconds are required from full-speed ahead to the stop position.

The switches for the machines are so arranged that any particular generator or motor may be taken out of service by simply throwing its switch from one position to another and this can be done without interrupting service to the propelling motor. In large installations this is accomplished by a mechanically operated "set-up" device.

With this type of drive provision is usually made for both pilot house and engine room control with a double throw switch on the main switchboard for transferring to the desired station. The control pedestal in the pilot house is arranged for remote generator field control and has the necessary ammeter, voltmeter and speed indicators to provide constant knowledge of the performance of the propelling machinery. Pilot house control is, to date, practical with Diesel-electric drive only, and is of great convenience especially for tug boats and other types of vessels when maneuvering in close waters. No time is lost or mistakes made in transmitting orders.

Overload protection for the generators and motors is provided in the form of line circuit breakers or line relays for opening the generator field in case of severe overload. Necessary interlocks and precautions are taken to insure proper operation and avoid mistakes.

Fuel Economy. A properly designed Diesel-electric propulsive equipment requires about 0.55 lb. of oil per shaft h. p. for all purposes, whereas the average high-grade steam installation of any type requires about 1.0 lb. of oil per shaft h. p. This superiority results in a great reduction in fuel cost and permits additional cargo due to decreased weight or an increased cruising radius for a given amount of fuel. The economy of either type of Diesel drive is far ahead of that of all other types and is, therefore, most attractive for the moderate and medium large size installation.

The Diesel engine system can be made ready for sailing on short notice and stand-by losses are eliminated. This is not true of the steam system which requires that the boilers, turbines, etc., be warmed up for a considerable period before getting underway.

Flexibility and Reliability. By providing a reasonable number of small generating units and using the Ward Leonard system of control with series operation of generators, the reliability of Diesel-electric drive is superior to that of any direct-connected drive, mechanically-geared drive, or any form of electric drive using single generating equipment. The smaller Diesel engines have probably been developed to a more reliable state than the larger sizes. Furthermore as the driving power varies as the cube of the speed a casualty to one of several generating units does not greatly impair the ability of the vessel to proceed. With a three generator installation the disabling of one engine set would reduce the ship speed to 88 per cent and the failure of two would reduce it to approximately 70 per cent of full speed. The only change in connections is the disconnecting of the disabled units and weakening the motor field to take the full load armature current. The faulty unit or units being of the comparatively small size may usually be repaired at sea. No other type of drive

will permit the utilization of the full power of the remaining units without overloading them or increasing the original size and weight. The reserve power thus obtained is far in excess of any other type of drive, including a-c. turbine electric. With a cross compound geared turbine single screw drive the failure of one element would give appreciably less than 50 per cent power from the remaining element and this would be with a sacrifice of considerable speed and economy.

As the generating units are independent of the propeller they may be located to best suit the engine room arrangement and being of the smaller type, lend more readily to the better utilization of available space.

Many Diesel electric installations include a double unit motor consisting of two armatures on the same shaft. This type of motor permits smaller diameter, added reliability and reserve power as one armature may be disconnected and the ship may still proceed with the remaining armature at approximately 70 per cent speed. The superiority of this feature to that of any other single screw drive is obvious. In the case of long cruises at reduced power this flexibility of units permits ideal conditions for economical operation. Any or all generators and motor armatures may be used in any desired combination by simple switching. Furthermore, the main generators may be used for operating cargo oil pumps, winches, etc., thus reducing the size of auxiliary generators to a minimum and only sufficient for port duty when a main generator is not running. For most ships this avoids considerable idle machinery while underway.

The Diesel-electric type of propulsion with the Ward Leonard system of control affords excellent maneuvering characteristics. When the generator field circuit is removed preparatory to reversing, or at any other time, the braking effect of the generator armature connected across the motor terminals brings the propeller almost instantly to a creeping speed, the energy being dissipated partly in friction, due to the motor being driven by the propeller and supplying power to the generator which, in turn, tends to drive the engine, and partly as heat in the motor and generator windings. The performance of the *J. H. Senior* and other Diesel electric vessels shows that the power delivered by the generator is not sufficient to cause any perceptible increase in engine speed and that the demand for maneuvering can be met without exceeding the permissible temperatures of the electrical equipment.

With multiple-screw vessels there is considerable increase in load on the propellers on the inboard side of a turn. This feature naturally tends to overload the prime mover and for turbine electric drive with alternating-current machinery is taken care of by limiting the steam supply to the turbine in order to keep a stable condition between the generators and motors. The inherent characteristics of the d-c. generators and motors used with Diesel-electric drive, however, are such that they will carry this increased torque without the least danger of becoming unstable. No special precaution need therefore be taken as there is always a stable coupling between the generators and motors.

Applications. Because of the attractive advantages previously described Diesel-electric drive is particularly applicable to barges, cable ships, cargo ships, coastwise vessels, dredges, ferry boats, fire boats, fishing boats, lake boats, packets, river boats, tow boats, tug boats, yachts and any other requiring economy and good maneuvering and performance characteristics over a wide range of speed.

The following table indicates those advantages offered by Diesel electric drive which are of particular importance in the various types of ships:

TABLE I

†While on duty.

In order to give a fair idea of the machinery pertaining to the propulsion outfit of typical Diesel-electric installations the following brief synopsis is offered.

Yachts

The three-masted schooner yacht *Alcyone* was originally fitted with reciprocating engines, but upon learning of Diesel electric drive with its cleanliness, absence of boilers and smoke, less vibration and numerous other advantages previously described, its owner, Henry W. Putnam, decided to change over to electric propulsion, using the same propeller and shafting. The *Alcyone* is 182 feet long overall, with a beam of 30 feet and draft of 16.2 feet, and is registered 420 gross tons. The propelling plant consists of two six-cylinder, 225-h. p., 250-rev. per min. Winton Diesel engine, each direct-connected to a Westinghouse 140-kw., 125-volt, shunt-wound, d-c. generator and a 15-kw., 125-volt, compound-wound exciter, chain-driven, at 900 rev. per min. from the generator shaft.

The propelling motor is of the double armature,

shunt-wound, self-ventilated type rated 350 h. p., 250 volts, 175 rev. per min. and is located well aft.

The control is arranged for the Ward Leonard system which provides all desirable features of flexibility, simplicity and ease of operation. Thirty economical speeds ahead or astern are afforded by the reversing rheostat located on the engine room switchboard and controlled by a handwheel.

At 8.5 knots the *Alcyone* has a cruising radius of 6450 miles on one engine and at her rated speed of 10.5 knots she has a cruising radius of 3915 miles on two engines.

The sea trials of this yacht more than met expectations and showed considerable reserve power for emergency. During maneuvering she could be stopped from full speed ahead in less than twice her length.

Several other yachts, some of which have control

from the pilot house, have been equipped with electric drive as will be noted from the tabulation of installations. The popularity of this system of propulsion is most certain to grow in the yachting field.

TUGS

The numerous and severe requirements of operation and maneuvering of tug boats presents an attractive field for the application of Diesel-electric drive with its valuable feature of pilot house control.

The Pennsylvania Railroad, after careful study of the advantages afforded, has installed Diesel-electric propelling machinery in one of their many tugs. This action, however, was not taken until they had tried out Diesel direct drive and found that it did not develop the power expected principally due to the small diameter propeller and comparatively high-speed engine.

The *Float* type of tug comprising about 80 per cent of all the railroad tugs was chosen for this installation. This tug is 105 ft. long with a beam of 24 ft. and a draft of 12 ft. 5 in. Observations showed that an average of 566 signals were given and answered on this class of tug every eight hours. Naturally pilot-house control with its safer and speedier operation was selected.

Two Winton, full Diesel, four-cycle engines are each direct-connected to a Westinghouse 235-kw., 250-volt, 260 rev. per min. shunt-wound generator with an attached 25 kw. compound-wound exciter. These exciters also furnish all other electric power needed

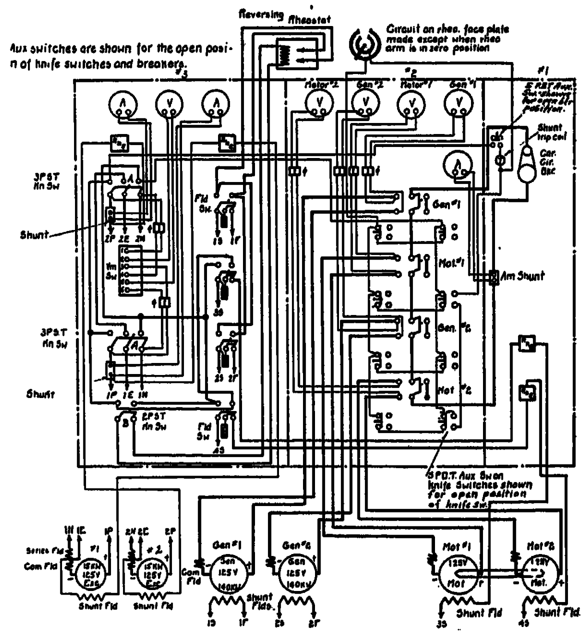

FIG. 6—DIAGRAM OF CONNECTIONS FOR *Alcyone*

on the boat. The propelling motor is of the shunt-wound double armature type rated at 575 h. p., 500 volts, 125 rev. per min. The Ward Leonard system of control and series generator operation is provided.

In addition to the generator voltage-control system, the motor is provided with a certain amount of speed variation by field control, the purpose of which is to enable the motor to operate at a lower speed when towing than when running light, without change of generator voltage. This feature enables the generators to operate at constant voltage when the tug is under full headway, and, in turn, enables the engines to develop full power when the boat is towing and when it

is running light. This is a primary advantage over the Diesel direct system for tug boats and constitutes a marked handicap over any direct connected or geared system and any form of electric drive using other than d-c. machines.

Tests proved the superiority of Diesel electric over Diesel direct drive in acceleration, greater speed and greater tow line stress at the same power. The Diesel direct drive tug with which the electric tug was compared required 15 per cent more power on its propeller shaft when running free and 26 per cent more power when towing than the electric tug. This is probably due to the propeller design. Even with the 16 per cent loss between the engine and shaft, due to the use of generators and motor there is a net gain of 18 per cent over the direct drive on the basis above mentioned. With Diesel direct drive the stress on the tow line was 32 per cent while with electric drive it was 41 per cent of the power delivered to the screw. The electric tug is lighter than an equivalent steam engine driven tug using Scotch boilers by a ratio of 165 to 177 tons and requires one man less to operate it. The fuel cost for eight hours is $12.96 for electric and $23.45 for steam drive. This with the reduced personnel and other advantages results in a saving of 24 per cent in operating expenses over the steam drive.

The further advantages of advancing toward a pier slowly or quickly with assurance of control, elimination of danger of mistakes in receiving orders, smooth taking-up on tow line relieving excessive strains, full power always available, ability to operate on one engine, avoidance of delay caused by condition of fires, quality of coal and inefficiency of firemen, appear to put electric drive far ahead of steam drive for tug boats. Also the time to take on coal and water and remove ashes for a steam tug requires two hours in 24, while the electric tug requires only two hours a week for taking on oil; less physical work is required of the machinery force and a better grade of men is attracted toward it. Navigators are greatly pleased to control propellers which, incidentally, require less thinking and less work than pulling bell signals.

The tug and fire boats *Van Dyke I*, *Van Dyke II* and *Van Dyke III*, equipped with General Electric machinery, are also rendering excellent service and exceeding all expectations.

These tugs are owned by the Atlantic Refining Company. They are 97 ft. long with a beam of 21 ft. and depth of 11 ft. 6 in.

The propelling machinery of each tug boat consists of two three-cylinder, 225-b. h. p., 257-rev. per min., Price Rathbun Airless Injection Diesel engines manufactured by the Ingersoll Rand Company, each direct-connected to a d-c. shunt-wound generator, rated at 155 kw., 125-volts with a 26-kw., 125-volt, compound-wound auxiliary generator mounted on the main generator shaft extension.

Each auxiliary generator is capable of supplying the excitation for the main generators and propelling motor and power for the electrically driven auxiliaries and lights.

The propelling motor is shunt-wound, rated at 375 s. h. p. at 250 volts. By adjustment of the motor field rheostat this motor will deliver 375 h. p. constantly at 240 volts, from 140 rev. per min. down to 107 rev. per min. with a corresponding increase in torque. This means that at reduced speeds the full output of one engine can be utilized on the propelling motor without exceeding the normal rated current thereby increasing the overall efficiency with one engine shut down.

There are two control stands similar in appearance to an engine room telegraph, one located on either side of the pilot house. The levers are interlocked so that either stand may be used.

This same system of Ward Leonard pilot house control was used in the Chicago fire boats, *Joseph Medill* and *Graeme Stewart*, placed in service in 1908.

The *Van Dyke* tugs are also used as fire and power supply boats.

In going to a fire, both main units may be used for propulsion and, after arriving at the fire, one main unit is used for maneuvering the ship and the other main unit is used for operating the fire pump.

Terminals have been brought out on either side of the engine room so that the tug boats may be used to furnish power to barges with motor-operated pumps.

Detail comparative tests have been conducted between one of these Diesel-electric tugs and a Diesel direct drive tug of similar characteristics. The results were very similar to those obtained with the Pennsylvania Diesel-electric tug previously described and show that Diesel-electric drive is superior in every way as compared to the Diesel direct drive for tow boat work, whether it be running light, towing, accelerating a tow or maneuvering. A more detailed report of these tests will probably appear in the press at a later date.

Ferry Boats

A particularly good application for Diesel-electric drive is found in the ordinary ferry boat. The ability to have complete control of the propelling motors from either pilot house is a highly desirable feature for a boat operating in a crowded harbor and docking so frequently.

The *Golden Gate* and *Golden West* ferries are typical of ferry installations to date. The electric propulsion machinery in each of these boats consist of two Pacific Diesel Engine Companies' engines driving General Electric shunt wound generators rated 360 kw., 250 volts, 225 rev. per min., each with a direct-connected, compound-wound 35-kw., 115-volt exciter. These exciters also supply all auxiliary power required for the boat.

For supplying power when the main engines are shut down a 25-kw., 125-volt, 950-rev. per min., Diesel engine-driven auxiliary generator is installed. The two pro-

pelling motors are rated at 750 h. p., 500 volts, 145/180 rev. per min. The higher speed is used on the stern driving motor. The lower speed is used on the forward motor and is just sufficient to relieve any dragging load caused by its connected propeller. The generators are connected in series and the motors in parallel. One generator will drive the after motor at 125 rev. per min.

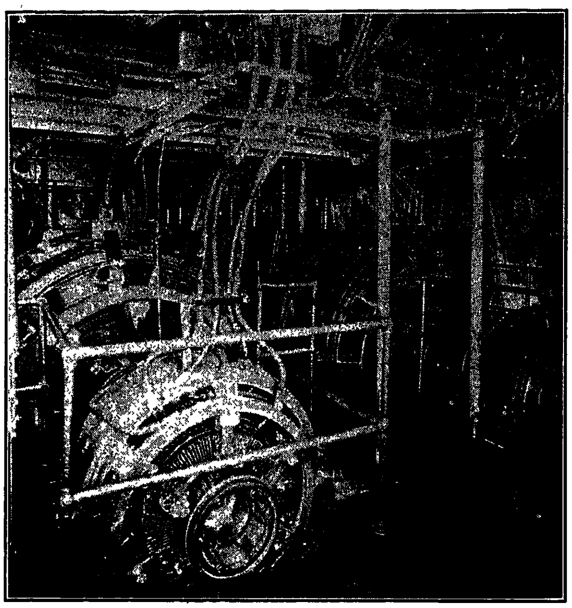

FIG. 7—GENERATORS AND DIRECT CONNECTED EXCITERS ON FERRY-BOAT *Golden Gate*

and this connection is used much of the time when the higher speed is not required to meet schedule.

The voltage of the propelling generator is varied to obtain the several propeller speeds. Sufficient instru-

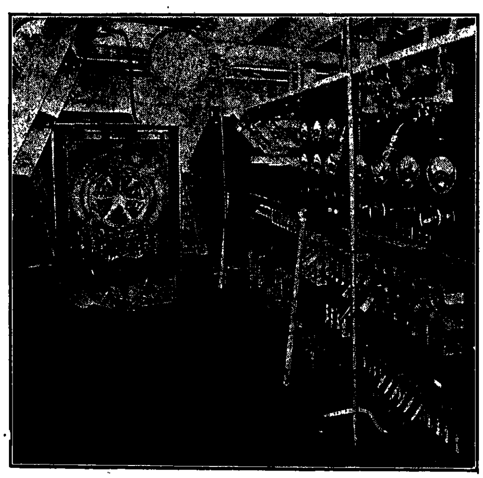

FIG. 8—ENGINE ROOM CONTROLLING RHEOSTAT CONTROL PANEL AND SWITCHBOARD, ON FERRY-BOAT *Golden Gate*

ments are provided with the control pedestal in each pilot house for close observance of the machinery operation.

The control panel in the engine room contains sufficient interlocked switches for disconnecting the main and field circuits and selecting operating stations; also sufficient field rheostats and instruments and the necessary contactors for controlling the armatures and fields in proper sequence. Pilot-house control permits the

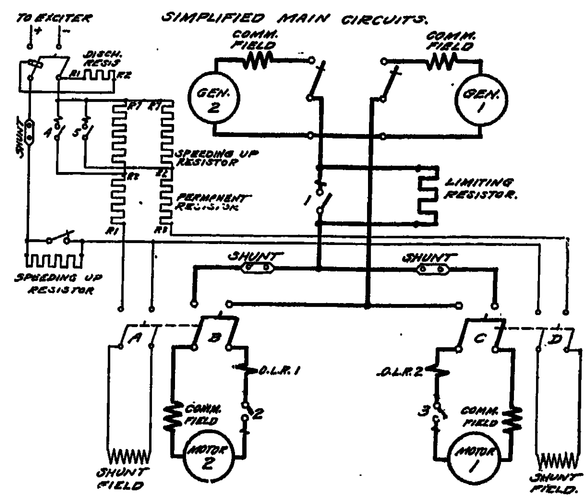

FIG. 9—SIMPLIFIED WIRING DIAGRAM, FERRY-BOAT *Golden Gate*

boat to be steered into the slip instead of being "jockeyed" in. These contactors and the generator field rheostats are controlled from the pilot house. The speed of the forward motor is reduced by short circuiting a step of resistance in its field circuit, the short circuit being removed when the motor becomes the stern motor. These ferries are giving splendid service.

FIG. 10—DIESEL-ELECTRIC MOTOR SHIP *Twin Ports*, MINNESOTA-ATLANTIC TRANSIT CO., STARBOARD SIDE OF ENGINE ROOM LOOKING FORWARD, SHOWING ONE OF THE MAIN GENERATORS CONTROL PANEL AND DISTRIBUTION BOARD

The ferry-boat, *Poughkeepsie*, is equipped with Westinghouse machinery and is also giving good performance. Several other Diesel-electric drive ferries are contemplated and in general this type of drive should show rapid progress for ferry installations.

CARGO BOATS

The application of Diesel-electric drive for the *Twin Cities* and *Twin Ports* will be of particular interest to

those interested in inland water ways. They are owned by the McDougall Terminal Warehouse Company and operate principally on the Great Lakes and New York State Barge Canal between Duluth and New York, but are also designed for coastwise trade from New York to Florida during the winter.

The propelling machinery of each consists of two Lombard Governor Company's Diesel oil engines, each direct-connected to a General Electric 250 kw., 230-volt, 260-rev. per min. compound-wound, self-excited, open-type generator. There is also a 40-kw., 230-volt, 360 rev. per min. auxiliary generator driven by a Diesel engine of the above manufacture. This generator may be operated in parallel with the 250-kw. generators for supplying power to the propelling motors and ships' auxiliaries and lighting when under way, but is normally used for supplying ships' power when the boat is at rest and the other sets are not running.

The two propelling motors per ship are each rated at 250 h. p., 230 volts, 180 rev. per min. and are of the separately ventilated shunt wound type.

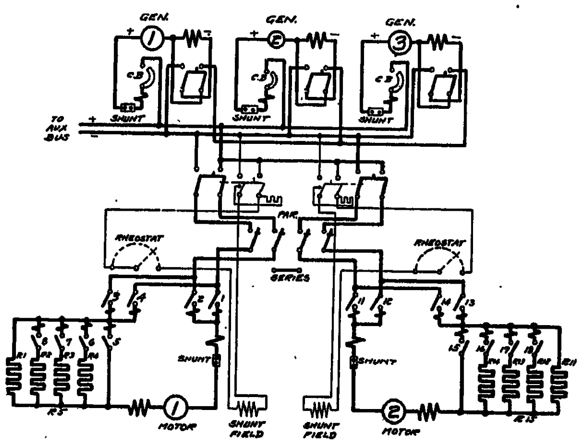

FIG. 11—SIMPLIFIED WIRING DIAGRAM, MAIN CIRCUITS, *Twin Cities* AND *Twin Ports*

The propulsion generators run at constant speed and voltage and the motors are started by the resistance method. Both the generators and motors are run in para lel for normal operation but the motors connected in series across 230 volts give a speed of approximately 135 rev. per min. on each motor. Sufficient flexibility of operation is therefore obtained for a vessel in this class of service. The propellers may be controlled from a deck type controller located aft and another located forward. The master controller is located in the pilot house.

The main control equipment is designed to control the operation of the three Diesel engine driven generators and the two propulsion motors under both normal and emergency conditions. It consists of an engine room control panel, a motor room panel, two motor control groups, two motor starting resistors, and the pilot house and deck controllers previously mentioned. Sufficient instruments, switches, field rheostats, starting and reversing contactors, protective devices, etc., for the complete control of all apparatus and the isolation of units are included.

It will be noted that the control for these boats is unlike that of most Diesel-electric ships, as the Ward Leonard system of generator voltage control is not employed. This simply goes to show the wide range of control of electrical machinery and the need of study for each particular installation. The *Mariner* and *Fordonian* have the same type of control as these two ships.

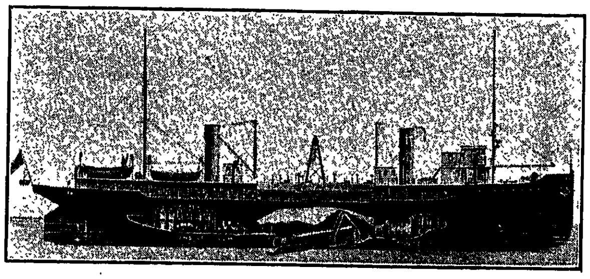

FIG. 12—THE ALL-ELECTRIC HYDRAULIC TYPE, SEA-GOING HOPPER DREDGE *A. acKenzie*

DREDGES

The ability of using the generators interchangeably for propulsion and dredging make Diesel-electric drive economically applicable for dredge propulsion.

U. S. Engineer Corps Hopper Dredges. The four U. S. Engineer Corps' hopper dredges, the first of which completed was the *A. MacKenzie*, are each 268 ft. long with a beam of 46 ft. and depth of 22 ft. They each have a capacity of 1250 cu. yd.

FIG. 13—PILOT HOUSE CONTROL STATION, SEA-GOING HOPPER DREDGES

The machinery installation in these dredges is particularly interesting and includes the largest Diesel electric plant ever installed in a ship. Each vessel is fitted with three main six-cylinder, four-cycle, air-injection, cross-head-piston, 1000-b. h. p., McIntosh & Seymore Diesel engines, each direct-connected to a Westinghouse 700- kw., 500-volt, 150-rev. per min., d-c. generator. Any two of the main generators supply power to the two 800-h. p., 480-volt, 110-rev. per min.,

double-armature propelling motors, which are also capable of developing full power at 90 rev. per min. for dredging speed. The third main generator supplies power to an 800-h. p., 480-volt, 135/160-rev. per min. single-armature motor driving the dredging pump.

generators. A 25-kw., 250-volt, gasoline engine driven set is also installed on the upper deck. Two balancer sets each consisting of two 5.5-kw., 115-volt generators are installed for lights and 115-volt motors.

A very interesting feature in this installation is the

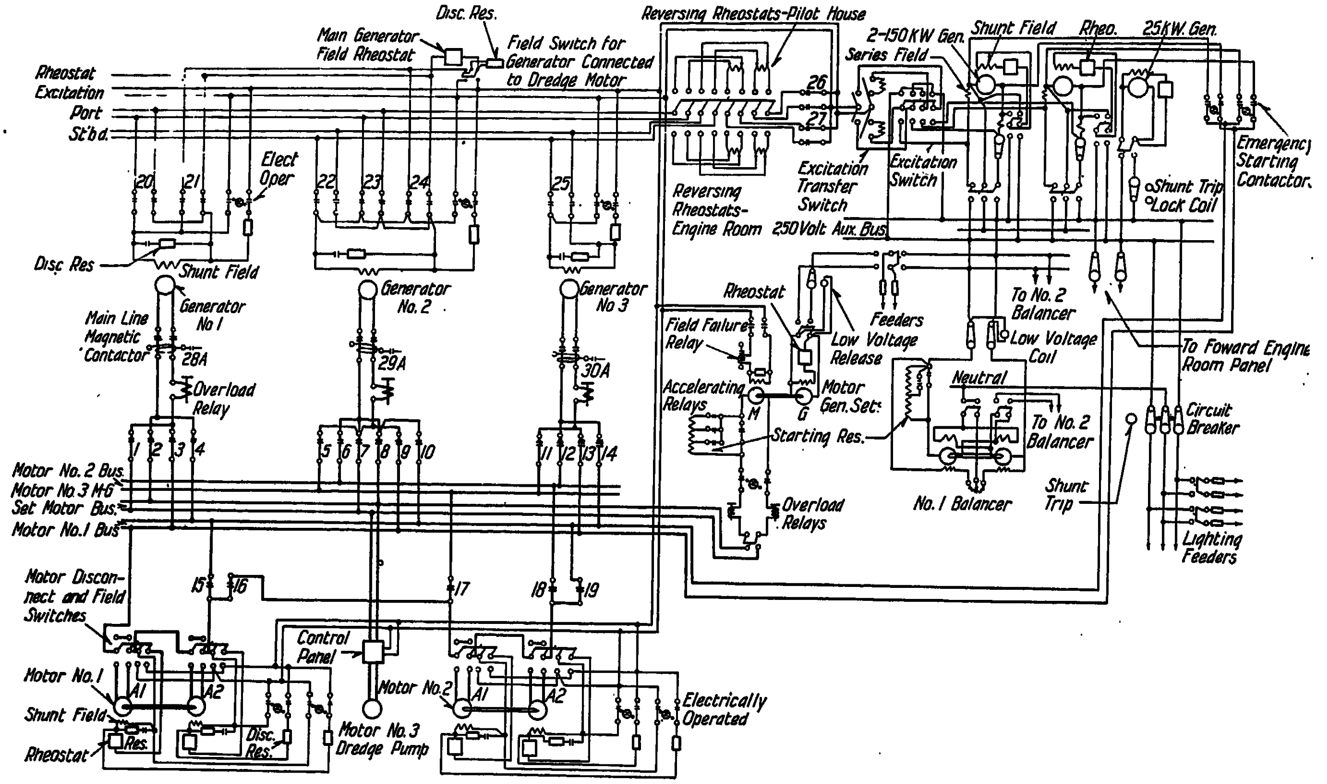

Fig. 14—Schematic Control Diagram of Main Circuits, Hopper Dredges

The generators and motors are totally enclosed and have forced ventilation.

In addition to the main power plant there are two Diesel engine-driven generating sets each consisting of a 225-h. p. four-cylinder, four-cycle, trunk-piston, air-injection type engine direct-connected to a 150-kw., 250-volt, 275-rev. per min. generator. These sets are used for excitation and auxiliaries on the vessel.

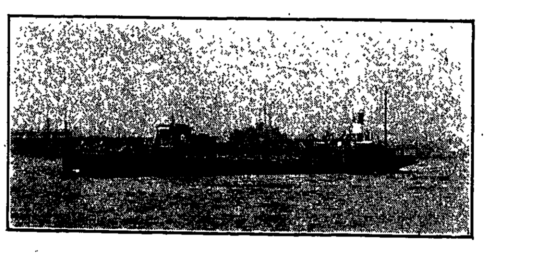

Fig. 15—S. O. Co. of New Jersey, Tanker *J. H. Senior*

There is also a motor generator set consisting of a 150-kw., 250-volt, generator driven by a 225-h. p., 480-volt, 1200-rev. per min. motor supplied from the main generator which supplies the dredge pump motor. This set is used for supplying the 150-h. p. jet-pump motor and other ship auxiliaries when desired, although normally they are supplied from the auxiliary 150-kw. control of the propelling and dredging machinery Eight combinations of connections are arranged in the hand-operated control switch group forming part of the main switchboard in the after engine room. Adequate

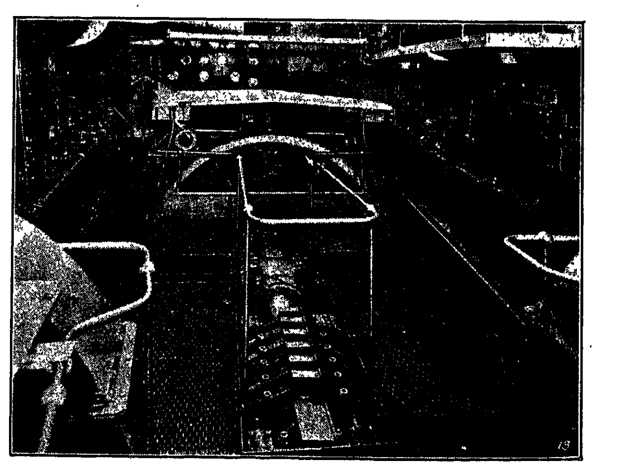

Fig. 16—Main Propelling Motor, *J. H. Senior*

switches, instruments, etc., are also provided on this switchboard for the complete control of the engine room machinery. Interlocks are provided to prevent

improper operation and the opening of main circuits until load is removed.

After the set-up connections are made complete

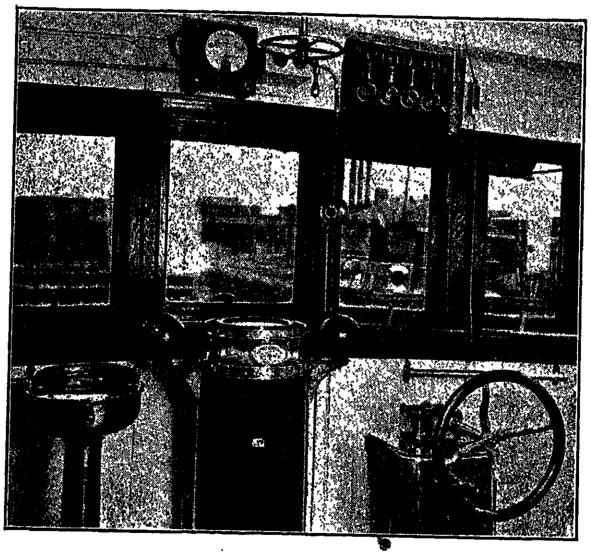

FIG. 17—PILOT-HOUSE CONTROL STATION, *J. H. Senior*

control of the starting, stopping, reversing and speed variation of the propelling motors is carried out by controlling the excitation of the generators supplying

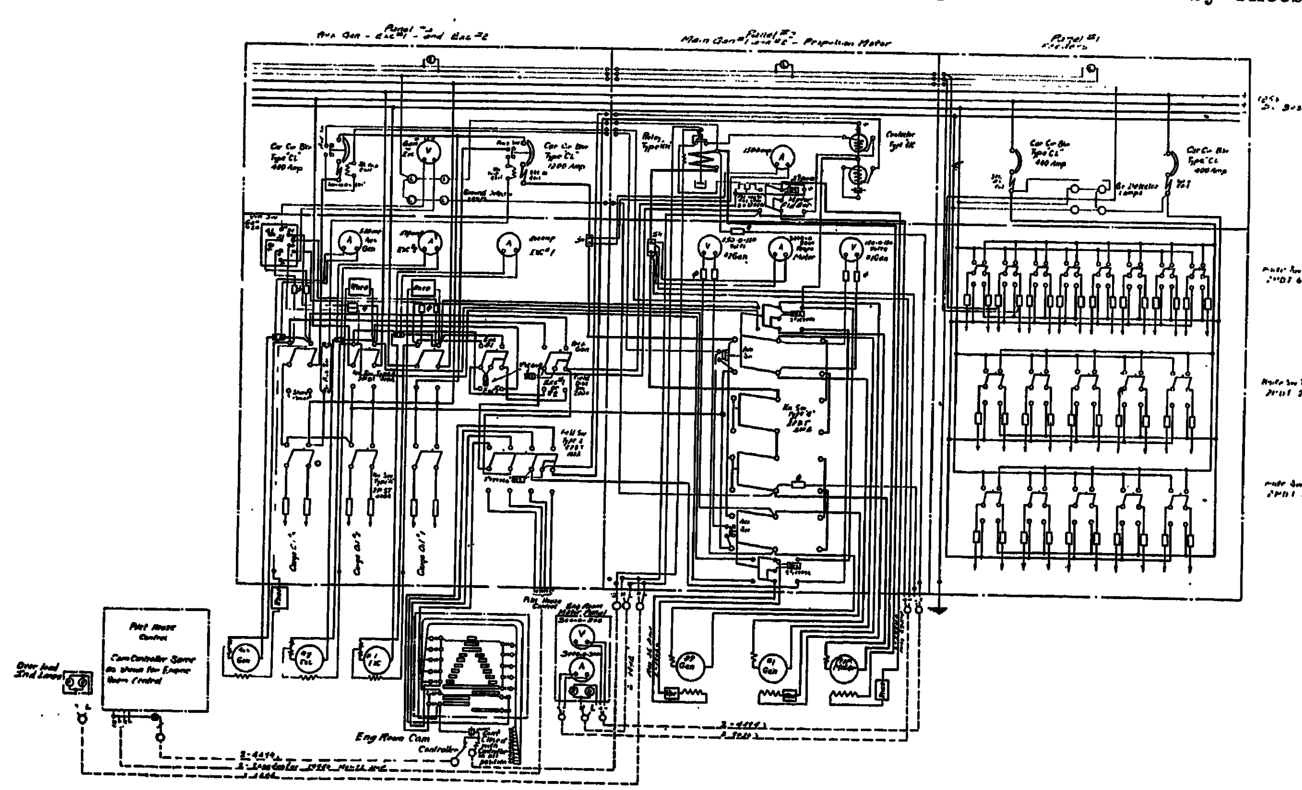

FIG. 18—WIRING DIAGRAM, *J. H. Senior*

them, both generators and motors being separately excited.

The Ward Leonard system of generator voltage control is provided both from the pilot house and the engine room. Sufficient instruments are located in the pilot house for observing the behavior of the electric propelling machinery.

Overload relays and magnetic line contactors pro-

FIG. 19—MAIN CONTROL ROOM, *U. S. S West Virginia*

vide protection against extreme overloads and short-circuits.

The dredge pump motor is started by rheostatic means using a drum-type master controller and a contactor panel.

No steam is used on the vessel for any purpose as all equipment is electrically operated.

It is believed by the Engineers Corps that these

electrically operated dredges will be considerabyl more economical than the steam operated ones.

Dredge for City of Portland. The new 30-in. Diesel electric dredge for the City of Portland, Ore., will be one of the largest and most powerful suction dredges ever constructed. There will be four main Diesel engines, two of 900 h. p. each and two of 800 h. p each. The 900-h. p. engines will be direct-connected to Westinghouse 610-kw., 500-volt, d-c. generators, while the 800-h. p. engines will be direct-connected to 540-kw., 500-volt, d-c. generators giving a total plant capacity of 2300 kw. The main pump will be operated by a 2700-h. p., 500-volt, direct-current motor capable of operating over a speed range from 250 to 360 rev. per min. The use of a d-c. motor with its simplicity and high efficiency was decided upon after careful comparison with an a-c. system.

An interesting feature in this installation will be the use of Ward Leonard system of control for the 250-h. p. cutter motor and the 75-h. p. swinging winch motor. Power for these drives will be furnished by a five unit motor generator set operated from the main 500-volt generator bus. Two of the five units will be 250-h. p. motors for driving the set and to furnish a neutral point for a 500/250-volt, three-wire system, the armatures of these two motors being wound for 250 volts and connected in series across the 500-volt bus. The remaining three units of this set will be a 200-kw. cutter generator, a 60-kw. swing generator and a 60-kw. auxiliary generator. There will be also a motor-operated hoist for the dredge ladder forward and another located near the stern for hoisting the spuds and for miscellaneous duty.

All control equipment on the dredge will be of the remote control type and complete manipulation of it will be possible from the pilot house.

Stern-Wheel Towboat

The success of the Diesel-electric stern wheel towboat *J. B. Battle* provides valuable information to operators of river boats in this country as to the economy and benefits to be derived by the use of this system for vessels of similar size and also for those of larger dimensions and powers.

This complete steel vessel was designed for the U. S. War Department in the office of the Chief of Engineers at Washington, D. C. She is 119 ft. 4 in. long with a beam of 23 ft. and depth of 5 ft. and draft loaded of 3 ft. 6 in. The machinery consists of two 150-h. p. four-cycle Winton engines each direct-connected to a Westinghouse 90-kw., 125-volt, 450-rev. per min., d-c., main generator and a 10-kw., 125-volt exciter. The propelling motor is rated 200 h. p., 240 volts, 600 rev. per min., and is flexibly coupled through a Fawcus 23 to 1 ratio double reduction gear to the lay shaft extending through both sides of the deck house. The two cranks on this shaft are connected by parallel rods to similar cranks on the paddle-wheel shaft thus transmitting power to the stern-wheel which is 15 ft. in diameter and 15 ft. long and has 13 buckets 30 in. deep.

There is also a 7½-kw., 125-volt Winton gasoline engine driven auxiliary generator for supplying auxiliaries and lights when the main sets are not running.

Complete Ward Leonard system of control of the propelling machinery is provided in the wheel house and includes adequate instruments for observing operating conditions at a glance. The excess power of the exciters not required for excitation of the propelling machinery is used for auxiliaries and lights.

The trials of this vessel were conducted in December 1923 and pronounced highly successful and the propelling machinery performed to the satisfaction of all concerned.

It is believed that the advantage of electric drive for this type of boat will induce the building of many more in the near future.

Tanker

One of the very interesting installations of the Diesel electric system of propulsion will be found in the Standard Oil Co. of New Jersey tanker

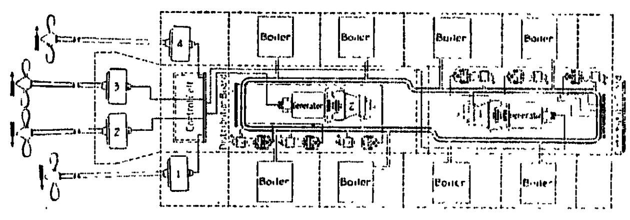

Fig. 20—Diagrammatic Arrangement of Propulsion Machinery, *U. S. S. California, Maryland* and *West Virginia*

J. H. Senior. This vessel is 220 ft. long with a beam of 38 ft. and draft maximum of 13 ft. Her propelling machinery consists of two McIntosh and Seymour 350-b. h. p., 275-rev. per min., heavy-duty Diesel engines, each, direct-connected to a Westinghouse 185-kw., 125-volt, d-c. generator and a 35-kw., 125-volt exciter.

The propelling motor is rated 455 s. h. p., 250 volt, 100 rev. per min.

The exciters provide, in addition to the excitation requirements of the propelling machinery, power for all auxiliaries and lighting. When the main units are not running in port, a 35-kw., 125-volt Diesel-engine-driven auxiliary generator supplies all the ship's power.

A unique feature in this installation is the use of one of the main units for supplying current to the three 35-h. p. cargo oil pump motors as well as other ships power thus keeping the size of the auxiliary plant to a minimum.

The Ward-Leonard system of control is used and two control stations are provided, one in the forward end of the engine room and one in the pilot house. At each station is provided an ammeter, a voltmeter and a propeller speed indicator.

The pilot house station is used almost exclusively and the control of the ship directly by the officer on watch without recourse to bells or other signals is considered by the owners and crew a valuable feature incidental to electric drive.

The main switchboard is located in the after end of the engine room and contains necessary air-break switches, instruments, rheostats, etc., for the complete control of the electrical machinery. Adequate interlocks are provided to prevent wrong operation and the switching system is arranged in a very simple manner for each manipulation.

electric drive and its wisdom in sponsoring it has been admirably substantiated.

The complete success of the collier *Jupiter* completed in 1913 was instrumental in causing the Navy to adopt electric drive for all capital ships beginning with the U. S. S. *New Mexico* in 1915. This act in itself is sufficient testimony of what the builders and users of war vessels think of its merits.

Service operation of several battleships has indisputably proven the prime requisite of reliability and economy of operation.

Electric drive, compared with other drives, shows

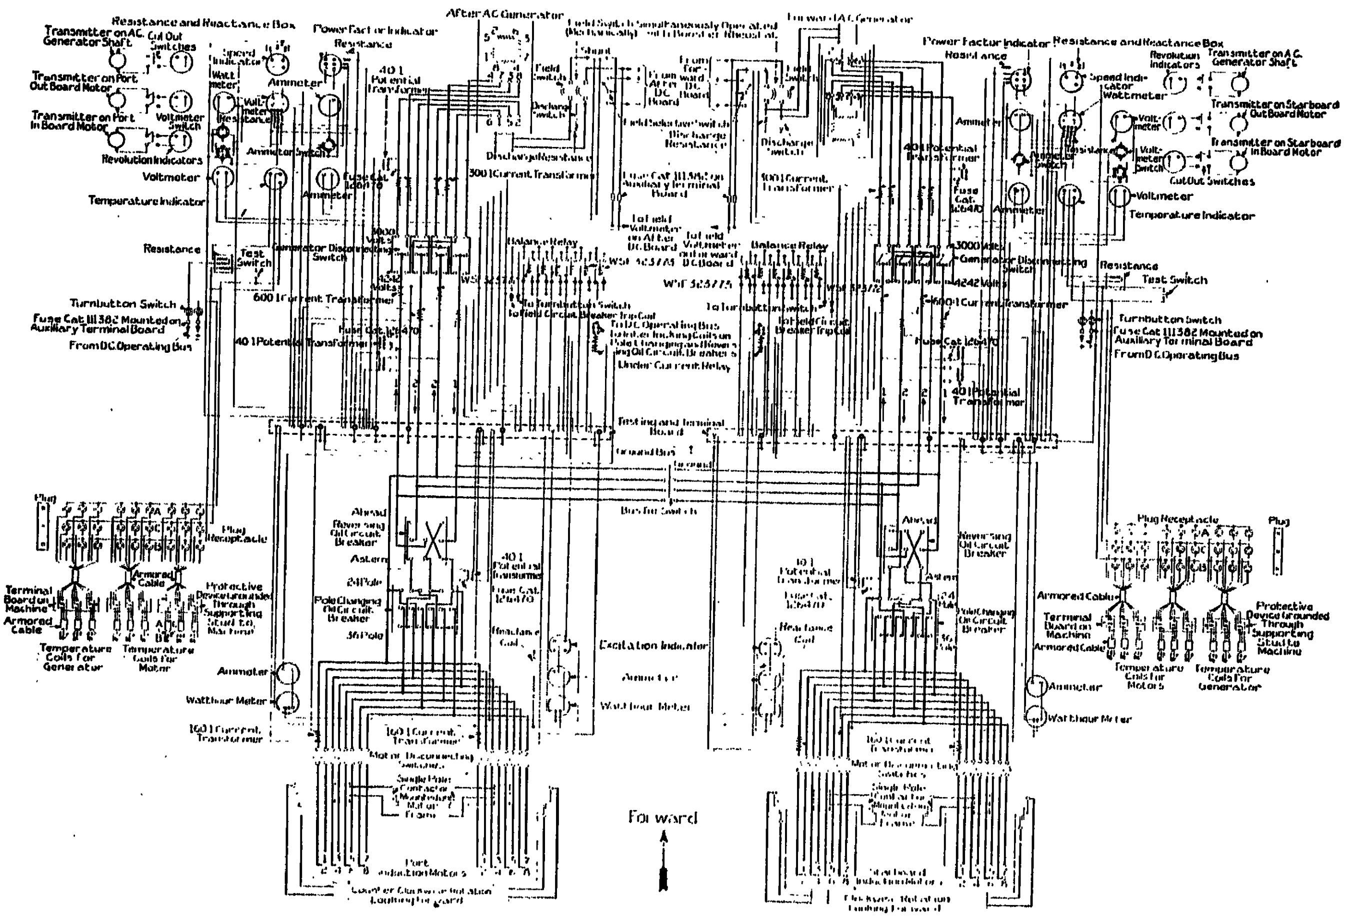

FIG. 21—DIAGRAM OF A.C. CONTROL WIRING, *U. S. S. California, Maryland* AND *West Virginia*

The trials of this vessel proved most satisfactory and met all expectations.

The *Standard Service* equipped with Pacific Diesel and General Electric machinery belongs to the Standard Oil Co. of California and is very similar to the *J. H. Senior*. This tanker has been in service for some time on the West Coast and has performed in a evry satisfactory manner.

U. S. NAVY

While the U. S. Navy is principally responsible for introducing turbine electric drive for ships it is not considered advisable to dwell in detail upon this branch of the marine field in this paper.

The U. S. Navy may be considered the pioneer in

superior protection from torpedo attack upon the machinery by virture of the flexibility of arrangement of the electric units and also provides superior maneuvering qualities.

Because of the large powers involved turbine electric is better suited for propulsion of war vessels than is Diesel electric. The development of larger Diesel engines for electric drive, however, may modify this situation in the near future. The present battleships are rated about 30,000 s. h. p. and the airplane carriers are rated 180,000 s. h. p. To date, therefore, electric-drive installations cover powers from less than 100 to 180,000 s. h. p. showing the extreme range of application.

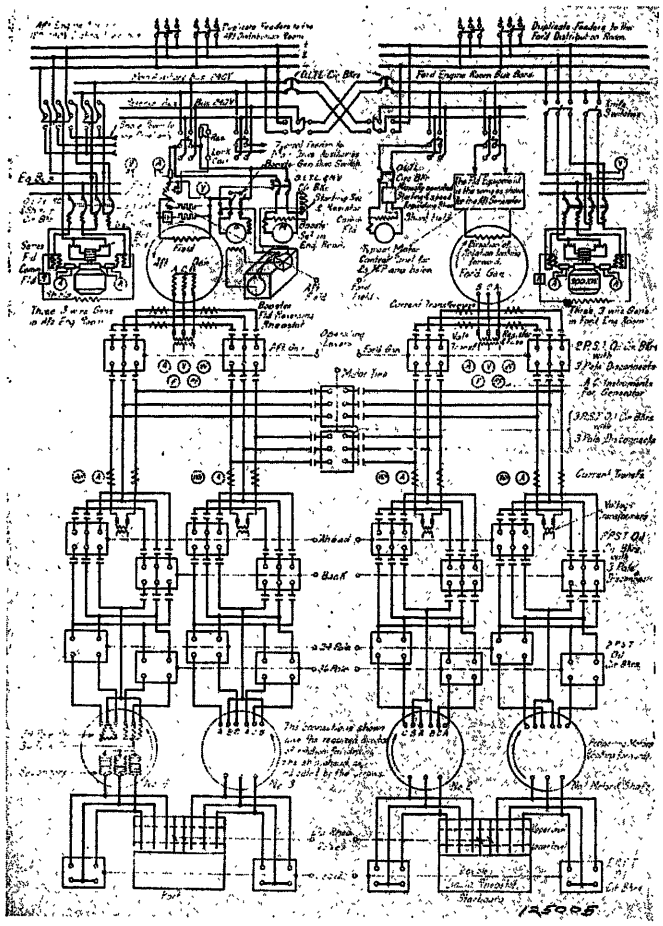

FIG. 22—SCHEMATIC ARRANGEMENT OF PROPULSION CONTROL, *U. S. S. Tennessee*

Induction motors of various rotor winding combinations have been used and all have proven satisfactory. Pole changing arrangements are provided for reduced speed and cruising conditions when using only part of the generating plant. This feature affords marked superior economy over other types of drive where the prime movers must all run at reduced speeds with correspondingly less efficient operation.

With full backing power available the electric drive ship possesses a decided advantage over the turbine drive ship when maneuvering. The ability to stop quickly and the positive control of all propellers are important features to a war vessel.

The control equipment is centralized and located in probably the most protected place in the vessel. The flexibility of control is such that almost any emergency resulting from casualty to any equipment connected with the propulsive machinery proper can be quickly taken care of by disconnecting the disabled unit from the source of power.

The control room is equipped with all necessary instruments, gages, etc., for affording the engineer in charge a complete pulse on the operation of the entire propulsion machinery.

The maintenance of electrically propelled battleships to date has been very slight. While casualties to the electrical machinery at sea appear quite remote, sufficient spare parts are carried for effecting repairs on board ship if circumstances warrant it.

Electric drive for capital ships is probably here to stay and is gaining reputation with every installation. Much credit is due the U. S. Navy for its advance step in the art of electric propulsion.

CONCLUSION

While the growth and adoption of electricity as a means of propelling ships was very slow for sometime, the past six or seven years in particular, have shown definite and rapid progress. Electric drive, after fair and impartial trial, has been well established and those who have been concerned with its development are greatly pleased with its growing popularity.

With the advent of the heavy oil engine the field of application of electric drive has been greatly broadened and the decided impetus already gained will carry this system of propulsion into practically all classes of vessels. The success of electric drive to date is beyond question and the widespread interest is conclusive evidence of its indisputable merits and most promising future.

The art of electrically propelling ships, while conceived many years ago, is comparatively new in application and it is a source of gratification to the pioneers that their early predictions are rapidly being fulfilled. After this system has passed through the lengthy stage of development common to the other types of drives the expectation of the most enthusiastic will undoubtedly be realized.

Discussion

V. Karapetoff: The Diesel engine is essentially a constant-speed prime mover, and I should like to ask Mr. Thau about its application to the tug service, which, to me, is essentially a variable speed application, and also one involving a high slip, either in the electrical equipment or between the propeller and the churning water. With a d-c. drive, the Diesel engine can run at a constant speed, and the d-c. motor on the shaft can be controlled either by a series resistance or by a resistance in the field circuit. But I should like to know how this is done with a-c. drive, or is the a-c. drive not suitable for the tug service?

I wish also to mention a specific engineering problem which arises in the turbine-electric marine drive with either induction or synchronous motors. The induction motor has a circle diagram, but this diagram holds true only at a constant current or constant voltage. In marine drive we have neither. If my information is correct, generators are usually operated at a constant field current, in which case the terminal voltage between the motor and the generator varies with the torque on the propeller shaft. As this torque increases, the generator voltage dies down. In computing the performance characteristics of such a set, we have a rather difficult engineering problem, because the internal reactance in the generator and its armature reaction have to be considered, as well as the constants of the motor itself, the voltage between the two machines being at the same time a function of the load.

C. H. Giroux: I shall confine my remarks to river boats, as I believe that many engineers from this vicinity are interested in this subject.

The authors have omitted reference to one vessel which I believe deserves mention, as it is one of the pioneers in its field, namely the *Chenoka*. The *Chenoka* is a stern-wheel towboat; 77 ft. long, 10-ft. beam, and having a displacement of 32 long tons.

During 1920, the Cincinnati district of the U. S. Engineer Department equipped it with electric propulsion, using a 25-kw., gasoline-electric generating set, a 50-h. p., shunt-wound motor, and rheostatic control. For experimental purposes, a producer was installed and the engine operated on coal gas for a short time. The intermittent service in which the vessel was used, however, was not conducive to good results with the producer, and it was finally abandoned. Kerosene was used with a fair degree of success, but the advantage of lower fuel cost was offset by operating difficulties, and the engine is now being run on gasoline only.

While the equipment on the *Chenoka* does not conform to present marine standards in many respects, it has been in successful operation for a sufficient length of time to prove the reliability of electric drive for small river boats where the maintenance is not always the best, and where skilled operators cannot be employed for monetary reasons.

Based on the results obtained on the *Chenoka* and the Diesel-electric towboat, *J. B. Battle*, the U. S. Engineer Department is designing and constructing a number of stern-wheel towboats for use on the Mississippi and Ohio rivers. These boats will have improvements incorporated which should cause them to show even better results than those now in operation.

The most important of these improvements is the adoption of a propulsion motor, the speed of which may be varied over a wide range by field control, keeping the horse-power output constant. Ward Leonard control for slow-speed running, accelerating and reversing is, of course, retained. The variable-speed motor allows full rated output of the prime movers to be applied to the wheel at any speed of the towboat from standstill to light-running speed.

This is a decided advantage over any direct drive system where the horse power varies with the speed of the paddle wheel. From tests on existing towboats it is estimated that the effectiveness will be increased as follows:

Conditions	Variable-Speed, Electric Drive	Other Systems
Towing effort at standstill, per cent....	160	100
Speed towing four barges, per cent.....	110	100
Speed light without tow, per cent......	100	100

The first condition means that the tow can be accelerated more quickly and a heavier tow can be maneuvered.

The second condition shows a substantial saving in time when handling heavy tows.

The third condition shows that there is no sacrifice in running light speed for the gain in towing ability.

As the weight of the tow is often limited by the rapidity of the current when going up-stream, the extra towing effort available may enable the boat to handle heavier tows and to make "double tripping" unnecessary in the more rapid parts of the stream.

Considerable attention has been given to the control equipment, with the idea in mind of simplifying the methods of operation. The next towboats built for the U. S. Engineer Department will be equipped with automatic control from the pilot-house. By means of a single master switch, the boat may be maneuvered from full speed ahead to full speed astern without the necessity of watching electrical instruments or without danger of overloading the prime movers. No adjustment of rheostats in the engine room will be required for handling tows of various weights, as this is accomplished by the automatic devices.

An attempt is being made to place the design of river boats on a more scientific basis than has been possible heretofore, not only by means of complete model tests, but also by securing operating data from vessels in service. Electric drive, with its attendant possibilities for accurate measurement of power under daily service conditions, will do much to aid the investigators in this attempt.

A. A. Coyle: The propulsion of vessels by electric power is yet in its infancy, and like most other inventions, will be improved from time to time as defects in design and mechanism develop. This is the history of mechanical devices, and while there may be exceptions, we know of none in which the original design has not been changed to meet the conditions under which they must operate.

Generally speaking, electric drive for boats has passed the experimental stage, the installations made in the past and the successful operation of the various craft in which the installations were made, demonstrate its practicability and efficiency for boat propulsion.

Boat owners and operators have been slow in adopting new or untried methods for the operation of their boats and the principal reason for their conservatism will be found in the fact that the margin of profit is so slight that experimental work could not be undertaken, or even considered. Operating costs have

more than doubled, and the receipts or advance in rates have not been in the same proportion, resulting in what is termed hand-to-mouth existence. With conditions unfavorable for successful operation of their boats, many have disposed of their interests, while others have continued the operation of their fleet with the hope that means for reducing the operating costs would eventually be provided. The successful operation of boats propelled by Diesel-electric power has inspired boat owners to investigate the advantages of Diesel-electric over the steam drive, the result of which has convinced many that the Diesel-electric power is what is needed if river traffic is to be revived, and the operation of river craft made profitable. Diesel-electric power for river boats has the following points in its favor:

a. Economy in operation (fuel and labor)
b. Efficiency in maneuvering
c. Concentration of responsibility in one man
d. Positive control
e. Insurance reduction
f. Cleanliness
g. Requires less deck space
h. More deck space available, due to storage of fuel in hold
i. Equal torque at all speeds

With the facts above mentioned brought to their attention, and the necessity of reducing operating expenses to the minimum to realize a reasonable return on their investment, many boat owners have decided to install Diesel-electric power on all boats to be constructed by them in future, and in some cases will remove the present steam installation and install Diesel-electric power. This will tend to revive river traffic, and the means by which the operators of river boats may recoup themselves for some of the losses sustained in the past.

As is generally known, there are in use three methods for the application of electric power to stern-wheel boats, *i. e.*,

a. Longitudinal shafts with bevel or worm gears
b. Chains running over sprocket wheels
c. Pitmans, similar to those in use for steam drive

For many reasons, the first and second methods are not satisfactory where applied to stern-wheel boats operating on rivers where silt and drift are prevalent. The construction, and the bracing of the paddle-wheel supporting beams must necessarily be light to insure the desired draft of boats for shoal rivers, and the wheel being subjected to both vertical and longitudinal movement (however slight) tends to throw out of alinement the drive shafts and gears, with a corresponding loss of power. There is also the danger of drift and broken buckets coming in contact with the shafting, which often causes serious damage to the parts and quite frequently disables the boat until such time as the parts can be unshipped, sent to a machine shop, repaired and replaced. As the boat is often some distance from a shop in which repairs might be made, it is evident that delay in such cases is very serious to the owners. For these reasons it has been the aim of designers and owners of stern-wheel boats to eliminate all rods, cams and gears from on or near the wheel. It may be said by those advocating the chain or gear drive that all parts may be housed for protection, but even though this housing may protect the parts so easily affected, they cannot prevent the vertical or longitudinal movement of the wheel, which tends to throw the driving mechanism out of alinement. The housing must necessarily be made very strong to withstand the usage to which they will be subjected, for if this is damaged it is a serious matter.

The third method, (pitmans) to transmit the power from the motor to the wheel shaft is in our opinion the best yet devised. However, the drive as applied, is not entirely satisfactory to many boat owners and it is thought that a much better arrangement can and will be designed, eliminating the objectionable features.

The installation on the U. S. Towboat, *J. B. Battle*, includes a large and very long counter-shaft, extending across and nearly the width of the boat. To this are attached the cranks and a large spur gear. This gear is attached to the counter-shaft at about the center, thus necessitating three or more bearings, a very bad feature when one takes into consideration the light construction of the hull to which the counter-shaft bearings are secured, because it is then impractical to provide foundations with sufficient rigidity to insure proper alinement—an essential feature in fuel economy. And while the shaft alinement is not observable, it is more or less out of alinement, the amount depending upon the rigidity of the hull to which the shaft bearings are attached. A single motor is used for the full power required to rotate the paddle wheel at the desired velocity, and, as all of the power is applied to the large spur gear attached to the counter-shaft, it is evident that when one of the pitmans is on center the full power of the motor is transmitted to the other pitman which, for *steam drive*, would be designed to transmit only half of the actual horse power developed. Under no circumstance could more than half the power be applied to either pitman. Therefore, it is evident that pitmans, cranks and wrists for the electric drive as now applied must be proportionately larger than those in use for steam drive with equal power, to care for the increased thrust. This addition for increase in strength and weight of the pitmans, cranks and wrists occurs where it is most objectionable, as our great problem is to keep the stern of the boat up, in order to obtain maneuvering benefits. With the counter-shaft extending across the boat, and, necessarily, three to five feet above the deck, the space aft of the counter-shaft is not available for other purposes.

We are of the opinion that it is possible to design, and apply a more efficient and better general arrangement than is now in use, and we are working with that end in view. We believe the power required to propel the boat should be in two units, (two motors) each acting independently on its own pitman, with a suitable control to cut out the current gradually as the pitman approaches the center, and again applying the current gradually immediately after the pitman passes the center, the application of power being similar to that now in use with steam drives.

There is a difference of opinion among electrical engineers regarding the practicability of such an arrangement, some contending that motors as now constructed, would not stand up under such usage but, as the motor is not stopped, or even perceptibly slackened, it occurs to us that if motors as now constructed will not meet the requirements, a motor can be built that will.

R. A. Beekman: My comments refer to several points in the paper as indicated in the following notations:

Paragraph beginning "The justification of the turbine electric system, etc." Taking transmission efficiency in its broadest sense, that is, from the boiler to the propeller, the efficiency of the turbine electric system using a-c. machinery is in many cases equal to, and in some cases better than, the corresponding transmission efficiency obtained with geared turbines. Namely—the geared-turbine losses including the losses in the gears, reversing element, cross-over connections, additional bearings, packings and lubricating oil required over and above that required by the turbine electric system, give a total of from 7 to 10.3 per cent of the total shaft horse power.

In the case of the turbine electric drive, the total loss including losses in the motor, generator, control, and cables, and the power required for excitation and for ventilation of the main machinery, is approximately 7.6 per cent of the power delivered to the propeller shaft. Furthermore, where single reduction gears are used, the turbine efficiency on the Rankin cycle should be higher in the case of the turbine for electric drive than the turbine for geared drive, since the former turbine can be run closer to its most economical speed.

Paragraph beginning "Turbines with reversing elements, etc." The larger diameter necessitates larger radial clearances with

reaction-type turbines, but if impulse-type turbines are used, radial clearance is not a factor.

Paragraph beginning "With turbine electric drive alternating current is more satisfactory, etc." Greater emphasis should be given to the advantages of d-c. turbine electric drive for the smaller ships where turbines are suitable. The important advantage is that a constant-speed turbine generator may be used which permits taking the auxiliary power either from the main generator or from the direct-connected exciter. We also have all of the advantages incidental to the flexibility and reliability of the Ward Leonard system of control repeatedly referred to in this paper.

Paragraph beginning "The electrical machinery is practically the same as used in land installations," etc. There is an increasing tendency to run the electric auxiliaries from the main propulsion generator, in order to get auxiliary power at approximately the efficiency of the main unit.

Paragraph beginning "A 75-kw., 115-volt, 900-rev. per min. exciter," etc. This exciter also supplies power for miscellaneous auxiliaries.

Paragraph beginning "The Ward Leonard system of voltage control is by far the most satisfactory," etc. The Ward Leonard system is not necessarily the most satisfactory system, inasmuch as the rheostatic-control system has been used most satisfactorily on at least five ships. The rheostatic control was selected after careful consideration of the special conditions to be met. Where two or more generators are used one generator may be operated at constant potential, furnishing power for excitation and the auxiliaries as well as for propulsion, and the second generator may be operated on the voltage-control basis. This is a combination of rheostatic and Ward Leonard control where all maneuvering of the ship between 50 per cent and 100 per cent propeller speed is obtained on a Ward Leonard, and hence, highly efficient, basis.

Paragraph beginning "With the series connection of generators," etc. The statement regarding Ward Leonard system being less expensive may be somewhat misleading, due to the fact that the necessary exciters should be considered a part of this system, both as regards expense and complication.

Paragraph beginning "The control board contains suitable switches," etc. In the early days of Diesel-electric drive it was thought to be desirable to have a time-delay element for limiting the speed of operation of the control, but experience has shown that this is unnecessary and that we can go from full speed to the stop point without hesitation.

Paragraph beginning "With this type of drive provision is usually made for both pilot-house and engine-room control," etc. Another advantage of pilot-house control of tug boats comes in being able to take slack quickly out of the tow ropes and uniformly accelerate the tow without objectionable strains.

Paragraph beginning "Flexibility and Reliability." The number of generators is not limited by either the rheostatic or Ward Leonard system of control.

Paragraph beginning "It will be noted that the control for these boats," etc. The *Fordonian* has a control which is a combination of Ward Leonard and rheostatic system, as described under Comment No. 6.

Paragraph beginning "The *Standard Service* equipped with Pacific Diesel and General Electric machinery, etc."

The *Standard Service* was put into commission in March, 1923, and similar tankers, the *Alaska Standard* and the *Hawaiian Standard*, were put into commission in December 1923, and February 1925, respectively. This is a good example of an owner having added Diesel-electric ships to his fleet after experience with the first boat.

W. E. Thau: Professor Karapetoff struck on two vital points in connection with electric drive; one relating to the flexibility of direct current for tug boats and the other the unit design of an a-c. propulsion system.

If an attempt is made to use alternating current for tug boats and that class of service, we should have a plant which is extremely inflexible in comparison with direct current; and, furthermore, if we had multiple-unit arrangements of engines, it would be necessary to operate a-c. machines in parallel, which is questionable, regardless of the arrangement; that is, the idea of operating Diesel-driven, a-c. generators parallel on board the ship. In addition, we would lose about 80 per cent of the flexibility which the d-c. system possesses for tugboat work.

Furthermore, by using the d-c. system, say with two generators and a single- or double-armature motor, we are able to operate that tug with one unit in case of failure of one of the engines. In case of failure of a direct-connected engine, the situation is helpless. This particular advantage has proved to be of great practical value in connection with the *P. R. R. Tug No. 16*, operated by the Pennsylvania Railroad in New York. On one occasion they had trouble with an engine and that engine was shut down and the tug operated on the remaining engine, without those for whom the towing work was done knowing whether one or two engines were in operation.

With the d-c. system, the Ward Leonard system of motor speed control is used. This permits the use of simple generator-field rheostats for providing a large number of speed values in each direction in the most economical manner. The engines run at constant speed. The generators are connected in series, thus dispensing with the necessity for parallel operation. The electrical efficiency is maintained near the full-load value throughout the entire speed range from 10 per cent to 100 per cent speed. In other words, the combined electrical efficiency curve is very flat.

In the case of alternating current, the speed control would have to be obtained by engine control or rheostatic control. The former is no improvement over the direct-connected engine and the latter is both complicated and wasteful.

Furthermore, the d-c. system permits full power to be had from a fractional number of engines, whereas with a-c. the engine speed would have to be reduced to suit the load in the case of operation on less than the full number of engines.

In case of turbine electric drive, the question of torque couple between the motor and generator was brought up. This is something that would probably be overlooked by the uninitiated, but the fact is that the whole system from turbines to control must be designed as a unit and the functions of each part correlated.

The pulling out of step of an a-c. drive is not due to the fact that the motor breaks its torque couple. The motor is designed for about one and three-quarters pull-out torque, and that gives it plenty of margin, so long as it is provided with a constant voltage. The real cause of pull-out between the generator and motor is the collapse of the generator voltage due to overload which Professor Karapetoff has mentioned.

In all land installations, we have a relatively unlimited supply of power and the generators are sufficient in number and in size to supply the total demands and take care of peak loads. Such machines are usually designed to provide about 5 per cent to 10 per cent torque margins at the nameplate rating.

In the case of ship drive, when the load varies with sea conditions, maneuvering, and so forth, we must provide an ample torque margin in the generator. That is provided by additional excitation. If we operate with too great excitation, the efficiency of the motor drops considerably. This condition is very pointedly shown in certain tests that are made on board battle ships, and are known as excitation, or drop-out tests. We start with a high generator excitation and gradually decrease it until the motor and generator torque couple is broken. The power input to the motors at the start of the test is appreciably higher than when zero torque margin is approached (approximately 10 per cent) and, therefore, it is uneconomical to run with too much torque margin. That condition has been recognized in the Navy, and steps have been taken to operate vessels with an economical torque margin. That margin is indicated by an

instrument called a stability indicator which shows the torque ratio at any instant.

Mr. Barrister brought out a point in connection with the steering gear on board the ship. This is another case where the complete facts must be known, and the motor, controller, and resistors designed as a unit and not with a motor picked here, a controller there and a resistor some other place. As already mentioned the various units picked at random have proven a failure. It is a definite application problem and where early failures have occurred, they can almost invariably be traced to the fact that the equipment has been taken out of stock and put on board the ship. Those of us who have had experience with the sea conditions know that that stock equipment does not work. When such care is necessary in the design of the equipment, it is no wonder we ask for competent electricians to take care of this electrical equipment.

Mr. Giroux is in a very good position to discuss the river-boat situation, being the electrical engineer for the United States Engineering Department at Washington, and having had considerable to do with practically all of their engineering work in that line, which he has so ably described.

The War Department is investigating and pioneering in that field and so soon as they prove to the private owners that the electrical is the proper system, we shall see private boats driven by the Diesel-electric system. Of course, the War Department is in a better position to make study and investigation of that kind because of its organization and funds. We civilians pay the taxes and they do the pioneer work in that and other fields. The results benefit every citizen in the country. The War Department is doing wonderful work along these lines, even though most of us are not aware of it.

Mr. Coyle has enumerated the advantages of electric drive for river boats from a designer's and builder's point of view, and it will be noted that he has confirmed, to a great degree, the claims for this type of drive in the paper. Mr. Coyle has spent practically his whole life in this work, and so is in a good position to analyze the situation.

We feel that he is correct in his statement, that gears and chain drives are not as applicable to stern-wheel, river-boat propulsion as the pitman drive. It represents a very intricate problem and one which will require much close study before it comes to a high degree of perfection. The fact that the electric motor tends to produce constant torque introduces a problem for consideration in design of pitman. If it were possible to regulate the motor performance similar to that of a steam-engine performance, it would help things along considerably. There has been devised a special form of pitman connection using two pitmans on each side of the wheel, and in each pair the pitmans are placed 180 deg. from one another. With that arrangement, having the other side at 90 deg., we have a system which will develop a constant turning effort on the wheel. That has a further good point, in that the wheel bearings do not have to be anchored solid. That eliminates a lot of trouble that might arise from any other pitman design.

I should like to make just a few remarks in connection with Mr. Beekman's discussion of the paper. I thought the paper recognized the suitability of d-c. equipment with turbine electric drive. We stated that the application for that type of equipment was confined more to the vessel requiring very restrictive maneuvering. For a vessel, such as a tug or a ferry, operating in unrestricted water direct current is better suited than alternating current, and while the cost is more, the installation of the direct current is justified by its increased flexibility.

The question of rheostatic control versus Ward Leonard is one that can probably be discussed for a long time. Some of the present rheostatic-control vessels are handicapped. In small installations there is no question that the rheostatic-control system can be used. I think that was mentioned in the paper and an example cited. Those applications that require constant voltage can be supplied by exciters of suitable capacity driven from the main engines.

The time-delay device, which was referred to, I believe, is absolutely necessary and essential on many classes of ships. So far, the application of Diesel-electric drive has been confined to slow-speed, coarse-line, low-inertia vessels, but when this type of drive is applied to fine-line boats with high powers, requiring considerable torque to stop them, some kind of a device will be required to regulate the current. D-c. machinery cannot be abused to the same extent as a-c. machinery. Mr. Giroux touched on that point in his discussion, and described how the U. S. Engineering Department expects to provide for a current-regulated device on its tow boats.

In the case of direct-connected impulse turbines the large disk area resulting from the large-diameter wheels is a factor contributing to additional losses which are comparable to the radial-clearance losses in the reaction turbine.

Auxiliary power cannot be taken from main units during maneuvering if the Ward Leonard system is used.

In any event, exciters or direct-connected auxiliary generators are very desirable for supplying auxiliary load, and they may just as well be made large enough to supply excitation for the Ward Leonard system. Therefore, they are not an added complication.

Coal-Mine Electrification

BY W. C. ADAMS[1]

Member, A. I. E. E.

Synopsis. *To purchase or generate power for mine requirements is determined on basis of minimum power charge against coal production. Alternating-current transmission results in better efficiencies and lower costs. The choice of coal hoisting systems is based on reliability with cost secondary. Skip hoisting for large mines gives lower costs of installation and operation, with greater reliability. Man-and-material hoists arrange to take care of every possible contingency against shut-down is advisable. Converting stations is the logical method of supplying direct current to underground equipment.*

THE conditions vary so greatly at the different mines that it is impossible to thoroughly cover this subject by discussions as to the many problems to be solved under varying conditions. This paper will include a brief discussion of some of the important problems of coal-mine electrification with descriptions of some concrete installations.

Power supply to the mine is an important factor and must be considered as coming from one of two main sources, either generated by a plant at the mine or purchased from a public utility company. Each has its place and the choice can be made only on the basis of cost as it affects the cost of coal production.

A vital part of a shaft coal mine is the hoisting equipment and reliability must be of first consideration. The economic side is also discussed to show why different types of hoists may be installed to meet special conditions. A general description of the largest coal hoist in the world is here given with a discussion of some of the problems involved in its design.

After the coal is hoisted to the surface it must be properly prepared and suitable features of control have a vital bearing on the success of the preparation.

The mining equipment in the underground workings must be supplied with power and here, the distribution problem is most important, as the life and maintenance of all electrically driven equipment and its ability to produce maximum results is materially affected by power distribution.

SOURCE OF POWER

The Public Service Companies have materially reduced the cost of power for coal mining operations. They have made it possible for the coal operator to purchase his power requirements at a much lower cost than that at which he could produce it with the make-shift uneconomical plants which used to be a feature of every mining operation. In doing this they have set up a bogey unit power cost for each mine. A generating plant owned and operated by the mining company is not warranted unless it can produce the power requirements at a cost at least equal to that of purchased power, which cost must include a reasonable return on the additional capital invested.

The Public Service Company has the advantage of a large output and a relatively high load factor which, for a mining operation, is usually about 14 per cent and rarely exceeds 20 per cent. Both the quantity of output and load factor might be increased if it were possible to serve some outside off-peak load; but this is rarely the case.

Where two or more operations can be served from one plant, the load factor will be improved, reducing the unit investment cost per ton output and cost per unit of power generated. In making a comparison of the cost of power generated and power purchased, the advantage of grouping is often over estimated unless a like grouping with a single metering point is considered for purchased power.

As an illustration, a mining company operating seven properties with purchased power metered for individual mines made the necessary investment for distributing lines from a single metering point. With this system the power bill was reduced 19 per cent, which represented over 20 per cent net annual return on the investment.

A Public Service Company can locate its plant at some advantageous point largely determined by the water supply. At a mine site the quality and quantity of water available for boiler and condenser uses is often inadequate. This factor must be carefully considered before it can be determined that a generating plant for mine requirements is even feasible, for the expense and losses due to a shortage of water supply during one prolonged dry period may offset the accumulated advantages of a mine plant over a period of many years.

As against these advantages, the Public Service Companies must pay freight on their coal, and usually, because of these freight charges, must buy high grade fuel, and then make a profit over their costs.

The individual operator can burn coal which he cannot sell or a grade which has relatively low market value or is hard to move. In the preparation of coal at almost every mine, impurities containing a certain amount of burnable material, are picked out, which if properly crushed and mixed with the low-grade sizes made in coal preparation, should give a fuel containing from 30 to 35 per cent ash.

Every coal-mining generating plant should be equipped to burn this product, thereby reducing materially the largest item of cost in power production by a Public

1. Allen & Garcia Co., Chicago.

Presented at the Spring Convention of the A. I. E. E., to be held at St. Louis, Mo., April 13-17, 1925.

Service Company. The plant must also be properly engineered, designed and equipped for the usual economies found in good Central Station practise, making allowances only for the difference in sizes of equipment.

Reliability of the power source is essential and a Public Utility System, with its vast net work of transmission lines, is often at a disadvantage as compared with a plant located at the mine site. A Public Service Company which cannot show a good record for continuity of service or that reasonably continuous service can be supplied, should not be considered a possible source of power for a coal operation where a power plant at the mine site is practical.

"The coal mine operator in installing a power plant for generation of his power requirements is entering a field for which he is not organized" is an argument very frequently used for the purchase of power. This, however, is not an argument that carries little weight for coal operators can and are now producing their own power requirements at a profit.

This is demonstrated by an existing installation where a power plant was put in for a shaft operation having a daily potential capacity of 7000 tons. This plant is designed to secure maximum economies consistent with capital investment, and is burning the crushed mine pickings, mixed with the lowest grade slack produced.

The estimate on which the decision to install a plant at the mine site was based, showed that the saving of power generating cost as against purchased power cost, would pay 11 2/10 per cent interest on an investment of $460,000.

This estimate of comparative power cost included for the generated power all items of labor, supplies, maintenance, fuel, water, amortization, obsolesence, and overhead items, excepting interest on capital investment. For purchased power, similar items were added to the power bill, and the cost of operating, maintaining, etc., a steam plant necessary for furnishing the steam required for heating, wash house purposes, air humidification and standby equipment was also included.

Based upon operation to date, it is safe to say that the saving estimated will be exceeded. This, together with the fact that the Public Service Company had not been especially reliable, has made the generating station at the mine a profitable investment.

Like estimates for a somewhat similar operation in a field where lower power rates were in force failed to show that any saving could be made by the installation of a generating plant at the mine. The failure to show any saving is partly explained by the fact that the capital investment was excessive due to the natural conditions affecting power plant construction.

An investigation of cost of generating power versus purchased power for a large operating company where two mines could be served from one plant, determined that by an additional expenditure of $760,000, power could be produced at a cost which would earn 7⅜ per cent on the investment in comparison with purchased power costs.

This plant would require some special provision for insuring water supply and this fact, considered with the earnings on the investment, resulted in a decision in favor of purchased power.

Opinions as to the proper returns that such an investment should show varies and is somewhat dependent upon the availability of capital from a company's reserves or the borrowing capacity. It must also be based upon the probable returns that could be secured by an investment by the company in other channels; another coal operation for instance. It should not be less than 10 per cent and might, in many cases reasonably be set as high as 15 per cent.

The last mentioned company is now purchasing power for the complete operation of one plant and partial operation of the second. The power is metered at one point and parallel transmission lines are to be provided from this point to the Power Company's system and to the second mine as an insurance against possible line trouble.

The service is taken from the Power Company's system at a point that is provided with transmission from one station over three routes, from a second station over one route and from a third station over one route, to make possibility of power failure remote. It is, however, not often possible to make such an ideal connection for power service, but wherever feasible, loop transmission should be provided with proper switching equipment placed at the mine site to take advantage of the same.

The practise of purchasing power for part of a mine's power requirements and maintaining a steam plant for the hoist is quite common although is a very expensive practise. This condition is usually the result of an attempt to minimize capital investment, either for supplying additional power requirements or the rehabilitation of the existing plant. The savings to be secured by using purchased power throughout are considerable and often obtainable by a relatively small additional investment.

Power Characteristics

Progressive mining operations are now being equipped with every mechanical mining device which will meet the requirements of the existing condition and reduce the cost of coal production. Motor-driven cutting machines, loading machines, loading conveyers and loading scrapers can be equipped with either d-c. or a-c. motors. However, locomotives have proved satisfactory only with d-c. motor equipment.

All this equipment operates at the mining faces, and it is necessary to provide transmission facilities for power to the extreme points of the area to be developed by a given operation.

A d-c. transmission system for small mines, having a

small assigned acreage, may be designed for efficiency and installed with reasonable expenditure. However, the cost for such a system for the larger mines with large assigned coal acres becomes prohibitive, both because of initial investment and subsequent operation.

The economical installation for such an operation employs alternating current for transmission with converting substations at load centers for the underground a-c. equipment and transformer substations for a-c. equipment.

A capital fund when a large operation is opened, set aside at four per cent interest to cover the cost and maintenance of such a system throughout the life of the property would be from 25 to 40 per cent of the sum required for a complete d-c. system, and the average efficiency of transmission would be at least 15 per cent lower with the direct current. It is impractical to consider a d-c. transmission system on the same basis of efficiency as an a-c. system with converting substation, as the returns from such an increased efficiency would not be adequate for the additional investment required.

An investigation for a large operation with an existing d-c. transmission system determined that to bring the transmission up to reasonable efficiency, additional copper at an estmated cost of $87,000 would be required. There would also be a yearly expense of approximately $300,000 additional for the life of the operation for reinforcement of copper. The initial expenditure for installation of motor-generator sets and substation was estimated at approximately $100,000 with an additional cost of $45,000 for changes of lines, bore holes, substations to keep the latter reasonably near load centers throughout the life of the operation. Therefore installation of motor generator sets showed a saving of $242,000 in capital investment through the life of the mine. The use of the motor-generator sets near the load centers made it also possible to maintain an average of 16 per cent better efficiency.

The advantages derived from a-c. transmission will outweigh any advantages that might be secured by d-c. motor drive for the tipple units, mine fan or shop equipment.

Therefore, the source, whether from a public utility company or a plant at the mine, should provide a-c. power.

Coal Hoisting

In planning a mine, and especially a mine of large capacity, the effect of loads and rope on the size, power costs, and initial investment for the equipment should be considered. The rope speeds that can be obtained in hoisting are limited; hence the maximum capacity of a mine is set by the load carried per trip. Where large capacities are set for mines on a basis of cage hoisting, it is always possible to reduce the hoist initial cost and the hoist operating cost by using skips whereby two or more cars of coal can be hoisted at one trip.

Table No. I and Fig. 1 will give a comparison between the hoisting equipment, the power consumption and the initial cost for two assumed installations, all designed for the same capacity. The first is a self-dumping cage installation and the second an installation using overturning skips.

Comparisons are made on the basis of a 400-ft. shaft and a hoisting capacity of 800 tons per hour. This, of course, is somewhat high for cage hoisting, although it is still within the limits of actual practise. If the comparison had been made on the basis of 1000 tons per hour, or for a deeper shaft, the skip installation would show only a moderate increase of power consumption while the cage installation would increase in such a rapid ratio as to soon exceed the practicable limits of construction and operation.

Obviously comparisons throughout could not be

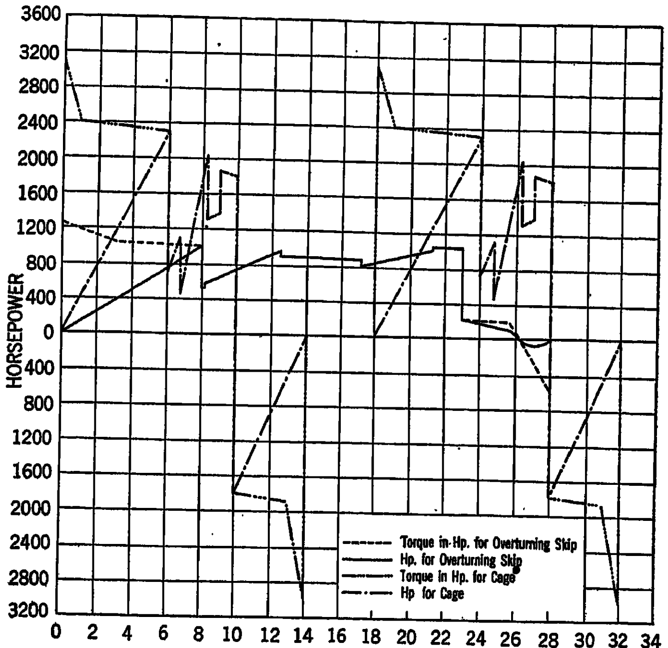

Fig. 1

made for two existing mines of these types, as it would be impossible to obtain an exact paralled. The figures used, however, are based on actual results and are worked out upon the same basis, so as give a true comparison between the different systems and for conditions assumed.

Comparisons are made on the basis of an equalized hoisting system which will limit the peak from the power source to approximately the average. On some power systems the peaks as imposed by the hoist motor used in connection with the skip hoist would be permitted and an induction motor type hoist could be used with a material reduction in first cost. (See Fig. 1.)

It will be noted that the peak of the cage-hoisting cycle is about 3100 h. p. while the skip-hoisting cycle is about 1300 h. p. The skip installation shows a power

economy of nearly 25 per cent as compared with the cage type. There is also a very great difference in cost between the hoisting equipments for cage and skip, this being approximately $37,000 in the examples cited.

Where steam hoists are used, there is not so great a difference in favor of the skip since the size of the hoisting engine is determined by the total load rather than acceleration peaks. However, the steam consumption will be reduced approximately as for the examples shown for electric hoists.

The consideration of steam hoisting is necessary only in case power is generated at the mine. For the Donk Brothers Coal & Coke Company's Mine No. 4, where there was a decision to generate rather than purchase power on the basis of savings that might be affected, the relative economies of a steam-hoisting engine and an electric hoist were carefully considered from every possible angle.

TABLE NO. 1

	Self-Dumping Cage	Overturning Skip
Depth of Shaft	400 ft.	400 ft. Pit 24 ft.
	Tipple 60 ft.	Tipple 46 ft.
Total Hoist	Dumping 6 ft. = 466 ft.	Dumping 19 ft = 489 ft.
Capacity	800 tons per hr.	800 tons per hr.
Hoisting Cycle: Loading or caging	4 sec.	8 sec.
Accelerating	6 sec.	8 sec.
Running	4 sec.	15 sec.
Retarding	4 sec.	5 sec.
	18 sec.	36 sec.
Weight of cage or skip	14,000 lb.	13,000 lb.
Car	4,000 lb.	....
Coal	8,000 lb.	16,000 lb.
	26,000 lb.	29,000 lb.
Size of hoisting rope	1½ in.	1⅝ in.
Hoist during dump	6 ft. 0 in.	13 ft. 0 in.
Net wt. available for OtWt.	12,000 lb.	8,400 lb.
Average rope speed	2,000 ft. per min.	1,050 ft. per min.
Max. rope speed	3,610 ft. per min.	1,480 ft. per min.
Size of cylindro-conical drum	7 ft. to 11 ft. diam. Direct connected	8 ft. to 11 ft. diam. Geared
Size of d-c. hoist motor sq. r. m. s.	2,000 h. p.	850 h. p.
Size of d-c. generator on Illgner set	1,400 kw.	600 kw.
Size of a-c. motor on same	800 h. p.	600 h. p.
A-c. input per hour	656 kw-hr.	525 kw-hr.
A-c. input per ton of coal	0.82 kw-hr.	0.650 kw-hr.
Hoist-overall efficiency based on 466 ft. hoist	43.0 per cent	53.8 per cent
Approx. cost f. o. b. factory 1920 basis) drum	$ 25,000.00	$30,000.00
Electrical Equipment	90,000.00	48,000.00
	$115,000.00	$78,000.00

The coal is hoisted in skips and the data upon which the hoisting equipment was based are:

Total distance of hoist	304 ft.
Maximum weight of coal per trip	18,000 lb.
Average weight of coal per trip	12,000 lb.
Weight of skip and yoke	11,800 lb.
Rest period	9 sec.
Total cycle	24 sec.

An electric hoist for this service must necessarily be of the equalized type, as the generating equipment installed for economical plant operation would not meet the peak demands of an induction-motor hoist superimposed upon the peaks of the mining load.

To secure comparable economy in plant operation when hoisting with steam equipment, the exhaust from the hoisting engines must be utilized. This requires the installation of a mixed pressure turbine with a regenerator to store and regulate the flow to the turbine of low pressure steam in accordance with the demand.

The electric-hoisting system would permit of greater flexibility of plant operation and give greater insurance against shut-down. The economy of the whole operation with steam hoisting depends upon utilizing the hoist exhaust steam for power generation. A failure in the mixed pressure turbine would necessitate wasting this steam and, for lack of sufficient boiler power a probable curtailment of production. Such an emergency might be cared for by the installation of a spare mixed pressure turbine, but this expenditure is hardly warranted. With the electric hoist all of the turbines would be of like type, and spare capacity could be provided for hoisting and mine load by one unit.

Comparative estimates of cost and economies of the two systems determined that the electric hoisting system would require an additional investment of $42,500 for hoisting equipment, buildings, installation, etc. The savings that could be effected by the electric hoist, including operation, supplies, maintenance, amortization, etc., for the two systems, equaled a 5.3 per cent return on the additional investment.

On this basis the steam hoisting system was installed with equipment as follows:

1 Pair 24 in. by 42 in. first motion hoisting engines.

1 937-kv-a. mixed pressure turbo-generator with the prime mover designed to carry 937 kw. with all low pressure steam at 0-lb. gage.

29 ft. dia. by 25 ft. long Rateau regenerators.

14,000-sq. ft. surface condenser.

The hoist equipment employs a double-rope system which so far as is known, is new in operation of this kind. A one-inch hoisting rope is used, both ends of which are fastened to the drum and coiled on in parallel grooves. The tension is equalized by a sheave on the skip-yoke.

This system permits of the use of a smaller diameter drum at a higher speed and makes it possible to use a first motion steam hoist. It will also be an advantage for installations of electric hoists when the single rope requires very low-speed motors or an excessive gear reduction.

When power is purchased, the coal hoisting equipment should be electric, except possibly in the case of changing over an existing mine with but a short life. The practise of purchasing power for the mining load and maintaining a steam plant and engines for hoisting, costs the operator from two to six cents per ton. Completing the electrification of such a plant has shown as high as 22 per cent return on the additional investment required for the installation of an electric hoist.

The system of electric hoisting applicable to any installation can be determined only by an analysis of the requirements to determine comparative efficiencies, operating characteristics, costs, etc., of the several types. The power source, limitations of peaks and peak penalties imposed by the power company serving the installation also have an important bearing on the proper equipment to be used to secure the desired mine output.

In designing the hoisting equipment for the Chicago, Wilmington & Franklin Coal Company, Orient No. 2 Mine, only the Ilgner-Ward Leonard system was considered. The hoist has a potential capacity of 14,400 tons in eight hours, with an expected average of 11,500 tons, making the operation the largest shaft coal mine in the world.

The coal is hoisted in skips and the data on which the hoist was based are:

Total distance of hoist	607 ft.
Maximum weight of coal per trip	26,000 lb.
Average weight of coal per trip	22,000 lb.
Weight of skip and yoke	15,100 lb.
Rest period	9 sec.
Total cycle	26 sec.

To fulfill the cycle, a maximum rope speed of approximately 4000 ft. per min. with a rope tension of 67,000 lb. for about 40 per cent of the travel, is required. This duty necessitates a carefully made rope provision for the fatiguing action which would result from the high-operating speed with the pronounced vibration that would be set up. A factor of safety of 8.1 based on the dead load is used. This factor of safety is provided by a two-in. diameter rope of the modified Seale construction using special strength plow steel wires.

The drum is of the cylindro-conical design having a minimum diameter of 10 ft., a maximum diameter of 17 ft. with a pitch of the grooves on the slope of 12 in. To take care of the side wear of the grooves which is greatest on the small cylindrical portion, the groove pitch for this section is increased to 2¼ in. as compared with 2⅛ in. on the large cylindrical portion. In designing the drum, careful consideration was given to the proper proportioning of the metal in the various sections and the ribbing to give strength and long life. Truss rods are provided which bring all parts of the drum shell in compression, thus giving the greatest possible strength to withstand the severe service expected.

The motor equipment consists of two 2000-h. p., d-c. force-ventilated motors, direct-coupled to the drum shaft one on each side of the drum,—two motors instead of one in order to reduce the armature inertia and permit the use of commercial units.

The forced ventilation made it possible to reduce the motor capacity required by approximately 20 per cent, thereby reducing the armature inertia, as well as the cost of installation. Fan capacity for 35,000 cu. ft. of air per minute is provided, together with necessary air washing equipment. The use of the forced ventilated equipment made a net capitalized saving of approximately six per cent.

The motor generator-set converting the power to direct-current for the hoist as received consist of two 1650-kw., 500-volt generators at 575 rev. per min., driven by a 2200-h. p. wound-rotor type induction motor. A 90,000-lb. flywheel 12 ft. diameter provides the necessary energy for equalization of hoist peaks and a 50-kw. exciter furnished excitations for the generating and hoist motors. All units are mounted on a single built-up bed frame forming a four-unit, six-bearing motor generator set with flywheel.

The units are connected in the order, generator No. 1 to motor No. 1 to generator No. 2 to motor No. 2, thereby limiting the potential on any part of the equipment to 600 volts.

Slip-regulator control equipment automatically varies the speed of the set with the load and permits the flywheel to hold the input from the line below a predetermined valued and when hoisting on the given cycle will hold the power input to within five per cent of the mean.

The Ward-Leonard system of control is used and the generator field is varied by contactors controlled by a master controller and current limit relays which function during both acceleration and retardation.

To maintain the cycle necessary to secure the large output expected from this mine, high rates of acceleration and retardation are necessary. The calculated rates of acceleration of the down-going skip is 13⅛ ft. per sec. per sec. Tests on rates of accelerations place the maximum without a dangerous slackening of the rope between 15 and 19 ft. per sec. per sec. With current limit control of acceleration only, it would be possible to attain a rate of drum acceleration with light skip loads or empty skip which would be dangerous. To prevent this occurring, the field contactors are controlled in addition to the current limits by a traveling nut switch which regulates the rate of building-up the generator voltage, thereby giving approximately constant acceleration rates irrespective of the load.

While the control is equipped with current limit relays to limit the pump back load in retardation, there is a question whether these should be depended upon for retardation in emergencies when the maximum rate possible is desirable. The retardation time can be reduced as compared to retardation with current limit relays by the use of a Tirrill type relay which will hold the regenerative breaking current value to a constant which may be the maximum capacity of the generators, or at a safe retardation rate.

In either of these cases, however, if the main breaker goes out, control of the hoist must be maintained entirely by the brake. To take care of this emergency there is provided short-circuiting resistance controlled by contactors which will be immediately inserted across the terminals of the hoist motors with the opening of the main breaker. This resistance will give maximum

safe load for the motors and this load will be maintained as near constant as is possible by two additional sets of contactors which close successively when the motor armature voltage is reduced by the slowing down of motor or drum speed to a predetermined value.

Provision for prevention of overspeeding at any point in the shaft, for slowing down when approaching dumping point, for overtravel and for starting in wrong directions are provided in duplicate by traveling nut-limit switches, cam turnoff device and limit switches, with necessary back-out switches. Men are not handled by this hoist; therefore protection for man hoisting is not necessary.

In order to properly coordinate the operation of the bottom dump station with that of the hoist to secure maximum hoisting speed, signals are given and certain gates are operated by the hoist control devices.

To thoroughly explain this feature, a description of the method of handling coal at the dump station is necessary. The coal is dumped by means of an air-operated rotary dump directly into weigh pans. The weigh pans are manually operated and discharge the coal through a chute to the skips. At the end of this chute there is a safety gate which is open only when the skip is at the bottom. These gates are operated by a crank-shaft which revolves 180 deg. in opening and closing. To this crank shaft a motor is connected through a train of gears. On the second reduction gear shaft there is a magnetic clutch for each gate.

There are three lights in front of the operator on the dump floor to show respectively when the skip is in the shaft clear of the safety gate, when the safety gate is opening or closing, and when the skip is landed and the gate is in the proper position for loading.

When the descending skip has just passed the lip of the loading or safety gate, a contact on the traveling nut limit switch releases the gate brake and sets the clutch to rotate the gate to open. When the gate is open a cam switch on the crank shaft resets the brake and releases the clutch. This operation requires about $^4/_5$ of a second.

The dump operator opens the weigh pan with the signal that the safety gate is opening. The weigh pan, in opening, energizes a time relay after which an interval of eight seconds gives direct to the hoisting engineer the signal to hoist.

Similar operations control the closing of the safety gate. The operations are repeated for both skips so that the hoist works on a set schedule and relays reduced to practically nothing.

Man and Material Hoist

The handling of men and material with the coal-hoisting equipment consumes considerable time, and, in many incidences, seriously curtails productions. An auxiliary hoist, preferably at the air shaft where men and materials can be handled at all times without interfering with coal hoisting, is desirable at any mine and a real necessity where large capacities are involved.

When skips are used for hoisting, the cage equipment at the man and material shaft must be suitable for handling solid-end cars. To meet this requirement at the Thermal Mine of the Donk Brothers Coal & Coke Company, and the Orient No. 2 Mine of the Chicago, Wilmington & Franklin Coal Company, an overturning cage is used.

An auxiliary hoist may be used for the early development of the mine as well as for handling rock, coal, men and material throughout the life of the mine. Both mines mentioned were developed to a daily capacity of approximately 2000 tons before the main hoisting equipment was put into service.

The man and material hoisting equipment for the Thermal Mine consists of a pair of first-motion steam engines. The exhaust steam from these units is carried to the main exhaust system with the main hoist, permitting the utilization of its steam for the mixed-pressure turbine and feed-water heating as required.

At the Orient No. 2 Mine, where power is purchased, the main drive for the man and material hoist is a 450-h. p. induction motor geared to a 7-ft. by 10-ft. diameter cylindro-conical drum, giving a rope speed of approximately 900 ft. per min. To meet the requirements of the power company's peak limitations during their lighting peaks, an auxiliary induction motor of 200-h. p. capacity with an additional gear reduction, is provided.

In order to be able at all times to operate the hoist for handling of men and material, a twin steam-engine unit is also provided and geared to the drum to be used in case of power failure. The steam is provided from a small boiler plant which must always be under steam for heating water for wash house, drying sand and heating purposes.

The larger motor is connected permanently to the drum drive by a flexible coupling. The auxiliary motor and steam engine are arranged with an interlocked-clutch device, so that only one can be connected at the same time. The three drives are also electrically interlocked, making it impossible to move the hoist if more than one drive is connected.

Safety devices are provided for both coal and man hoisting for all three driving units. These safety devices are so interlocked that it is impossible to move the hoist unless the proper set for the drive to be used is connected. Signal devices are provided to show in the hoist house, at cage landing and at the bottom landing, to indicate whether the man-hoisting or coal-hoisting safety devices are connected.

Fan Drive

Normally, the mine-ventilating fan is electrically operated. However, there is provided, for emergencies' sake, such as motor trouble or failure of power, an

auxiliary steam engine which receives steam from the auxiliary steam plant mentioned above.

This steam engine has sufficient capacity to furnish the full air requirements of the mine and is direct-connected to the fan shaft by means of a jaw clutch. The engine is equipped with a heavy flywheel to eliminate any back lash.

Considerable saving in power consumption for mine ventilation can be made by reducing the fan speed at such times as the mine is not working. However, this method of operation, has not met with much favor in the middle west field, due to the effect of varying quantities of air on the roof and to the liability of gas accumulations. The general practise is to carry a constant volume at all times. This eliminates the necessity of using a variable speed motor, the most satisfactory type under these conditions being the squirrel-cage induction motor or a synchronous motor, provided the latter is of a type that will accelerate the fan to full speed or is provided with a satisfactory clutching device for connecting the fan after the motor is up to speed.

The fan at Orient No. 2 Mine was originally installed with a 50-h. p. squirrel-cage induction-type motor and using short-center belt drive with idler. This motor to be used during the early development period and later changed to a size adequate for supplying the mine requirements.

During the development of the mine, there is, of course, a steady increase in demand for air; this is provided for by changing the pulley on the driving motor and increasing the diameter as increase in fan speed is required. In the development of the mine, the increase in the demand for air can usually be cared for by four pulley changes.

This results in a lower first-cost installation as compared with the variable or adjustable speed type motor and better operating efficiencies.

Preparation Plant

In the process of preparation and loading at Orient No. 2, the coal is handled from the receiving hoppers to which coal is delivered by belt conveyor from the auxiliary shaft and skips in the main shaft, by two pan feeders delivering to two screens. From the screens the coal passes onto picking tables and thence to loading booms. The 1¼-in. screenings may be delivered by belt conveyor to the rescreening plant for further separation by shaking and vibrating screens. In addition to the preparation and loading equipment, there are a number of conveyers for conveying of coal, degradation and gob.

With exception of the main feeders and the main screens, the equipment is driven by constant speed induction motors. In normal operation of screens and feeders, there is usually required about 10 to 15 per cent variation in speed to take care of the different rates of feed required, and the different conditions of the coal which may require a faster or slower screen speed in order to secure the best separation.

Wound-rotor type motors do not prove entirely satisfactory, it being impossible to maintain a fixed partial motor speed with varying load conditions and for the most satisfactory results, motors having shunt characteristics must be used.

For this duty the a-c. motor commonly known as the brush-shifting type, should prove satisfactory, as it is not frequently necessary to vary the speed, hence the mechanical control of speed would not be objectionable.

There has always been considerable discussion regarding the proper housing for tipple motors and it is often argued that open type are satisfactory, since the coal dust does not materially injure a motor. There is no doubt but that the collection of coal dust even though it will not directly injure the installation, is detrimental to the motor, as it seriously impairs ventilation. This is apparently recognized even by one who advocates the open type motors, for it is a common sight on a tipple where open type motors are installed, to see small wooden enclosures built over the motors to protect them from dust.

Enclosed or totally enclosed ventilated type will give the best satisfaction in tipple operation. This policy was carried out to a certain extent at Orient No. 2 Mine, where motors which were subject to a great deal of dust were totally enclosed.

The controls of the motors are automatic and control-stations are located at two points in the tipple and two points on the rescreener, accessible to attendants normally overseeing the preparation or loading of the coal. The control-boards are fitted with signal lights and speed points at which they are operated.

Connecting conveyers, between the auxiliary tipple and the main tipple and between the main tipple and the rescreener, are provided with interlocking controls to prevent starting, or to stop units from the receiving end to prevent the possibility of delivering coal to equipment not in operation.

There is installed in the auxiliary tipple three motors aggregating 75 h. p., in the main tipple, seventeen motors aggregating 300 h. p., and in the rescreener twelve motors aggregating 290 h. p.

The motors all operate on 220-volt circuits, with power supplied through three banks of transformers. The motors on the auxiliary tipple are fed from the service transformers which supplies 220-volt power for the shop and other miscellaneous motors. For the main tipple and rescreener separator, 2200-volt lines are installed from the central switching station located in the auxiliary hoist house to two banks of transformers, one located in the main tipple and the second in the rescreener.

The motors are grouped as convenient on the distribution lines originating, at the transformer secondary busses and each line controlled by an oil circuit breaker. Control lines are provided from the low-voltage coil of these circuit breakers with cut-out

switches conveniently located so that the equipment can be shut down quickly in case of trouble.

The underground system of power distribution between the central switching station and the various buildings housing the surface equipment of a mining plant, is by far the most satisfactory. The original cost of such an installation is approximately 160 per cent of the cost of a well-designed overhead system. The saving in upkeep, longer life and elimination of power interruptions will more than effect this difference in first cost.

Very satisfactory results have been obtained with underground system using fiber conduit in concrete with lead-covered conductors.

The location of the central-switching station is dependent on local methods of operation. Wherever possible, location which would require extra operating labor should be avoided.

Converting Stations

For the operation of underground mining equipment consisting of locomotives, chain machines and mechanical loaders requiring d-c. power, converting stations must be supplied. These stations should be located at the various load centers at the face. The number of stations installed must be governed by the system of mine development, but should be as few as practical without necessitating excessive lengths of d-c. distributing stations. This can often be accomplished by combining two or more sections carrying the connecting cables along room-entries between the parallel cross or main entries. In mines of large capacity it is usually necessary to also provide a converting station near the shaft bottom to supply adequate power for the main-line haulage motors.

In general, the economical method of transmission of power from the central-mine switching station to the converting stations is by overhead lines carrying such voltage as is necessary to transmit the required load economically. High-voltage underground transmission should be avoided wherever possible as it is not only expensive, but introduces an element of danger.

The substations may be placed either above ground with the d-c. feeders entering the mine through bore holes, or the converting units may be placed below ground, thus necessitating the carrying of high-voltage feeders into the mine.

The substation on the surface has the advantage of—

Lower first-cost.

Keeping high voltage out of the mine.

Better ventilation.

Greater accessibility for repairs.

Better inspection facilities.

Can be kept in better condition.

The disadvantages are—

Makes it necessary to support heavier copper in bore holes.

Cannot be reached as quickly in case of trouble.

More liable to malicious damage.

Underground converter stations must be in fireproof rooms, preferably with concrete walls and floor and roof thoroughly secured by I-beams. Adequate provision must be made for ventilation, and, to secure the best results, an air-split should be provided with a continually moving current of air through the substation room.

The cost of an underground substation room and the installation of the equipment varies greatly because of the difference in the material underground conditions existing in different mines. In specific instances, this cost has been 200 per cent of the cost of the building and labor of installing on the surface, and it is safe to say that, with proper underground room, the cost of same will always exceed the surface installations.

Motor-generator sets have, in general, proven the most satisfactory for mine service. The driving unit should be of the synchronous type, wtih capacity for such power-factor correction as is necessary to bring the resultant power factor of the total mine load up to economical values.

Semi-automatic control,—that is, the equipment started by a push button and further operation automatic,—is desirable and will usually prove their worth in the elimination of station attendants for either surface or underground installations. These controls are now standard with manufacturers of electrical equipment and embody all the necessary safety features for protection of the units.

The necessity of providing load-limiting features can only be determined by a study of local condition. However, it is seldom that such protection has a material value in coal mining installations.

It is sometimes possible to eliminate the automatic features on the a-c. driving motor installed in underground substation. However, where the starting of the set is by manual control, there should be a man conveniently near to act as station attendant in connection with other duties.

Rotary converters are also used in mining installations, but before such an installation, a careful study should be made to determine their adaptability to local power and load conditions.

Based upon results that are being obtained with mercury arc rectifiers both in this country and abroad, it would appear that better results can be obtained by use on mining loads in place of either the rotary converter or motor generator set when cooling water is available.

The converting equipment for the Orient No. 2 Mine for a daily production of 6000 tons consists of three 300-kw. synchronous motor-generator sets, located in a concrete substation room approximately 1000 ft. from the main shaft.

When the producing entries have advanced a sufficient distance, substations will be installed near the face in at least two sections, leaving only sufficient

equipment in the present substation to take care of the main line haulage. These prospective stations will be moved from time to time as it is necessary, in order to maintain an efficient d-c. distribution system for the ever advancing working faces.

Mining Equipment

The choice of mechanical mining, mechanical loading and haulage equipment is largely determined by the natural mining conditions and mining system used. The advantages of various types of equipment for these operations from an electrical standpoint, are usually considered secondary to their ability to produce desired results in the mining, loading and transportation of coal.

The electrical features of the equipment furnished as standard by the manufacturers may often be altered to secure better economies under certain working conditions, but such changes must not be allowed to detract from the ability of the equipment to produce coal.

Discussion

Carl Lee: There are a few examples cited in this paper which might require amplification or qualification for an engineer not familiar with this particular industry. Estimates are made showing returns of 6 to 20 per cent on the investment made on labor and fuel-saving equipment. Yet the cost in some cases runs up to nearly half a million dollars. The ordinary coal company would hardly decide to add so much to its capital investment for a small return. The normal conditions of coal mining are so frequently interrupted by strikes, poor market and competition that the smaller the mine investment the nearer the operator can come to breaking even in the long run.

Without discussing the various points in detail, it might be said that this paper emphasizes the fact that in the mining industry, which has been so rapidly electrified, it is important that the electrical engineering problems be given due consideration. To do this certainly requires the services of an engineer who has had experience in that line. Haphazard decisions will likely mean a loss in one way or another, which might be avoided by the analysis and recommendations of a properly qualified engineer.

E. J. Gealy: The only correct basis of deciding whether a coal-mining company should purchase power or generate it is an economic one as presented by Mr. Adams. All phases of the question should be given due consideration.

If a coal company is not prepared to give its own power plant proper consideration and a fair opportunity to operate at best efficiencies, it is surely arguing itself into using purchased power. Often a coal company will do more to help reduce its power bill received from a utility company than it will to help its own power plant to operate economically. A power bill represented by cash to an outside company is always given more thought than costs to operate a mine power plant. Consequently a coal company will often do more to centralize its load, operate with a good load factor and good power factor when purchasing power than when generating its own energy.

At most coal mines, low-grade fuel is available for use in the power plant. This low-grade fuel if loaded, shipped and sold at a remote point often represents a loss. In such cases the coal company using this fuel in its own plant may rightly credit the plant with the amount of this loss rather than charge it for the fuel at its selling price.

Evidence of the fact that a coal-mine power plant can successfully compete with a public utility is found throughout the coal fields. Outstanding examples are the Consolidated Coal Company plant near Staunton, Illinois, which sells power to the town. Another large coal company in Central Pennsylvania has been selling power to a public utility company for years. Such examples indicate quite clearly that the advantages are not all conclusively upon one side or the other. Careful and thorough consideration must be given the question in all cases.

I also know of a company which generates most of its own power but ties in with the power company which carries the peak loads. Thus the load factor upon the coal company's plant is almost unbelievably good. The company has a large pumping load most of which is off in the day and on at night.

Specific examples show that it is quite possible to generate power at or near some coal mines. From the tipple of the No. 12 mine of the O'Gara Coal Company near Harrisburg, Illinois, one can see almost directly under his feet the coal company's power plant and also one of the largest public utility plants in Southern Illinois. Again, in Pennsylvania the Glen Alden Coal Company generates more power than the public utility company in its district.

However, there is another phase of this question to be considered. Many coal companies can effect much larger savings from capital invested in machinery used in the mining and preparation of coal than by owning their own power plant. Obviously a coal company should first consider placing capital where it will effect the largest savings or profits.

Turning to the use of motor-generator sets at coal mines, it will be interesting to note that records obtained early last year show that 73 per cent of the automatic power-converting substation equipments furnished by the large manufacturers was equipped with motor-generator sets.

Where considerable induction-motor load exists the synchronous motor-generator set lends itself admirably for power-factor correction. A large anthracite company is now using a 440-volt synchronous motor on one of its motor-generator sets and correcting power factor right where the poor power factor originates.

W. C. Adams: While an engineer's natural tendency is to put in equipment to secure the greatest efficiencies, sometimes, irrespective of the cost, there is a limit to the amount that should be expended to secure this better operating efficiency which is based on the earnings to be derived by such improvements. There is a difference of opinion of the yield required to warrant an expenditure. I believe that an investment should yield at least 10 per cent, and for conservative estimates, 15 per cent should be used.

There is a tendency and feeling among coal operators—and it is often right—that they should limit their investments in one operation to as low a figure as possible, with the thought that they can secure better returns on their money by other investments which may be operations in another field.

Often available capital is limited and it is necessary to sacrifice some efficiency to secure the essential features necessary for a successful operation.

With such a condition, an expenditure of $500,000 for a power plant might not be warranted, even though it would result in a yield of from 10 to 15 per cent. However, if such a power plant is dispensed with, it should be certain that a reliable source from which to purchase power can be secured.

Irrespective of efficiencies that may be obtained, the amount of capital expenditure warranted for a given operation must be based on all the facts covering possible earnings and return of investment. To secure the correct answer, a careful study and analysis of the existing conditions must be made and the decision must be an economic one.

Applications of Motors to Mine Locomotives

BY W. A. CLARK[1]

Associate, A. I. E. E.

Synopsis.—This paper discusses the rule of thumb method of applying motors to mine locomotives. It shows why the speed of a locomotive should be considered in selecting motor horse power. It indicates a rational method of selecting motors for locomotives for general application.

* * * * *

IN successfully applying a motor to a mine locomotive, it is necessary to have the following information:

Weight of locomotive, gage, limiting height and width, maximum and average grade, minimum radius of curve and service to be performed. The weight required for a given service is determined by the weight required to haul, accelerate or brake the heaviest train on the steepest grade. The minimum radius of curve determines the maximum wheel base allowable. This, with the gage and the limiting height, determines the space available for the motor. The weight and speed of the locomotive determine the approximate horse power of the motor, and the all-day service determines the continuous capacity required of the motor to perform the service without overheating.

All manufacturers of mine locomotives have standardized on certain weights of locomotives and on definite motors for these weights varying with the gage and height limitation. The horse power of the motors for a given weight locomotive is approximately 10 h. p. per ton, but varies from this, depending upon the speed and other conditions. The basis of 10 h. p. per ton was established at the time all manufacturers built non-commutating pole motors, and all locomotives had rated speeds of six to seven mi. per hr. On this basis, the slipping point of the wheels did not require currents in the motors in excess of the commutating range of the motor. Speed should have been considered in selecting the motor horse power in addition to the weight.

If the hour rating current is not exceeded at the rated draw-bar pull of the motor, the motor will never be called upon to operate at currents beyond the commutating range and will have sufficient thermal capacity to stand the accelerating currents.

The horse power is readily determined from the formula:

$$\text{h. p.} = \frac{\text{Tractive effort} \times \text{mi. per hr.}}{375}$$

Tractive effort is equal to draw-bar pull plus locomotive friction, which may be assumed at one per cent or 20 lb. per ton. The rated draw-bar pull with steel-tired wheels is 25 per cent of the weight of the locomotive, or 500 lb. per ton. The tractive effort is the sum of these values, or 520 lb. per ton.

Substituting in the above formula it becomes:

$$\text{h. p.} = \frac{520\ T. \times \text{mi. per hr.}}{375}$$

Where T is the tons weight of the locomotive.

This gives the horse power at the wheel, at rated draw-bar pull and speed. However, mine motors are rated in horse power at the pinion, so that to find the motor horse power required, it is necessary to introduce into the formula the gear efficiency. With the standard arrangement of single reduction spur gear this is considered to be 95 per cent. The formula then becomes:

$$\text{h. p.} = \frac{520\ T \times \text{mi. per hr.}}{.95 \times 375}$$

$$\text{or} \quad \frac{\text{h. p.}}{T} = 1.46\ \text{mi. per hr.}$$

$$\text{or} \quad \frac{\dfrac{\text{h. p.}}{T}}{\text{mi. per hr.}} = 1.46$$

From this formula it is readily seen that if the horse power per ton per mile per hour is 1.5 or more, the hour rating current of the motors will not be exceeded at the rated draw-bar pull. The maximum starting draw-bar pull with steel-tired wheels is 30 to 33 per cent of the weight of the locomotive. The starting draw-bar pull will then be approximately 33/25 = 1.33 times the rated draw-bar pull. Using brakes to hold the wheels from slipping the maximum load on the motor will be the current corresponding to 40 per cent adhesion or 40/25 = 1.6 times the rated draw-bar pull. With motor outputs corresponding to 1.33 and 1.6 times the rated draw-bar pull, the corresponding current in the motors will be approximately 1.25 and 1.45 times the current at rated draw-bar pull. If the motor has a rating of 1.5 h. p. per ton per mile per hour, the maximum overload on the motor will be less than 50 per cent overload. A commutating pole motor will stand 100 per cent overload current for short periods without sparking or injurious heating. Therefore, a commutating pole motor with a horse-power rating of considerably less than 1.5 h. p. per ton per mile per hour will be large enough to satisfactorily handle the service provided it has sufficient continuous capacity.

1. Of the Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925.

The ability of a motor to perform a given service without overheating depends on the continuous capacity and not on the hourly rating, although with similar designs, the continuous capacity is proportional to the hourly rating. The continuous rating of a mine motor is measured in amperes at reduced voltage in line with the standardization *Rules of the American Institute of Electrical Engineers.* The rating is in amperes so that it may be readily checked against the root-mean-square current as figured or measured for a given service. It is taken at reduced voltage because the average voltage impressed on a motor on a mine locomotive, during a definite time cycle of operation, will be approximately half the trolley voltage, or less, as the locomotive is standing with no voltage on the motors a large proportion of the time and is operating with resistance in series with the motors or with the motors in series during acceleration, at which time the voltage across the terminal of one of the motors is considerably less than the trolley voltage. This neglects the line-drop in the trolley wire from the substation to the locomotive.

The continuous rating will vary with the design and size of the motor. Since it depends principally upon the radiating surface, it will be a smaller percentage of the hour rating current on larger motors than on smaller since the surface per weight, or volume, is less on the larger motor. The continuous rating of an enclosed motor will vary from 30 per cent to 50 per cent of the hour rating current. If ventilating covers are supplied on the motor and the armature is equipped with a fan, the continuous rating will be increased in proportion to the efficiency of the ventilation. However, in a mine, a self-ventilated motor draws in a large amount of sand and coal dust. While the fan will keep the motor cleaner than an enclosed motor, the dirt in the ventilating air has a destructive affect on the surfaces over which it passes.

Another way to increase the continuous rating is the use of forced ventilation. A motor-driven blower is mounted on the locomotive and forces screened air through the main motors. By the use of forced ventilation, the continuous capacity is more than doubled. This method of increasing the continuous capacity has the disadvantage of requiring an additional piece of apparatus on the locomotive with additional space required for mounting the apparatus and the air conduits. On large locomotives this is not a serious disadvantage as it is easier to find place for the blower and air conduits than for the much larger motor required, if the motor were an enclosed motor without ventilation. The blower equipment is standard on the larger three-axle locomotives of several of the larger manufacturers of mine locomotives. It is also used on some smaller three-axle and two-axle locomotives, where mine clearances will not permit the use of an enclosed motor with sufficient continuous capacity to perform the service.

In applying motors to a locomotive for any given service, the first thing to determine is the weight of the locomotive required. As stated in the early part of this paper, this is determined by the weight required to haul, accelerate or brake the heaviest train on the steepest grade. Based on steel-tired wheels and level tangent tracks, the formula for determining the weight of locomotive is as follows:

$$W = \frac{L\,(R + A)}{0.30 \times 2000 - A}$$

Where W is the weight in tons of the locomotive required.

L is the weight in tons of trailing load $= N\,W$ where N is number of cars and W is weight in tons of car.

R is the frictional resistance in pounds per ton of the cars and varies from 15 lb. to 30 lb. depending on the weight of the car and type of bearings.

A is the acceleration resistance. This is 100 for one mi. per hr. per sec. acceleration and is usually taken as 10 or 20, corresponding to an acceleration of 0.1 or 0.2 mi. per hr. per sec.

30 per cent is the starting adhesion with steel-tired wheels.

2000 is a factor to give the adhesion in pounds per ton.

Where there are grades, the weight of locomotive required to haul the train up the grade is determined by the formula:

$$W = \frac{L\,(R + G)}{0.25 \times 2000 - G}$$

Where G is the grade resistance in pounds per ton or 20 lb. per per cent grade, and 25 per cent is the running adhesion of the locomotive.

The weight of locomotive necessary to start the train on this grade is determined by the formula:

$$W = \frac{L\,(R + G + A)}{0.30 \times 2000 - (G + A)}$$

A comparison of the last two formulas shows that a locomotive which will haul a train up the grade will have ample capacity for accelerating the train provided the grade is more than one and one-half to two per cent since the increase from 25 to 30 per cent adhesion on starting will more than make up for the addition of the accelerating resistance in the formula, since A is then relatively small in comparison with the sum of $R + G$.

Where the grade is in favor of the load, the formula becomes:

$$W = \frac{L\,(G - R)}{0.20 \times 2000 - G}$$

and to brake the train on the grade:

$$W = \frac{L\,(G + B - R)}{0.20 \times 2000 - (G + B)}$$

Where B is the braking effort in pounds per ton and equals 100 lb. per ton for a braking rate of one mi. per hr. per sec. or 10 lb. per ton for a braking rate of 0.1 mi. per hr. per sec. From the safety standpoint, the adhesion is taken as 20 per cent. It can, of course, be increased by the use of sand provided the grade is short.

If there are curves in the track of lengths equal to a train length, it is necessary to introduce in the above formulas the curve resistence, as for example,

$$W = \frac{L\,(R + G + C + A)}{0.30 \times 2000 - (G + C + A)}$$

where C is the curve resistance in pounds per ton. Curve resistance in pounds per ton for a train of mine cars may be determined by the formula:

$$\text{curve resistance} = \frac{WB \times 2000}{5 \times R}$$

Where $W\,B$ is the wheel base of the car in feet, and R is the radius of the curve in feet.

Having determined the required weight of the locomotive, it is necessary to determine whether the standard locomotive of the weight required has motors of sufficient capacity for the all-day service. If this is gathering service, it is rather difficult to figure the root-mean-square current of the motor, but the proportion of the time in which the locomotive is operating at high draw bar pull is very low, so that a motor applied in accordance with the formula of 1.5 h. p. per ton per mi. per hr. will have ample capacity for any gathering service, and a motor of smaller horse power than determined by this formula would usually have the required capacity.

In haulage service it is, however, comparatively easy to figure the root-mean-square from the motor curve, the profile and the loads. Where the hauls are not too long or the grades long and steep, the standard motor on the basis of 1.5 h. p. per ton per mi. per hr., or approximately 12 h. p. per ton, will usually have ample capacity for the service. But where the hauls are very long, so that the layover time at the end of the trip is very small in proportion to the total time, the root-mean-square current may figure higher than the continuous capacity of the standard motor. In this case, it is necessary to use a larger motor than standard for a given weight of locomotive, or apply forced ventilation.

In gathering service, the standard motors have ratings of approximately 10 h. p. per ton of the nominal weight of the locomotive, which is ample for locomotives with rated speeds up to seven mi. per hr. This speed is much higher than necessary for gathering service. Storage battery locomotives with rated speeds at 3½ mi. per hr. are able to gather almost as many cars per day as the higher speed trolley type gathering locomotives. Both speed and horse-power rating of the motors on gathering locomotives can be reduced considerably without reducing the daily output of the locomotive, but with a corresponding reduction in power consumption and peak loads. In gathering service the runs are short, and on most of the runs the load consists of one car followed by a run with the locomotive light. A locomotive which has its speed at rated draw-bar pull of 6½ to 7 mi. per hr. will have a balanced speed running light or with one car on the level, of 10 to 15 mi. per hr. This is a higher speed than can be reached in the short runs in the rooms, so it is necessary to operate with resistance in series with the motor a large percentage of the time. If the motors on gathering locomotives are designed for speeds of four to five mi. per hr. at rated draw-bar pull, the power required from the line will be 20 to 25 per cent less, the motor may have a correspondingly lower rating and the actual time of the trips of the light locomotive or of the locomotive hauling a light load will be approximately the same, since the motor will operate for a large proportion of the time with resistance cut out. On runs with heavy loads, the speed will be reduced, but if feeder capacity is limited, the reduced current draw of the lower speed locomotive will give a higher voltage at the locomotive which will increase the relative speed of the locomotive.

Discussion

C. Lee: The last paragraph of Mr. Clark's interesting paper brings out a point that has not been considered of much weight in the past, but which has recently been taken into account in some installations of gathering locomotives. It should be considered in all cases.

The duty cycle of a gathering locomotive and the physical condition of tracks, curves, etc., on which it operates certainly make it impractical to take advantage of the full-speed characteristics of a 7-mi. per hr. gathering locomotive. Locomotives built and rated at such speed have been sold to mine operators, because the operators have asked for a standard locomotive. The manufacturer offers a 7-mi. per hr. locomotive as a standard. In some cases the operator wants a locomotive that can be used interchangeably for gathering or hauling service. A locomotive built to meet such requirements is not the most practical.

Therefore, it seems that the manufacturers should build, rate and sell gathering locomotives rated at a speed of 3½ to 5 mi. per hour, as *standard* gathering locomotives.

E. J. Gealy: As an added bit of information necessary to apply a mine locomotive successfully to a given service, I might suggest that the size rail be considered. Most mining companies use smaller rails than advisable from a tractive point of view. To put a relatively heavy locomotive on a small rail is uncommon. Under such a condition the top of the rail is so narrow that a new set of locomotive wheels rides on a line contact for a considerable period before wearing down to the shape of the rail. Thus it is impossible for the locomotive to develop its full drawbar pull.

Another important detail about a mine locomotive is the clearance of the motor casings above the rails. At cross-overs and especially on uneven track, locomotive motors often drag and produce a heavy load. In service, wheels with false flanges and under-size wheels reduce the original clearance. The common practise of using undersized wheels from one type of locomotive on another type must be carried on with consideration. Excess loads may be placed on the motors by oversize wheels and the

clearance under the locomotive be greatly reduced when undersize wheels are used.

Ever since the first trolley locomotive was built the motor horse power per ton of locomotive weight has been increased. The ultimate limit for the ordinary haulage locomotive with the usual type controller, wheels and speeds, seems to have been reached. This ratio, about 12 h.p. per ton, appears to be nearly the limit because a locomotive so equipped will slip its wheels before it can be seriously overloaded. However, with the increased use of dynamic-braking controllers, which place the motors in service both when hauling and braking, still larger motor ratios per ton of locomotive weight may be required.

The ability of a slow-speed storage-battery locomotive to gather as much coal as a high-speed trolley locomotive, is significant. In gathering service, high speeds can rarely be attained, consequently much energy is used up in the control resistance to keep the locomotive running slowly. When we consider the reduced speed for which storage-battery locomotives are designed, we see a very good reason for their low h. p. per ton.

W. A. Clark: Mr. Lee feels that the manufacturers should sell as standard, gathering locomotives with rated speeds of 3½ to 5 mi. per hour. A motor which will fit in a definite space will have a horse-power rating varying almost directly with the speed of the motor. The horse power of the motor on low-speed locomotive would, therefore, be low. As shown in my paper the horse power of the motor need not be high but the general demand from mines is for large horse power irrespective of the speed. When the demand for slow-speed gathering locomotives becomes great enough, they will become standard.

Electric Lighting Equipment on Automobiles

BY J. H. HUNT[1]

Member, A. I. E. E.

Synopsis.—The convenience and flexibility of electric lighting is the principle reason for the development of the present type of automotive electrical equipment. The conflicting requirements of good illumination for the drivers and the elimination of glare for the driver of the on-coming car have lead to the adoption of light-directing devices according to specifications drawn up by the I. E. S. Lights conforming to these specifications give good results under ideal conditions but under bad road and car springing conditions cause a great deal of discomfort to the drivers of on-coming cars and considerable dissatisfaction with the results.

There is a great need of improved result. The possibility of obtaining improved result by the use of polarized light, by the means of light filters, by the use of more diffused light, is discussed very briefly.

THE convenience and flexibility of electric lighting is one of the principal reasons for the present universal use of complete electrical installations on automobiles. Electric lighting for automobiles was experimented with from very early days; the first installations provided parking lights from storage batteries, which were removed for recharging, as no charging generators were fitted. Headlights were not used, as the high-efficiency concentrated filament lamp was not available and the current requirements would have been prohibitive with the lamps available. Generator systems appeared with the development of the metal filament lamp, the early generators usually having complicated controls. However, intensive effort followed, and by 1910 generator-charging systems were applied as standard equipment on some makes of cars, to be followed by the complete starting and lighting systems a year later.

The metal filament of the six-volt lamp could be concentrated to such an extent that a very narrow beam could be obtained with a fairly short-focus (1¼ in.) parabolic reflector. This beam gave better penetration than the competing acetylene lamps, although the roadside illumination left much to be desired, which limited visibility when making turns, or when driving on winding roads. The high candle power in the center of the beam, combined with the existance of very little side illumination to aid the driver of oncoming vehicles, caused the public to protest because of glare, and laws were passed requiring dimming when meeting other vehicles.

The problem was studied by committees of the Illuminating Engineering Society and the Society of Automotive Engineers, with the final result of the adoption of the I. E. S. specifications for the distribution of the light from automobile headlamps. This distribution is shown in Fig. 1, which shows the permissible candle-power limits of the beam from a pair of lamps. This distribution curve is naturally a compromise between the needs of the man behind the lamp (who must be able to see a dark object 200 ft. ahead on the highway) and the needs of the driver facing the light, who should be able to see the roadway as well as the car in question, when illuminated by his own headlamps, and whose vision must not be impaired or dazzled for an appreciable interval after he passes the others lights. When the headlamp is placed according to the present S. A. E. recommended standard, 36 in. above the road, the light which is at the *B* point, the center of the highest permissible candle power, strikes the road 172 ft. ahead of the car. This is undesirably close, since it causes bright illumination immediately in front of the car, and hinders vision of more distant objects. The light at the *D* point is the light which strikes the eye of the on-coming driver after he has turned aside to pass. The 800 c. p., specified as a maximum, would be considered glaring by an appreciable percentage of individuals, but it does not leave persons of normal vision momentarily

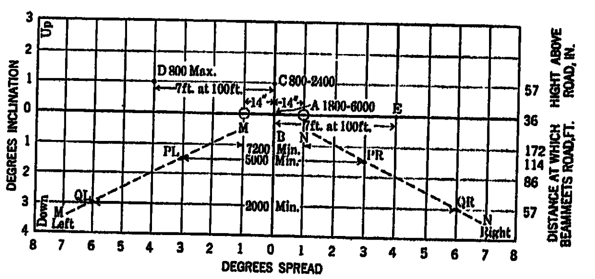

FIG. 1—S. A. E. SPECIFICATIONS FOR HEADLAMPS

All points on Curves *MM* and *NN* are six ft. from a line midway between and parallel to the axes of the lamps at the point where the beam meets the road.

blind. It must be remembered that a considerable amount of light, causing no objectionable glare when passing through a clear windshield, will make seeing quite impossible through a dirty windshield, or one covered with drops of water. Everyone could see fairly well with clear windshields, if, at the moment of passing a lighted vehicle, he concentrated his attention on the roadway about to be passed over, instead of glancing at the approaching lamps. Most of the states require that lights be left on full in passing, for investigation has shown that more accidents are caused by lack of conforming to the I. E. S. specifications than otherwise.

It must be admitted, however, that while lamps conforming completely to the I. E. S. specifications give excellent results on level, improved roads, combinations of conditions arise wherein the results are anything but

1. Head Electrical Division, General Motors Research Corp., Dayton, Ohio.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925.

satisfactory. On rolling roads, or even roads which cause the car frame to rock about a transverse horizontal axis (a thing which often occurs on paved roads with certain combinations of speed and car springs) the high c. p-beam is flashed into and out of the eye of an approaching driver. On narrow, high-crowned country roads, drivers head directly at each other until very near, and when they finally do swerve out, the rear end of the car tends to slide off the road, throwing the beam center of the light up and out to the left, directly into the eyes of any other approaching driver. As a result of this condition and the attendant dissatisfaction, Ohio and Michigan still require the dimming of headlights when within a specified distance of an approaching vehicle.

Today, gas-filled bulbs, giving 21 mean spherical c. p., are universally used for headlamps. These consume about 15 watts each. The 6-8-volt (rated) lamps give full c. p. at a terminal voltage of 6.5 volts. The 12-16-volt lamps give full c. p. at 14.6 volts. These voltages are the results of careful survey by the lamp manufacturers to determine the voltages actually existing on cars in service, and are determined by a weighted average, the computation being made on such a basis that the average life would be the designed life of 100 hours. Recently there has developed a very lively controversy between representatives of car manufacturers and lamp manufacturers as to whether the proper basis has been taken for rating lamps. For reasons that will be discussed in the section devoted to batteries, the voltages impressed on the lamps will vary over very wide limits, and since the designed life is very short and based on a voltage much lower than can and does exist on a considerable percentage of cars, unsatisfactorily short life occurs in enough cases to cause car manufacturers considerable annoyance. Some of the car manufacturers are experimenting with bulbs designed for longer life, and a reasonably satisfactory compromise will undoubtedly be worked out.

From the illumination standpoint, the effect of variation of voltage upon candle power, and, incidentally, upon glare, is clearly of great importance. Voltages at the lamp-terminals are found to vary from 5.9 volts to 8.3 volts, the lower voltage being due to undercharged batteries and poor wiring, and the high voltage to charging a very cold battery already pretty well charged. The law of candle power variation with voltage is the same for the automobile lamp as for the house lamp, and it is evident that the candle power at the *D* point of Fig. 1 can greatly exceed the specified minimum if the device has been so designed that 800 candle power is approached for a lamp at normal candle power.

Distribution, approaching that shown in the chart, was maintained for a considerable period exclusively by the use of a properly focused bulb in a simple parabolic reflector combined with a so-called lens, which, as a general proposition, is not a lens at all but simply a circular sheet of glass into which various combinations of prismatic sections have been incorporated. This results in rearranging the distribution of the light from the parabolic reflector, changing from a distribution giving a circular section perpendicular to the beam to one giving a rectangular section, or a very pronounced ellipse, with the shorter dimension vertical. The ideal device would take the beam from the parabolic reflector and, while leaving the full intensity in the horizontal and just below it, would divert the light above the horizontal to the sides and slightly below the horizontal, in conformity with the chart.

The pressure for reduced cost is just as effective in regard to lighting as with respect to any other details on a motor car. To meet this demand, some car manufacturers have recently adopted a headlamp in which the reflector itself has been modified from the parabolic form so as to give the desired lateral distribution of the light without increasing the depth of beam over that obtained by the plain parabolic reflector. No lens is used and it is obvious that there are many ways in which a mirror could be modified to accomplish this result.

One method which is used considerably at the present time is one having the mirror made up of small vertical sections, each of which is generated by a right line moving parallel to itself and following a parabola at its center point. This parabola has its focus at the lamp filament. Very satisfactory results are obtained by use of this principle and such reflectors have the additional advantage of being unaffected by the breakage of glass. High optical accuracy is not maintained in the manufacture of headlamp glassware, and apparently the commercial results of the use of the fluted reflector, in spite of theoretical difficulties in maintaining reflector shape, are as good as for the usual combinations of reflector and deflecting glassware.

The most frequent cause of complaint against the lighting equipment, so far as glare is concerned, is due, however, not to design but to faulty adjustment. The desire for low cost has led to the use of many devices which are not mechanically secure, with the result that lamp bulbs although once properly focused, can shake out of focus; and the driver carelessly continues to use them with this faulty adjustment. Trouble has also been caused by the lens which carries the light bending prisms turning around in the headlamp door, resulting in a light distribution entirely different from that intended. Another reason for the tendency of owners to leave lamps in faulty adjustment has been the difficulty of opening the lamp with some types of designs.

The Society of Automotive Engineers has recently adopted recommended practises calling for securing the lenses in place by a notch interlocking with a lug in the door itself, thus making turning impossible. They have also recommended a type of door more easily opened than the present type with the bayonet lock. The bulb manufacturers have made great progress in improving the accuracy of the lamp filament mounting

with respect to the base of the lamp, making an accuracy of plus or minus 3/64 in. With this degree of accuracy it is possible to design the reflector or the combination of reflector and lens so that with proper design of glassware there will be no necessity for provision for adjustment. Therefore, the distribution of the light would be within the permissible limits so long as the so-called precision lamps are used. To many familiar with the situation it seems that the commercial application of such a system will result in very real improvement for the whole situation. Replacing the bulb too often results in faulty adjustment.

Faulty tilting of the lamp is undoubtedly a cause of considerable trouble from glare. Inspection of the chart of Fig. 1 shows that if the minimum permissible candle power at the *B* point were raised to the *A* point, a light exceeding the maximum permissible would be obtained. This shift represents a shift of 1 deg. in tilt. The shorter wheel-base light cars on the market rock more than a degree, front and back, when the load is changed from one passenger to five passengers. If the headlamps have been adjusted to give a satisfactory driving light just inside the limits for one or two passengers, a glaring light inevitably results when the car is loaded. Of course, the lamps are supposed to be adjusted with the full load in the car, but when this is done the bright light of the center beam strikes the road so close to the driver that if he pays any attention whatsoever to lamp adjustment, he is almost certain to raise the angle of the beam.

Tilting headlamps, or rather a tilting of the beam, is a method of eliminating glare much more satisfactory than dimming. This can be accomplished by a mechanical control of the mirror from the dash, (a means which has been employed for several years by certain makers;) or by tilting the part of the mirror which reflects the greater part of the light flux directly back of the bulb. This tilting of the smaller part of the mirror can be accomplished by a combined spring and magnetic control without requiring a great amount of current. Recently a scheme involving the use of a double-filament bulb, having one filament at the focal point and one filament above, has been proposed. The beam is tilted down when switching from the filament at the focus to the upper filament, making a very simple electrical control. This latter method has not yet received universal approval by the state authorities but will probably ultimately find extensive use in one form or another.

Altogether we may say that the headlighting is a phase of the application of electricity to the motor car that is least satisfactory as regards relations between the motor car drivers and the public. It seems reasonable to believe that, as a result of the great demand for improvement, some method will be developed in the comparatively near future to provide real relief to the situation. However, the engineering complications are only a small part of the difficulties at the present time. We have forty-eight sovereign states, each with the right to set up their own inspection service and provide their own rules for inspection and their own regulations. While fortunately these regulating bodies are showing a great disposition to cooperate, it is obvious that they can cooperate only upon the basis of mutual consent. Such being the case, one or two gentlemen of rather fixed opinions, properly placed, can postpone the adoption of a device of merit for a considerable period, since the universal use of the motor car for touring makes it necessary that the equipment on a car sold in Texas shall be satisfactory to the authorities of California and Massachusetts, as well as all states between.

No discussion of the other lamps on the car will be undertaken here, except a brief reference to the so-called spotlight. This is a lamp small in size, but usually of high candle power at the center of the beam. 21-c. p. lamps are generally used with a reflector smaller than that in a headlamp. While it was originally intended to be a manually directed lamp used for picking up direction signs, in states requiring dimming it is usually used to light up the right edge of the road. However, being controllable, it is frequently abused and some states forbid its use entirely. Even when pointed down and to the right, the diffused light from the reflector is often so bright as to cause momentary confusion to the eye of a passing driver when the lamp is mounted high on the left windshield post as is usually the case. Therefore, its presence is somewhat objectionable. If mounted on the right windshield post, its use would be much less objectionable, especially if it were fixed. A committee of the National Conference on Street and Highway Safety has recently recommended that the mounting of spotlights on the left side of the car be forbidden.

Some possible methods of improvement might be mentioned as a matter of general interest, merely to point out possibilities, with no intention to pose as a prophet.

Dimming, tilting the headlight beam, or permanently limiting the height of the beam are all done so that an approaching driver will not be prevented from seeing objects illuminated by his own lamps, but any of these expedients on the part of the meeting drivers limits the vision of each. The most important area to be illuminated is that immediately about the approaching car, particularly the road to be passed over. Each driver might illuminate this space about his own car, and this could easily be done without glare to anyone, for very little forward-projected light would be required. This could be accomplished by switching from the regular headlamps to special lamps when cars are within 200 or 300 feet of each other. Sufficient illumination of the space about the car, especially at the left, would go far toward compensating for the blinding effect of the headlamps at full brilliancy. Since conditions of the road surface will greatly affect the results from the

illumination standpoint, it is doubtful if headlamps can be completely dispensed with by the adoption of such a scheme. An effort has been made in this direction by one car maker, but obviously the scheme cannot succeed unless universally applied, which would require legislation and impose somewhat of a hardship on owners of old cars, the electrical systems of which would not lend themselves easily to its application.

Illumination of the roadway by a permanent lighting system would also take care of the problem, and it is reasonable to expect that the main arteries of travel approaching our larger cities may be so lighted in the not-too-distant future. This is particularly desirable where they carry practically solid lines of traffic for several hours of the day, as is already often the case.

In the early days of the automobile, acetylene lamps were used without nearly so much complaint regarding glare as there is today. These acetylene lamps did not have so great an intensity in the central part of the bulb as that of the electric lamp, but they did give a large amount of side illumination immediately in front of the car, which was of considerable advantage to the driver of the oncoming vehicle. A return to this general type of illumination is being advocated today by several different interests, the claim being that the more uniform light distribution gives a much more satisfactory result, and that the lack of penetration in the center of the beam is more than compensated for by the fact that the driver's eyes need not to be adjusted to the effect of the very bright spot on the road directly in front of the car such as exists with the present type of lamp adjusted to the I. E. S. specifications. On the other hand the rather high intensity of illumination at the side of the car greatly aids the driver of the oncoming vehicle.

Two schemes of obtaining this general result have recently come to the author's attention. One of these, originated by W. D'A. Ryan, involves the use of a shallow, hyperbolic reflector, so mounted in a lamp with a bowl-shaped front glass that the filament itself projects beyond all opaque parts of the lamp and throws a light directly on the side of the road. The maximum candle power in the center of the beam is from 30 to 40 per cent of that obtained with the parabolic reflector, and with such a system, one can read the street numbers on houses being passed and still have the necessary vision of the road ahead. This side illumination is also of considerable assistance to oncoming drivers. Another system for obtaining much the same result involves the use of a large frosted bulb having the filament of greater candle power than is now used, say 36 or 40, mounted in a parabolic reflector. This lamp also gives a very satisfactory side illumination, but has much less candle power in the central beam. However, it has the advantage of simplicity and ease of application to cars already in service.

Everything indicates that such types of lighting will be given rather careful consideration in the near future, as there is a determined effort on the part of many influential people to have the whole question of road illumination reopened and the basis of the present approved design reconsidered. Preliminary tests indicate that very satisfactory road illumination can be obtained in this way, the penetration being quite sufficient for road speeds up to the usual 35 mi. per hr., and the side illumination gives an added feeling of security on winding roads, as compared to a narrow concentrated beam. However, a large amount of light rising from the lamps would cause trouble in fog sooner than a beam with a cut-off parallel to the road.

One reason for the adoption of the type of lighting just mentioned is the difficulty of maintaining satisfactory inspection, at reasonable cost, of lamps installed according to I. E. S. specifications. It is claimed that in states where inspection is maintained one can have his lamps adjusted at an official inspection station in one town and be stopped by the police in the next town, a new adjustment being required. Where inspection is not provided for, the results are naturally bad. Ohio required approximately I. E. S. results for a short time, all devices approved being subjected to test. There is every reason to believe that the preliminary inspection was carefully done, but as no inspection was maintained on service equipments, the glare situation became so bad, that the law requiring state approvals of devices was repealed and a dimming law enforced. It is claimed by the advocates of the lighting schemes involving the spreading light with the candle power of the central beam reduced in intensity, that inspection in service would become a very simple matter.

A system of some theoretical interest has been proposed, based on the idea of the use of polarized light. If the headlamps of a car emitted plane polarized light, polarized parallel to a plane inclined 45 deg. to the vertical with the lower end at the left, and a plate on the windshield having the property of polarizing by absorption, (as in the case with tourmaline), were arranged with plane of polarization at the same angle, it is obvious that a driver would see objects illuminated by his own lamps, and that the light coming directly from the lamps of a similarly equipped car directly facing the first, would be quite completely cut off with no glare. Goggles containing analyzers could be substituted for the polarizing sheet on the windshield. It would probably be commercially possible to polarize the light emitted by reflection without prohibitive cost or weight in the headlamps. High optical properties are required in the system through which the reflected light is returned, and no substances of the necessary properties for a polarizing windshield plate are yet known, while analyzing prisms for goggles are quite out of the question commercially. Therefore, it will probably be some time before such a system could be put in use. One cannot recommend the expenditure of a great amount of money in the development of the required materials, since such a system would require universal legislation

to put it into application, under which conditions the restrictions likely to be imposed would undoubtedly prevent any very great profit in its application. With the proper materials, however, it would seem that the head-lighting problem should be solved.

Glare can also be avoided by other schemes permitting the driver to see the light on the road as thrown by his own headlamps, but cutting out the light of the headlamps of oncoming cars. One method which might be used would be application of colored filters, the two-filter combination being so selected that the amount of light from an ordinary tungsten headlamp passing the filters of two colors, would be so small that the light which would pass through the filter on the headlamp of the one car and then through the filter on the windshield of the meeting car would be minimum and could, therefore, cause very little glare. Thus, if all drivers going east or north, used orange filters in their headlamps to give sharp cut-off, stopping all light of wave lengths shorter than 580 $m\ \mu$ carrying the same colored filters on their windshields, while all drivers in the reversed direction had blue-green filters, cutting off all wave lengths longer than 580 $m\ \mu$, it is obvious that there would not be much trouble from glare.

Roadside markers, informing drivers which filters to use, could be incorporated in the ordinary route markers, and simple means to change from one combination of filters to the other, controllable from the driver's seat, could be incorporated in the design. The dividing line for the colored filters should be chosen for wave lengths longer than that corresponding to maximum sensitivity of the light, since more energy would be available for the longer wave lengths than for the short.

However, compared to the polarized light scheme, and due to the loss of light of the most effective wave lengths, such a system would have the disadvantage of lower efficiency, since filters with a vertical cutoff line are not now or likely to be available, and the cutoff comes close to the point of maximum sensitivity. There would also be difficulty for a small percentage of persons having a very bad form of color blindness, and the affect of the colored light on the roadside might be objectionable to some people, although preliminary experiments indicate that the subjective effect is not as great as one might think. Changed color for danger signal lights would also become necessary although this would be only a minor part of the difficulty which would be caused by the fact that it will be necessary to have universal legislation.

An attempt has been recently made to sell such a system to motor car manufacturers. In this particular system, invented by Karl D. Chambers, a green filter is used for one combination and a magenta for the other, provision being made for the equivalent of two pairs of headlamps, one pair for each color and for means of switching from one colored headlamp to the other when switching filters. To take care of the rather large losses in light flux, due to the fact that only a small part of the visible light is used, 100-c. p-lamps are used in place of the usual 21-c. p. The light flux which passes through the filters on the headlamps is approximately equivalent to 21 c. p. of white light. Road tests have demonstrated that this system does eliminate glare, as when using it one can see the whole of the approaching automobile instead of simply the headlamps as at the present time and also see this automobile in its proper relation to the roadway. The greatly increased current consumption requiring a larger generator and a new current control make an undesirable increase in the cost. This would undoubtedly make it difficult to get the required legislation as the great majority of the cars on the road are of the type where it would be exceedingly difficult to fit generators of the capacity that would be needed.

The schemes which have been mentioned above will undoubtedly seem very wild to the average engineer. However, it appeared desirable to bring them to your attention in the hope that they might stimulate thought on this very important question and possibly cause the development of more practical plans than those discussed. A proper and universally satisfactory solution of the headlighting problem is one of the most important needs in the automobile industry. There is no disposition on the part of the author to seem to criticize unkindly the work of the I. E. S. in developing our present specifications. Under ideal conditions there would be very little criticism from anyone. Unfortunately, however, conditions are far from ideal and there is a great amount of adverse criticism. It, therefore, seems necessary to reconsider the whole question, as a joint committee is now doing. If it is found impossible to develop a more satisfactory method of meeting the problem that we now have, we shall at least have convinced more people that this is the fact.

Discussion

R. N. Falge: Mr. Hunt points out that with headlamp beams which meet the I. E. S.-S. A. E. specifications at the *B* point (175 ft. ahead of the car) the vision of distant objects is interfered with by high road brightness near the car. It is true that this criticism applies to some of the equipments which meet that specification, but only because they are poorly designed. The fault is not with the intensity directed to the *B* point but rather because of the excessive intensities directed to the lower angles and striking the road near the car. Such undesirable light distribution is not at all inherent in the specifications. The better equipments follow the *S. A. E. Recommended Practice* which provides for a relatively high intensity at the *B* point and a gradual reduction in intensity at the lower angles to provide satisfactory uniformity of road illumination for distances of several hundred feet ahead of the car.

Mr. Hunt says that very satisfactory road illumination, quite sufficient for speeds up to 35 mi. per hour, can be obtained from lamps provided with 36 to 40 candle power filaments and large frosted bulbs when used in parabolic reflectors with plain cover glasses. That there are conditions under which this would be true, I quite agree, but as a general statement covering the range of road, atmospheric, driving and car-voltage conditions over

which headlights must operate, there is ample evidence to disprove its adequacy. One might, to be sure, drive for a considerable time with these frosted lamps without encountering the more exacting conditions for vision and be quite oblivious of the potential hazards which the inadequate lighting entailed and of the extra eye strain and fatigue imposed. When, however, a car is equipped with two sets of headlamps, such that the driver can shift at will from the frosted-bulb distribution to the recommended beams, he very quickly arrives at an appreciation of the advantages offered by the latter. We have had much experience with such facilities and the various observers have all come to the conclusion that the light from the frosted bulbs is dangerously inadequate. There is furthermore, a large amount of data available as to the minimum illumination desired for safety under different road and driving conditions as determined by numerous observers in a car equipped so that they could vary the form of beam and the intensity at all angles while driving. These data indicate that devices are needed designed to direct to the road intensities of the order of those called for by the *S. A. E. Recommended Practice.* The determinations did not involve any unusual conditions as far as atmosphere or driving were concerned although they were made on roads with which the observer was not familiar. Memory and assurance of the absence of any special hazards could, therefore, not be counted upon to take the place of vision. The frosted bulb gives a maximum of only 3000 to 4000 candle power and this has most clearly been shown to be insufficient.

So much for the requirements of the man behind the lights. But what of the man approaching, who faces but 800 candle power with the conventional devices and 3000 to 4000 candle power with the frosted bulbs. Here again careful investigation and long experience has demonstrated that something of the order of 1000 candle power is the maximum value that one can face on the road without undue interference with vision. Even with that value there is glare; hence the advantage of the further relief afforded by the depressible beam, even on level roads. Without wishing in any way to discourage the careful study of all possibilities which may lead to better driving conditions at night, I feel it desirable to point out this tremendous gap between what has been found necessary on and above the road, and what is provided with the frosted bulb.

L. C. Porter: Mr. Hunt rather strongly advocates the use of the large frosted bulbs of 36 or 40 candle power, stating that this lamp gives very satisfactory side illumination. That is true; but I should like to call attention to the fact that the frosted bulb itself becomes the light source, or at least a partial light source, and the reason that it gives the side illumination is, because it is so far out of the focal point of the reflector. For the same reason the light is spread upward as well as to the sides, and it is spread upward at such a steep angle that lenses and other glare-reducing devices cannot control it. Headlamps using such bulbs, therefore, would be very glaring, and unquestionably exceed the glare limits set by the various state laws. A headlamp of this type reverts to the same general conclusion as the old Warner lenses, which were beautiful from the driver's point of view, as they illuminated all of the surrounding scenery,—even to the tops of the trees, but were abominable from the point of view of the approaching driver, and for that reason have been absolutely ruled off from the road.

W. D'A. Ryan (by letter): This paper is a direct and timely exposition of one of our greatest public menaces resulting in accidents and mortalities which are mounting at an alarming rate with each succeeding year. Unless something tangible is done to improve the situation the present automobile headlight laws and regulations must of necessity fall into disrepute. It must be admitted, however, that were it not for the I. E. S. specifications, which have been quite generally adopted, the situation would be much worse.

Some maintain that the majority of accidents are caused by glare, others claim that glare may be disagreeable but not particularly dangerous and that insufficient light on the road surface is the weak point. I am inclined to believe that if glare were eliminated we would find that we had sufficient illumination on the road surface at the present time when using the best units available. I am not opposed to increasing the illumination and believe it should be done if possible but this would be of little avail unless glare is eliminated. Just so long as we are allowed from 800 to 2400 candle power at the *C* point dangerous glare cannot be eliminated and we may as well realize this fact now. If the headlights are set for 800 to 2400 candle power at *C* point we will have glare but will comply with the range of 160 to 180 ft. as called for in the different states. If we cut the light down so that there is no glare at *C*, the range in most cases will be reduced to less than 100 ft. which is not sufficient for safe driving. This combination is brought about by the inherent defects in the design of a majority of the headlights in use to-day.

There is no rough and ready way of checking the I. E. S. specifications with any degree of accuracy in the existing testing stations. The rule now seems to be in a great many of them to tilt the headlights by bending the forks or otherwise until they consider that there is no glare, with the result that the maximum light strikes the road surface far short of the legal requirements for range. As Mr. Hunt points out, the lamp adjustment practised in one state does not of necessity comply with the adjustments in other states. I know of two cities within a comparatively short distance of each other which have entirely different ideas as to what is legal and what is not. You may have your lamps adjusted in one city and passed o. k. and be arrested in the other for improper adjustment. If the facts were known very few headlights, if any, in service would be found to comply strictly with the legal specifications on all points, and as matters now stand it is difficult to offer any useful constructive suggestions for a radical improvement before something tangible is available in the way of improved automobile headlights, other than to suggest federal control or other means of unifying the regulations in all of the states. Until this is accomplished the present absurd situation is bound to continue.

One serious objection to the use of frosted lamps, especially of high candle power, (36 or 40 as mentioned in the paper), is that the entire reflector becomes a disagreeable source of glare and as Mr. Hunt points out a great deal of this light would be reflected upwardly with sufficient intensity to give serious trouble in fog. This can be obviated with clear-bulb lamps by projecting the main beam so that the high candle power rays do not rise above the horizontal. I have found from experience that driving with such a light when you are looking over the main beam to the distant range and not through it, allows good visibility in the fog. This is further helped by direct light (not reflected) in the front and to the sides of the machine which, on account of the low candle power intensity, does not brilliantly illuminate the fog but is of sufficient intensity to make the sides of the road, edges and fences discernible.

After headlights permitting control of glare are placed on the market, high-candle power lamps to give greater road illumination may be approved, but until such time it will be difficult to convince the authorities having to do with automobile headlight regulations that a 21-candle power lamp, improperly focused, is a much greater source of glare than a 50-candle power lamp operated under proper conditions; so that for the present we are confined to the 21-candle power lamp, (which is standard for most of the states) and any improvements effected must be the result of better distribution, the utilization of stray light including that now producing glare and the elimination of losses in the housing and front door or lens. In view of the fact that there are few headlights today that are effectively utilizing more than one-third to two-thirds of the total lumens of the source, there is a fair opportunity to obtain considerably more useful light even under

the 21-candle power handicap and other limitations imposed by the diversified laws of the different states.

The requirements of a first-class headlight can be summed up as follows:

First. A non-glare unit having a range between 200 and 300 ft. on a level road. It should be non-focusing, capable of operating with lamps of any candle power without change of focal adjustment.

Second. The light distribution should be of fairly wide characteristic with reasonable depth and should be homogeneous with a gradually increasing intensity from a point near the machine to the most distant point and the reflected beam should not rise above the horizontal. There is always sufficient light from even a macadam road surface to take care of softening the cut-off above the horizontal at long range. The area of greatest intensity should not be concentrated in a small spot of high candle power but should have a reasonable lateral divergence. It is important to bear in mind that a very intense spot, particularly on a wet road surface introduces a new element of glare (reflected) which should be avoided.

Third. A reasonable amount of light should be projected at right angles to the plane of the main beam and even a few degrees to the rear so as to light up the gutters and make turns safe in difficult places and also make possible the reading of road directions on either side without the use of spotlights.

Fourth. Sufficient light should be thrown on the front of the machine, that is the radiator, forward wheels and bumper, so that they are clearly visible and if one light fails there should be no chance of mistaking an automobile for a motor-cycle. The cut-off of the beam should be such that there would be no upward high-candle power rays to scatter in the fog and reduce visibility.

Fifth. There should be a general dispersion of unreflected light to illuminate trees, telegraph poles and give general vista without glare so that distance can be judged at night as in daylight driving. If the non-glare feature of the unit is further improved by lighting up the front of the machine and the general surroundings, the intensity of the source becomes less brilliant by simultaneous contrast. Furthermore, the main beam should be of such a nature that it will become even more dead as the car is approached which in turn will improve the ability of the oncoming driver to see beyond the approaching car.

Sixth. The lights should be definitely focused for city and country driving so that there would be no necessity for dimming, tilting or other manual operations which in the majority of cases with the present increased automobile traffic is impracticable, unless operated at the low point practically all the time.

Now from a mechanical point of view:

First. The lamp should be adaptable to modification of designs to meet the aesthetic lines of the car and embody the elements of true art which at a glance suggest that the unit is primarily a functioning light source rather than a decoration.

Second. It must be sufficiently rigid in construction so that it cannot get out of adjustment.

Third. It should be dust and rainproof and a simple means of opening the door should be provided so that the replacement of lamp or cleaning of reflector can be done without the use of tools or unusual exertion.

Fourth. A simple means of adjustment of the beam should be provided which will not require bending of forks, difficult manipulations or technical knowledge; in fact, so simple that anyone can make the adjustment and there will be little excuse for failure to comply with state or police regulations.

Fifth. The headlights must be produced at a cost which will not make them prohibitive even for the low-priced cars.

I believe the above specifications are well within the range of possibility and can be made without great difficulty and at reasonable manufacturing cost.

J. H. Hunt: It seems to me that as far as the S. A. E. specifications are concerned, the greatest criticism is not against the unfavorable results that come under the special road conditions, but against the difficulty of enforcement. The regulations specify definite quantities of light flux at definite angles. The enforcing officers do not use instruments to make measurements on these requirements.

In line with what Mr. Falge has stated, it seems to me there is one defect in the specification. I wish to make the point that the maximum intensity strikes the road at 172 ft. If it strikes the road at this point, it is not available for greater distances. It would seem that an additional specification should be added to the S. A. E. specifications, limiting the light below the horizontal as well as above the horizontal.

Some comments have been made as to the speed limits of driving with cars with frosted bulbs. In the chart shown in the paper, the light along the horizontal for the frosted bulbs is about half the candle power available along the horizontal from lamps conforming to the S. A. E. specification. Now, the eye is not a physical instrument. It probably works in conformity to photochemical laws, and the relation between illumination and seeing is a logarithmic relation. As a result, the visibility of distant objects when using the frosted bulbs is very much greater than half the visibility when using lamps conforming to the specifications, particularly since there is not so much interference because of high illumination directly in front of the car. It is my personal opinion that it would be perfectly satisfactory to drive 35 mi. an hour with the frosted bulbs. This is based on considerable experience.

The only reason I am bringing these particular lamps to your attention is because they seem to offer a possibility which should be studied and they are absolutely fool-proof in their application. I will defy anybody to make an installation very much worse than the best installation can be with them.

With the windshield clean, it is perfectly possible for drivers of two cars, equipped with both of these lamps, to drive past each other on the road without dimming, and maintain 35 mi. an hour, without any more risk than is involved, I believe, in driving by with a tilted lamp. It would take quite a little investigation to find out whether they will be practicable under every conceivable condition.

With respect to driving in foggy weather, I have had a limited experience with the frosted bulbs in foggy weather, and I am convinced that in a light fog, I would be just as willing to use the frosted bulbs as the S. A. E. specification lamps. I have not had an opportunity to drive in a very dense fog and it is quite possible that they will not meet that situation. I had not expected, however, very much more trouble with them than that experienced in an ordinary fog.

Load-Building Possibilities of Industrial Heating

BY C. L. IPSEN[1]

Associate, A. I. E. E.

Synopsis.—*The author gives a brief survey of the more recent achievements in industrial electric heating, and shows the increasing tendency of industries to adopt electric heating, particularly for high grade products. Specific installation for such processes as steel treating, copper and brass annealing, vitreous enamelling, glass annealing, baking japans, cores, bread, etc., on a large scale, are described and illustrated.*

It is shown that the quality of product has been improved by the use of electric heating with little if any increase in cost, and in many cases, at a lower "over all" cost.

The desirability of heating load for the central station is emphasized, due to its high power factor and load factor.

* * * * *

THE success attained during the past few years in the application of electric heat to manufacturing processes, indicates that the electric heating load will have a far-reaching affect on the future development and growth of central stations.

A general survey of some of the more important achievements in the industrial heating field will be attempted in the hope that such a survey will assist the various central stations of the country to analyze the load-building possibilities of industrial heating in their respective territories.

The use of heat in the preparation of raw materials, including the use of arc furnaces for steel melting and electrochemical processes, will not be discussed in this paper. Attention will be directed rather to the heat required in manufacturing operations subsequent to the preparation of raw materials.

An appreciation of the extent to which heat enters into such manufacturing operations can probably best be gained by considering the various steps in the manufacture of some well-known product. A familiar example, and one of which the manufacture probably best illustrates the extent to which electric heat has superseded other heat sources, is the electric motor. Heat must be supplied for annealing and enameling the punchings, annealing frame castings, and copper, for enameling and varnishing the wire, for japanning end shields, heating coil moulds, heating impregnating tanks and baking ovens, soldering, preheating rotors, melting aluminum used for rotor bars, and for heat-treating the dies and tools used in this line of manufacture. Electric heat is now being successfully applied to most of these processes.

An analysis of the heat and power required in the manufacturing of most products reveals the fact that the energy required for heating greatly exceeds that required for power. Whether the electric heating load will ever equal the power load, as has often been prophesied, will thus depend upon the extent to which electric heat will be able to supersede other heat sources. At present, only tendencies in this direction can be definitely stated. These tendencies can probably best be brought out by considering the achievements of electric heating in individual applications. Accordingly, a few installations in each of the following fields, where electric heat is now successfully competing with other heat sources, will be discussed:

I. Steel Treating
II. Copper and Brass Annealing
III. Vitreous Enameling
IV. Glass Annealing
V. Baking Ovens
VI. Impregnating Tanks

Steel Treating. Heat is used in steel treating chiefly for annealing, hardening, drawing and carburizing.

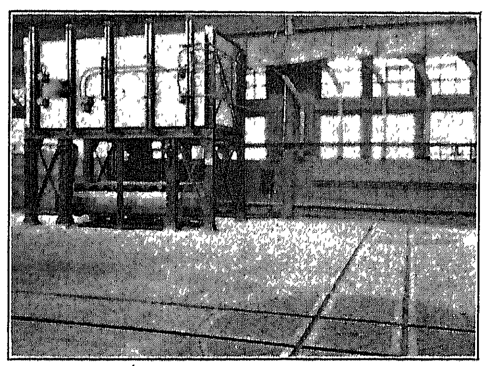

FIG. 1—ELECTRIC SHEET-STEEL-ANNEALING FURNACE

Annealing has for its main object, the softening of steel to increase machinability or ductility, the relieving of casting strain, or, in the case of electrical sheets, the reduction of eddy current and hysteresis losses.

Fig. 1 shows an electric-annealing furnace of the elevator type, for annealing sheet steel. The sheet steel is stacked directly on top of the furnace car without the use of the annealing boxes familiar in fuel-fired practise, and the car is charged into the furnace by a hydraulic elevator. This type of furnace is used in preference to the more common car bottom furnace with doors, since the air can be more effectively excluded and the furnace atmosphere controlled.

Since the heat in the fuel-fired furnace must be supplied by combustion within the furnace chamber, prod-

1. Industrial Heating Dept., General Electric Co., Schenectady, N. Y.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925.

ucts of combustion are present which have a strongly oxidizing effect on the punchings or other material being heated. Heavy steel or iron boxes which, in many cases, exceed the weight of the punchings themselves, are required to protect the punchings from this oxidizing atmosphere. Thus, the fuel-fired furnace labors under the disadvantage of heating practically twice the material heated in the electric furnace for a given output of punchings and, at the same time, is charged with a high annealing box depreciation. These two factors have made it possible to materially reduce annealing costs with the electric furnace.

This advantage, coupled with others of lower maintenance costs, more uniform product and better working conditions, indicate that the field for electric annealing of sheet steel is one capable of great future expansion. Fourteen electric furnaces of this type, having a total connected load of 2200 kw., are now being operated by one concern.

The widespread adoption during the past few years of electric-melting furnaces by steel foundries, is now being followed by the general adoption of electric furnaces for annealing. Since annealing can be carried on without attendance, it is usually done at night to secure the advantage of low off-peak rates. The advantages secured are a better and more uniform product, less scaling and better working conditions.

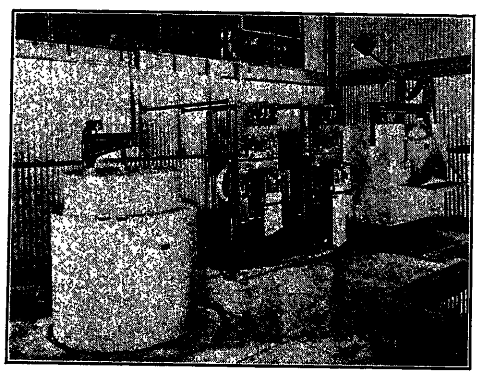

Fig. 2—Electric Tool-Hardening Furnaces

Steel is hardened by heating above its critical or transformation point and cooling quickly by immersion in some quenching medium, such as water or oil. This treatment greatly increases the hardness and tensile strength at the same time decreasing its ductility or toughness. The proper combination of hardness, tensile strength and toughness is secured by subsequent heating, known as drawing. Hardening and drawing are applied to tools and dies to give hardness and strength to the cutting edge, and to automobile parts, etc., to give maximum strength and toughness.

A typical tool-hardening room equipped with electric furnaces is shown in Fig. 2. Tool-room furnaces are usually of the box or pit type and require an energy input of from five to forty kw., depending on their size. These small electric furnaces have been found particularly useful in demonstrating to manufacturers the superiority of electric heating, and have in factories where they are used thus formed the basis for the more extensive use of industrial heating, for other processes.

Uniform heating of steel to the proper temperature throughout its mass is essential in order to secure maximum properties of hardness and strength. Even a slight deviation from these conditions will greatly reduce such properties, or may even cause the breakage of a tool or die in quenching. This clearly marks the hardening of dies and tools as the field of the electric furnace, with its accurate temperature control and uniformity of heating.

It is interesting to note that these advantages can be secured at average commercial rates for electricity without additional operating cost. To definitely establish this point accurate tests have been conducted in several plants. It might be well to add, however, that undue prominence is often attached to the cost of fuel or electricity for heating operations. A careful cost analysis, made of several steel parts, showed that the cost of electricity used for heat treating averaged only one-half of one per cent of the factory cost of the parts, while improvements in these parts equal to many per cent could, in most cases, be definitely credited to the electric furnaces.

The advent of the automobile, with its requirements for lightness and great strength, has given pronounced impetus to the heat treatment of steel. Some parts, such as ball bearings, are heated as many as six times during their manufacture. The same care and accuracy in heating are required as for tools and dies and, accordingly, many of the automobile manufacturers are turning to the electric furnace as a means of securing maximum results.

The operation of electric furnaces for this work over a period of three or four years has clearly demonstrated that not only can maximum results be obtained through their use but that these results can be secured at a lower "over-all" cost. In most cases the cost of electricity exceeds the cost of oil but this higher cost is more than offset by lower rejections, greater uniformity of hardness making possible the speeding up of subsequent machining operations, less cleaning, less labor, and more favorable working conditions which, in turn, results in lower labor turnover.

Continuous furnaces, in which the parts are pushed or carried through the furnace and quenched automatically, are used extensively for this work.

Fig. 3 shows a rotary-hearth furnace in common use for heating gears and small parts. A furnace of this type was installed by one concern four years ago. This concern now has seven such furnaces in operation with a total connected load of 1200 kw. Space permitting, numerous other examples could be given in the aggregate showing a very definite trend toward the complete

electrification of this important field with its enormous load-building possibilities.

Carburization of steel consists in increasing the carbon content of the surface of a soft steel part by heating it to high temperature in the presence of carbon. The steel parts are packed in a suitable container with carbonaceous material, heated in a furnace to the proper temperature and held at this temperature for a period

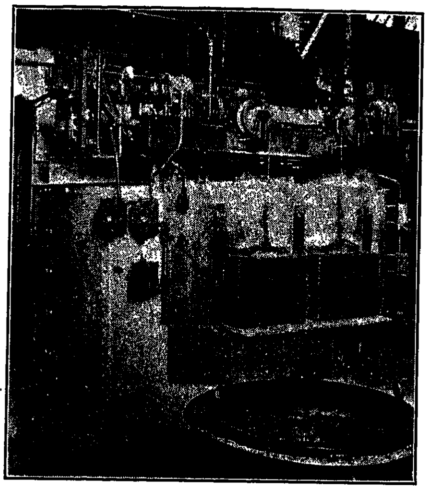

FIG. 3—ELECTRIC ROTARY-HEARTH FURNACE

of several hours. Numerous installations of electric furnaces have proved them ideal for carburizing and on the cost basis alone able to successfully compete with fuel-fired furnaces. This is due to the high efficiency of the electric furnace during the long "holding" period.

Longer life of carburizing boxes, less labor and more uniform results are advantages gained by the electric

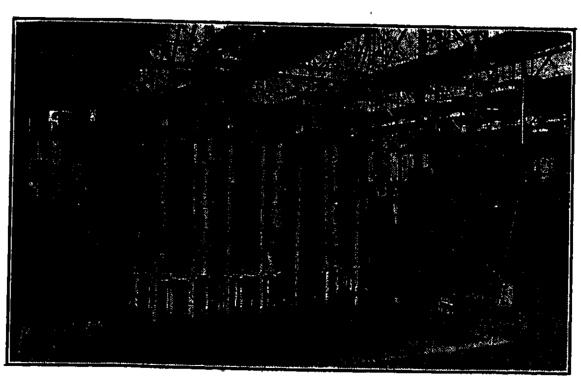

FIG. 4—ELECTRIC COPPER-ANNEALING FURNACE

carburizing furnace which promise to give great impetus to its future use.

Copper and Brass Annealing. The working of copper and brass increases its hardness and reduces its ductility. With continued working, the hardness of the metal reaches a point where any further reduction would cause it to break. It is then necessary to restore its softness and ductility by heating or annealing. In the manufacture of light gage sheet or wire it may be necessary to anneal several times. A final accurate annealing of some finished products is of vital importance. A good example is the copper used for electric motors and generators where great ductility is required to prevent crystallization and breakage due to vibration.

An electric furnace for bright annealing copper wire is shown in Fig. 4. In charging the furnace the platform, with its load of copper, is lowered by a hydraulic cylinder into a pit filled with water. The furnace is mounted on wheels and, by means of another hydraulic cylinder, is pushed into a position directly over the submerged charge of copper. Raising the platform to its original position then places the charge inside the furnace chamber. Two platforms are provided in order that one may be loaded or unloaded while the other is being heated.

Heating units are mounted on the walls of the furnace, radiating their heat directly to the charge.

FIG. 5—ELECTRIC VITREOUS ENAMELING FURNACE

Bright annealing is secured by keeping the furnace chamber filled with steam and thus precluding the air. Accurate temperature control and uniform heat distribution produce uniform results which can be absolutely duplicated in every heat.

In the fuel-fired furnace, steel muffles are required to exclude the products of combustion from the working chamber.

The chief advantages gained by electric furnaces of this type are lower costs and better and more uniform product. One company has five of these furnaces in operation with a total connected load of 900 kw.

For brass annealing, a large tunnel type of furnace is usually employed. One such furnace, with a connected load of 500 kw., has been in continuous operation for three years. The cost of electricity slightly exceeds the cost of oil but advantages, such as less scaling, greater uniformity of hardness, and lower rejections, have made the "over-all" cost in the electric furnace lower. Several such furnaces are now in operation.

Vitreous Enameling

In applying the vitreous enameled coating, familiar in lighting reflectors, kitchen ware, and sanitary ware, it is necessary to heat the metal to a high tempertuare to fuse the coating and render it adherent to the metal. The coating, consisting essentially of pulverized glass, is applied to the metal either as a thin paste or liquid by dipping, or, as a powder, by dusting it on the hot metal. The former, or wet process, is used chiefly on sheet metal parts such as kitchen ware, and the latter for cast iron parts such as sanitary ware.

Fig. 5 is a typical installation of the furnace used for enameling sheet metal. The chief requirements of the enameling furnace are: 1. High rate of production, since the labor of charging the furnace constitutes a large part of the enameling expense. 2. Pure furnace atmosphere to prevent contamination of the enamel. 3. Uniform heating to the correct temperature to maintain a high quality product. 4. Low maintenance cost. 5. A minimum of interruptions in production.

In order to meet the requirement of a pure atmosphere, it is necessary to either fire the fuel-fired furnace intermittently while the furnace is empty, thus reducing production, or to interpose a muffle between the combustion chamber and the working chamber. This also retards production and gives rise to frequency interruptions and high maintenance cost.

On the other hand, the electric furnace ideally fulfills all these requirements. At average rates for electricity, it suffers the disadvantage of a somewhat higher cost for heat. However, the large number of furnaces in operation have demonstrated conclusively, that in most cases other advantages of the electric furnace readily outweigh this higher heat cost and give a product of better quality at a lower "over-all" cost. One enameling company has, over a period of four years, increased its electric furnace installations to sixteen with a total connected load of 3500 kw.

Glass Annealing

Glass, as it comes from the moulds in which it is formed, is at a high temperature. If permitted to cool quickly in air, strains would be set up in it that would cause easy breakage. The formation of these strains can be prevented by cooling the glass slowly in a furnace or lehr. This lehr is usually of the continuous conveyer type, in which the temperature is graduated and the speed of the conveyer so set as to cool the glass to room temperature at the proper rate. There are certain critical temperatures in the cooling curve where great accuracy of temperature control is required to prevent the formation of strains.

Fig. 6 shows a typical electrically-heated glass lehr. It is heated by resistors mounted beneath the conveyer on the side walls and in the roof. These resistors are divided into five independent zones, each of which is arranged for automatic temperature control. The location of heating units gives a uniform temperature throughout the cross section of the lehr and the several automatically controlled zones make it possible to accurately govern the cooling of the glass along any desired curve.

This accuracy of control has made it possible to produce a glass of much greater strength, particularly noticeable in the reduction in breakage of electrically

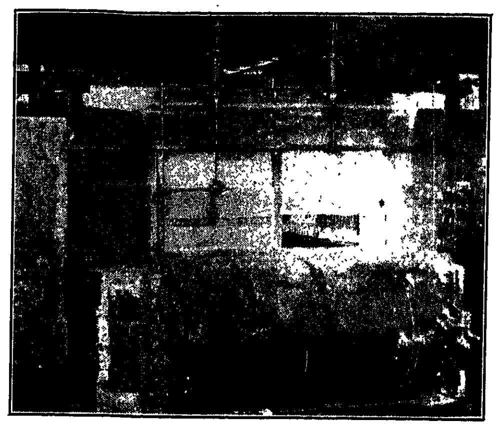

Fig. 6—Electric Glass Lehr

annealed glass in bottling machines. The cost of electricity for heating the lehr is, in most cases, higher than the cost of oil, but, as in many other instances referred to earlier in the paper, the cost of heat for annealing represents such a small portion of the cost of the finished product that even a slight improvement in quality will offset the additional cost. One company

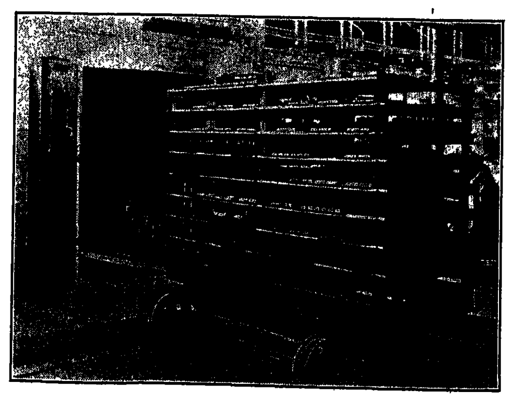

Fig. 7—Electric Core Oven

has installed eight lehrs during the past three years, with a total connected load of 1800 kw.

Baking Ovens

Baking ovens cover such a broad field that space will permit of only brief reference to a few of the more important applications, such as japanning, core baking, and bread baking.

The development of low temperature heaters for baking ovens preceded by several years the development

of suitable high temperature heaters for steel treating and other high temperature applications previously discussed. Accordingly, the low temperature applications have been more fully developed and still represent the greater part of the industrial heating load, exclusive of arc furnaces.

The extensive use of japanned metal for automobile parts, furniture, typewriters, cash registers, etc., make the field of the electric japanning oven from the standpoint of load building one of great importance. There are numerous installations throughout the country

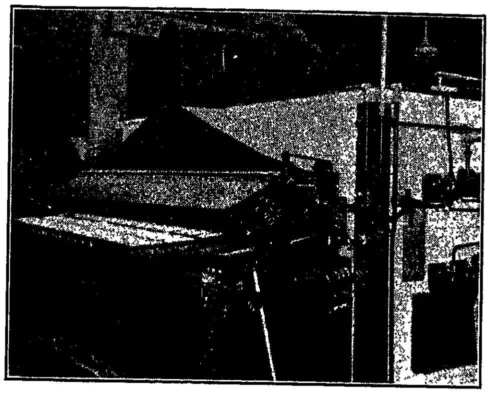

Fig. 8—Electric Bread-Baking Oven

ranging from small-box type ovens to great batteries of conveyor ovens. One company has a connected load of 12,000 kw. for japanning, built gradually up to this point over a period of ten years.

Because of the superior quality of electrically baked cores, electricity is becoming more generally used for core baking. Fig. 7 shows one of a battery of eighteen ovens used by one company. Another installation of 1000 kw. in core ovens is now in process of erection.

Bread baking by electricity has, for a long time, been successfully practised in homes, hotels and small bakeries. However, it is only recently, that the use of electricity has been considered for large bakeries. Fig. 8 shows a 450-kw. oven recently placed in successful operation. This oven is 9 ft. wide and 80 ft. long, and has an output of 4000 pounds of bread per hour. Accurate temperature control of the oven is secured by a large number of automatically controlled heating zones.

One 800-kw. oven and several smaller ovens are being used by one company for baking breakfast food. The cost of electric heat required for baking usually represents such a small part of the total cost of the product that even a slight improvement in quality will readily compensate for the additional cost of electricity for baking.

Impregnating Tanks

An interesting installation of electrically-heated vacuum impregnating tanks is shown in Fig. 9. Because of the fluctuations in steam pressure and the difficulty of securing high enough temperatures for all purposes, electric heating units were applied to these tanks. Contrary to expectations, the cost of heating electrically exceeded by only a few per cent the cost of heating with steam. Increased production as well as improved quality, made possible by uniform temperature distribution and automatic temperature control, actually reduced the cost per unit of product.

In addition to the large capacity installations discussed under these various headings, there are numerous other applications such as melting pots, soldering irons, glue pots, local heating units, etc., which, in the aggregate, represent a large load. These devices possess the advantage of low first cost and low operating cost and thus find a ready market.

The many advantages of electric heat over other heat sources thus established in numerous individual installations through a broad field of applications, indicate that the coming years will witness a great expansion of this central station load. It should not be overlooked that it represents a particularly attractive load from the standpoint of the central stations, for it is all at unity power and high load factor. Most of the furnaces

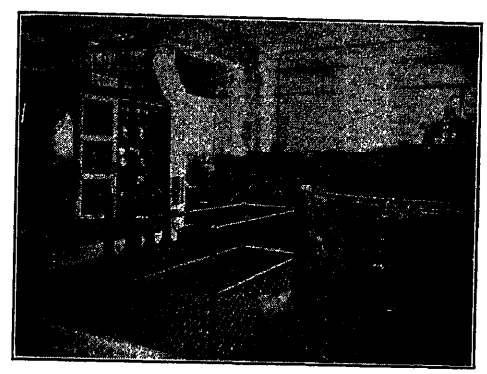

Fig. 9—Electric Impregnating Tanks

operate twenty-four hours a day but many can operate to advantage only during off-peak periods.

The rate of expansion of the heating load will depend, to a large extent, on the amount of effort spent in educating manufacturers to the advantages of electric heat. Effort was required to establish the electric light and electric motor as accepted standards in their respective fields; it now appears that similar effort on the part of electrical manufacturers and central stations will ultimately establish electricity as the accepted standard for industrial heating.

Discussion

H. N. Shaw: The maximum temperature of electric furnaces is fixed by the limitations of the heating elements available. Above 2000 deg. fahr. metallic elements are impractical due to their loss of mechanical strength, but non-metallic elements are now available which are practical for use in industrial furnaces operating at temperatures up to 2500 deg. fahr.

During the last few months, tests have been run on forging

furnaces operating at 2400 deg. fahr. in which a non-metallic element is used, and the results have proven that a forging furnace with automatic temperature control can be built so as to be as successful as the electric furnaces now used for steel treating.

This development opens up a new field for the sale of power in very large blocks to forging shops and steel mills. One large shop, for example, will require more than 20,000 kw. when all the oil furnaces are replaced by electric furnaces. Preliminary tests have shown that the electric furnace will cost less to operate and will require one less workman, due to the automatic temperature control. Besides this direct saving, the shop will be converted from a hot smoky place to a clean cool shop and thereby reduce the labor turnover.

The use of electric forging furnaces should bring about decided improvements on present-day forging practise, in a manner similar to that in which improvements in japanning practise were brought about, by the introduction of the electric japanning oven.

C. L. Ipsen: I was very much interested in Mr. Shaw's description of a new form of heating unit which he considers suitable for use in forging furnaces. A great variety of electric forging furnaces have been designed in the past which have clearly demonstrated the desirability of using electric heat for forging but none of these has proved successful on account of the high cost of maintenance.

The question has been raised concerning the power surges caused by electric furnaces. The various ovens and furnaces covered by my paper are all of the resistance type and operate at practically unity power factor. The load is of much the same nature as the incandescent-lighting load and consequently does not give rise to any power surges.

Concerning the desirability of this type of heating load to the central stations—it might be of interest to point out here that one large central-station company made a study of the relative returns from their heating load and from their lighting and power load. It was found that the lighting and power load returned a revenue of $26 per year for each kilowatt of demand and that the heating load returned $43 per year for each kilowatt of demand,—indicating very clearly the inherently high load factor of industrial heating equipment.

A High-Frequency Induction Furnace Plant
For the Manufacture of Special Alloys

BY P. H. BRACE*
Non-member

Synopsis.—*High-frequency induction furnaces have been used for some time for the laboratory preparation of special alloys on a relatively small scale, and, to a limited extent, on a commercial scale. High-frequency power has, in general, been secured from spark-gap oscillation generators. Recently the Westinghouse Electric & Manufacturing Company installed a plant having a nominal capacity of 20 tons per month, in which alloys are being produced in high-frequency induction furnaces supplied with power from a 100-kw., 5000-cycle inductor-type alternator. Zirconium silicate finds extensive use for furnace linings and thermal insulation. Alloys of great purity, which meet unusual and severe requirements, are being produced at a cost which compares favorably with that of oridnary commercial materials of the same nominal composition but having much inferior properties.*

THE plant described in the following paper was developed for the express purpose of manufacturing, on a commercial scale, metals and alloys of the same degree of purity, and having the properties of those heretofore available only as the result of costly small-scale laboratory production. The general plan of operation has been to melt the purest metals obtainable under conditions insuring the minimum of contamination, and very gratifying results have been obtained by the use of electrolytic metals and high-frequency induction furnaces of the type originated by Dr. E. F. Northrup.

The equipment of this plant falls into three main groups as follows:

1. Electrolytic iron refinery
2. High-frequency power plant
3. High-frequency furnace plant

The description which follows will be divided along these lines.

ELECTROLYTIC IRON REFINERY

The electrolytic refining of iron is no new thing, and the practise followed in this plant does not differ fundamentally from that found successful in the laboratory. The electrolyte is a distilled-water solution of the best grade of technical salts, as given by Table I.

Chemical control of the plant is maintained by periodical analysis of the electrolyte, to determine the acidity and concentration of iron as well as the proportions of the other components. The acidity is measured by electrometric titration in terms of the hydrogen-ion concentration.

In practise, it has been found that the concentration of the electrolyte and the relative proportions of the component salts may vary over a considerable range without causing serious difficulty. Satisfactory deposits are obtained with the iron concentration within limits of 45 and 55 grams per liter, and with the hydrogen-ion concentration between 1.5×10^{-6} and 0.7×10^{-6}.

The acidity is adjusted by addition of hydrochloric acid or ammonia, the latter being very conveniently added by injection into the circulating system from a tank of liquid ammonia.

The temperature of the electrolyte ranges between 25 deg. and 35 deg. cent. the only heat supplied being that due to the passage of the electrolyzing current.

In order to clarify the electrolyte and maintain uniformity of composition, it is circulated continuously through a nine-foot, five-tray Dorr thickener. The chief difficulties in the operation of the plant have been connected with the circulation and clarification of the electrolyte. These have been due to the fact that

TABLE I
Composition of Electrolyte

Salt	Quantity	Concentrations (group per liter) Fe	Cl	SO_4	NH_4
$FeCl_2 . 4\ H_2O$	75 grams per liter (4.7 lb. per cu. ft.)	21.1	26.8		
$FeSO_4 . 7\ H_2O$......	150 grams per liter (9.4 lb. per cu. ft.)	32.0		45.5	
$(NH_4)_2\ SO_4$.........	100 grams per liter (6.25 lb. per cu. ft.)			68.0	31.2
	Totals.....	53.1	26.8	113.5	31.2

aeration of the electrolyte from any cause results in oxidation of the ferrous salts and the precipitation of the iron as basic hydrates. As the removal of the iron proceeds, the acidity of the electrolyte rises, and shiny, brittle, deposits are produced, which peel from the cathode sheets and fall to the bottoms of the tanks. It has been necessary to arrange the pumps and piping and the inlets and outlets of the tanks so as to avoid turbulent flow and prevent entrainment of air. Clarification of the electrolyte is necessary to prevent contamination of the deposited iron by inclusions of sludge from the anodes.

The anodes are made from hot-rolled slabs of Armco iron two inches (5.1 cm.) thick by 28 inches (71.2 cm.) wide by 40 inches (102 cm.) long. They are supported in the tanks by two L-shaped lugs, arc-welded to the corners of the slabs at one end.

*Research Engineer, Westinghouse Electric & Mfg. Co.

Presented at the Spring Convention of the A. I. E. E., at St. Louis, Mo., April 13-17, 1925.

The cathodes are cut from ordinary soft steel sheets. They are clamped between brass bars which support them in the tanks. The general appearance of the anodes and cathodes is shown in Fig. 1. The anode at the right has been in service for some time and the uniformity of the corrosion is noteworthy. The cathode shown has received a deposit approximately ¼ inch (0.6 cm.) thick, and will be ready for stripping when the deposit is approximately ⅜ inch (0.9 cm.) thick.

Armco iron was chosen for anode material because it was but slightly more expensive than other suitable material and because its very small content of impurity would minimize the contamination of the electrolyte by foreign metals and sludge.

A large proportion of the insoluble impurities remains on the surfaces of the anodes as the iron is eaten away and forms a black, somewhat gelatinous, coating which interferes with the corrosive action of the electrolyte. If this sludge is allowed to accumulate, the bath will become impoverished in iron; therefore, the anodes are removed from the tanks about every

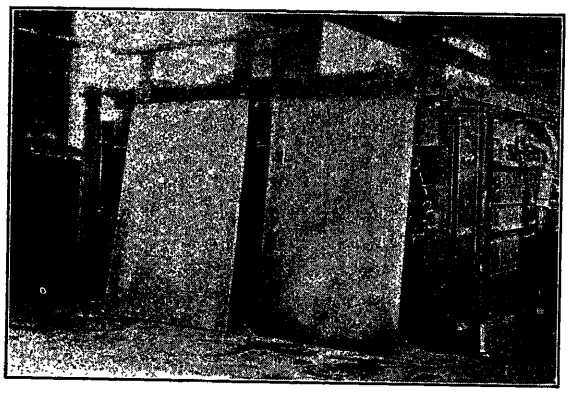

FIG. 1—ELECTROLYTIC IRON REFINERY CATHODE (LEFT) WITH ¼ IN. (0.6 CM.) DEPOSIT OF ELECTROLYTIC IRON; ANODE (RIGHT) AFTER APPROXIMATELY FOUR WEEKS' USE. NOTE UNIFORM CORROSION

third day and washed with a strong stream of water from a hose.

The cathode sheets are prepared for receiving deposits by cleaning to remove grease and rust and heating in a gas furnace to a dull red heat for a short time. A thin coating of black iron oxide is produced which prevents strong adhesion of the deposits and makes it an easy matter to strip the electrolytic iron from the sheets.

Carbon and sulphur are the most objectionable impurities. The former is removed very completely by electrolytic refining, as it remains in the tanks as part of the sludge. The sulphur in the original iron is not transferred, but some sulphur is introduced by the occlusion of electrolyte in the deposit. Analysis of a sample of good electrolytic iron by the "evolution" method will show a sulphur content of the order of 0.002 per cent or less. The same sample may show a sulphur content of 0.015 per cent when analyzed by the "oxidation" method. The latter method should always be used when analyzing electrolytic iron for sulphur because it determines the sulphur present as sulphates as well as that present as sulphide, while the evolution method shows only sulphide sulphur.

The deposits on the cathodes are allowed to build up to a thickness of approximately ⅜ inch (0.9 cm.) and are then washed for 48 hours in hot water agitated by steam jets. Two changes of water are used. By this means the total sulphur can be kept below 0.01 per cent and occasionally as low as 0.006 per cent. After washing, the deposits are stripped, broken by hand hammers to approximately two inch (5 cm.) size and stored ready for melting.

TABLE II.

Outline Specification for Electrolytic Iron Refinery

Total floor space	71 ft. (21.6 m.) x 32 ft. (9.7 m.)
Output	700 lb. (310 kg.) per 24 hr.
Current	2000 amperes maximum
Current density	10-12 amperes per sq. ft. (120-144 amperes per sq. m.)
Voltage	20 maximum
Power supply	50 kw., 2000 amperes, 20 volts separately excited, d-c. generator with field control, driven by 70-h.p., 2200-volts, 3-phase, 60-cycle induction motor.
Tanks	18 wooden tanks, connected in series, each containing 10 anodes and 9 cathodes. The tanks are 3 ft. (91 cm.) wide by 6 ft. (183 cm.) long and 4 ft. (122 cm.) deep inside.
Piping	Lead and stoneware.
Fitting, valves	Durion.
Pumps	Two Durion centrifugal pumps, rated at 100 gal. per min. (37.8 l. per min.) at 50 lb. per sq. in. (3.5 kg. per sq. cm.) driven by direct-connected 10-h. p., 220-volt, 3-phase induction motors.
Clarification	9 ft. (275 cm.) diameter, 5-tray Dorr thickener, operating with a flow of 50 gal. per min. (188 l. per min.).
Anodes	Armco iron, 2 inches (5.1 cm.) by 28 inches (69 cm.) by 40 inches (102 cm.)
Cathodes	Sheet steel, 1/16 in. (0.15 cm.) by 30 inches (76 cm.) by 40 inches (102 cm.) with coating of black oxide to prevent sticking of deposits.

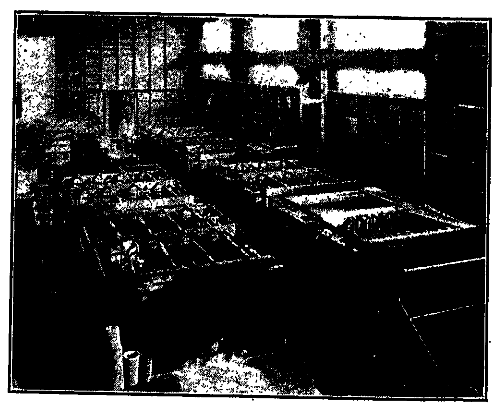

FIG. 2—GENERAL VIEW OF ELECTROLYTIC IRON REFINERY. DORR THICKENER INSTALLED BEYOND PARTITION AT FAR END. MIXING TANKS, LEFT-CENTER. WASHING TANKS, EXTREME LEFT

The principal data concerning this plant have been summarized in Table II, and Fig. 2 gives a general view of the installation.

High-Frequency Power Plant

High-frequency power for the induction furnaces is furnished by a motor-generator set designed and built especially for this work. This machine was designed by C. M. Laffoon of the Power Engineering Department, Westinghouse Electric and Manufacturing Company, and has been described by him in some detail*. The alternator is of the inductor type with a cylindrical rotor, and operates normally at 3750 rev. per min., giving a frequency of 5000 cycles per second at this speed. The machine delivers 400 amperes continuously at 250 to 300 volts, corresponding to an output of 100

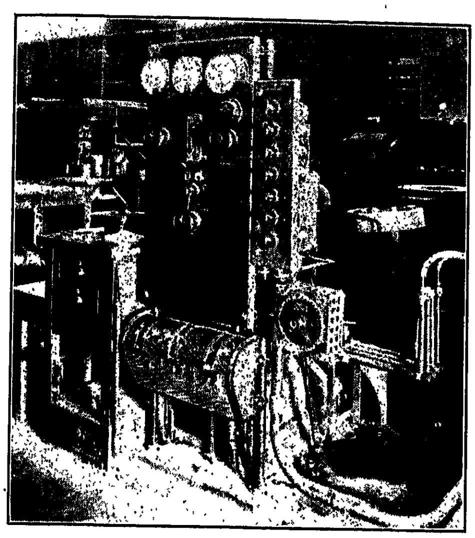

Fig. 3—Control Panel for High-Frequency Power Plant. Furnaces and Driving Motor of High-Frequency Alternator Seen in Background at Right.

to 120 kv-a. Under these conditions there have been no indications of excessive temperature rise in the windings, and the mechanical performance has been excellent under all conditions. The alternator is driven through a standard Westinghouse turbine reduction gear, giving a speed ratio from generator to motor of 4.12 to 1. The motor is a standard Westinghouse Type S K motor, rated at 200 h. p., 230 volts, 910 rev. per min. provided with field control to give a frequency range from 4500 to 6000 cycles per second.

The entire control of the high-frequency power supply is centered in the control panel shown in Fig. 3. This panel carries the following equipment.

1. Relay switch for operating the automatic motor-starting equipment.
2. Motor field rheostat for controlling motor speed.
3. Field switch for high-frequency generator.
4. Field rheostat for high-frequency generator.
5. Push-buttons controlling the solenoid-operated condenser switches.
6. Frequency meter calibrated in cycles per second and operating from a speed-indicating magneto direct-connected to the motor shaft.
7. Direct-current ammeter for measuring field current of high-frequency alternator.
8. Thermal ammeter for measuring high-frequency generator output.

Thus, one man has complete control of the starting and stopping of the high-frequency generator, of frequency, of condenser capacity, and of the voltage and current output of the alternator. For a given material and weight of charge, the furnace operations soon reduce to a routine matter of shoveling in the charge and the following of a definite current-time schedule.

The windings of the alternator are divided into twelve similar sections,—six on each end of the stator,—and these are operated in series-parallel connection, giving six groups, each having two coils in series. These six groups are connected in parallel to the busbars through 60-ampere, 500-volt fuses and the equalizing transformers. The purpose of the equalizing transformers is to ensure equal division of current among the paralleled

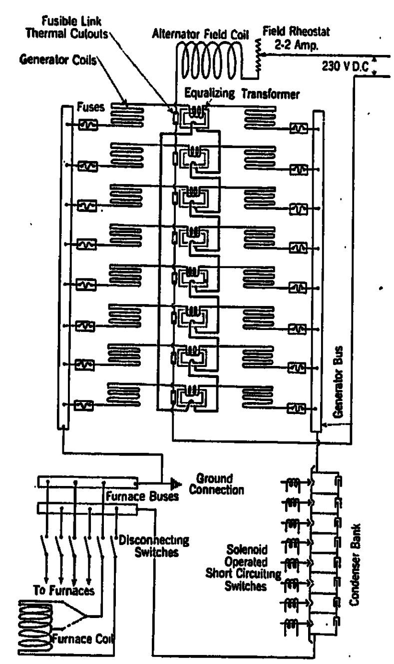

Fig. 4—Schematic Diagram of Circuits of High-Frequency Alternator, Condensers and Furnaces

sections of the windings. Previous experience with a small alternator of this same type showed that it was very difficult to get similar characteristics in all the coils, and that the relative characteristics of the coils would sometimes change appreciably with time, because of alterations produced in the dimensions or relative positions of the parts of the machine by temperature changes or other causes. As a result, it was impossible to form a grouping which would give an equal distribution of load under all conditions.

Fig. 4 is a schematic diagram of the generator, equal-

*High Frequency Alternators, by C. M. Laffoon: *Electric Journal*, Sept. 1924, Vol. XXI, No. 9, p. 416-420.

izing transformer, condenser and furnace circuits. From this it will be seen that the equalizing transformers consist of cores with a primary winding on each and that one of these primary windings is in series with each series pair of generator coils. All the cores are linked with a common secondary winding which is short-circuited on itself. Thus, the secondary current is always alike in all the transformers and the tendency is to maintain the equality of the primary currents; hence equal distribution of current among the various coil groups. If, for any reason, an open circuit develops in

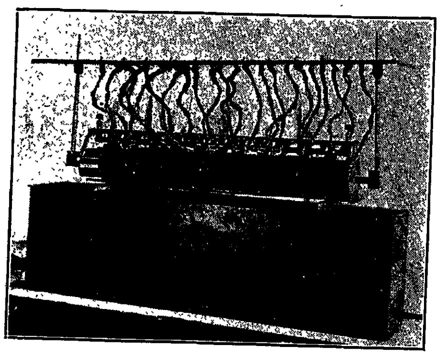

FIG. 5—SHOWING TRANSFORMER TANK, CORES SURROUNDED BY SECONDARY CIRCUIT, FUSIBLE-LINK THERMAL CUT-OUTS AND LEADS TO PRIMARY COILS

any coil group, the iron of the corresponding transformer core is immediately subjected to the full magnetizing force due to the secondary current impelled by the remaining transformers, and destructive temperatures are soon reached. The transformers are safeguarded against this contingency by placing a link of low-melting alloy in the oil immediately above each core. These links are connected in series with the field coil of the alternator. Hot oil rising from any overheated core melts the corresponding fusible link. This interrupts the field current and protects the transformer, while, at the same time it gives notice of trouble to the operator. This arrangement has worked satisfactorily on the few occasions when accidental overload has caused rupture of a fuse in series with one of the coils.

Fig. 5 shows the structural details of a group of equalizing transformers. The cases for the fusible links are seen above the cores. The common secondary consists of a copper tube, (to allow water cooling), which passes through the toroidal cores, and is provided with end-plates connected by flat copper bars to complete the circuit. The cores consist of stacks of 5 mil enameled four per cent silicon-steel ring punchings.

The alternator is connected in series with the furnace, inductor coil and the bank of condensers, as shown diagrammatically by Fig. 4. This condenser installation was designed by R. E. Marbury, Supply Engineering Department, Westinghouse Electric & Manufacturing Company and has been described elsewhere*. Westinghouse oil-insulated paper condensers, such as are regularly used for 2300-volt power-factor correction service, were used to build up this bank of condensers. The individual units have a capacity of 1.21 μf. and there are eight groups of them, each containing 20 units in parallel. Each group is provided with a remote controlled short-circuiting switch and adjustment of the condenser capacity is effected by manipulating these switches to vary the number of condensers in the circuit. Table III shows the great flexibility made possible by this arrangement.

TABLE III.
Capacity Range of Condenser Bank

No. of Groups in Circuit	Max. Total voltage	Capacitance microfarads	Max. Total Kv-a.
8	4650	3.2	2040
7	4050	3.46	1780
6	3500	4.02	1540
5	2900	4.85	1275
4	2320	6.05	1110
3	1740	8.07	765
2	1160	12.10	510
1	580	24.2	255

The condensers are mounted in grounded structural iron frames, from which they are insulated by porcelain insulators designed for a maximum stress of 10,000 volts. Much ingenuity was exercised in arranging the electrical circuits within the iron frame in such a way as to avoid

FIG. 6—GENERAL VIEW OF HIGH-FREQUENCY POWER PLANT. FROM LEFT TO RIGHT, AUTOMATIC CONTROLLER, HIGH-FREQUENCY MOTOR-GENERATOR SET, CONDENSER BANK, 225-LB. FURNACE, VACUUM PUMPS, CONTROL PANEL (FROM REAR), VACUUM FURNACE

heating of the iron work by the high-frequency magnetic field surrounding the busbars and no trouble has been experienced from this cause. The condenser frames and condenser switches are enclosed in a grounded, expanded, metal housing. Busbars are carried around the top of the condenser frame and disconnecting switches are placed at intervals, and the several furnaces are supplied with power through these switches

*The Application of Static Condensers to High Frequency Furnaces, by R. E. Marbury: *Electric Journal*, Sept. 1924, p. 421-422.

which are hand-operated by means of the usual wooden hook-stick.

This condenser installation is much more elaborate than would usually be necessary, and was made so purposely in order to provide flexibility, for, although the plant as a whole was designed as a productive manufacturing unit, the expectation was that it would also serve as an experiment station for the practical development of other applications for high frequency power, particularly in connection with heating problems. In passing, it may be said that this expectation has been fully realized.

Fig. 6 shows a general view of the motor-generator set, condenser bank, and a furnace being assembled for charging.

High-Frequency Furnaces

The high-frequency furnaces used in this plant are the same in principle as those which Dr. E. F. Northrup has so successfully developed for use with high frequency power derived from spark-gap oscillators. Slight modifications in design have resulted from the fact that the applied voltage is practically sinusoidal instead of being a series of impulses, as in the case of the spark-gap oscillator. From an electrical standpoint, a high-frequency furnace may be considered as a special case of the transformer. Physically it consists essentially of a water-cooled helix of copper tubing surrounding the material to be heated. The magnetic field produced by high-frequency current traversing the coil, or primary, induces voltage in the charge, or secondary, and the resulting currents cause heating. It will be obvious that if the resistivity of the charge is very high or very low the heating effect will be small, for, in the first case only negligible currents will flow, and in consequence, the product $I^2 R$ will be small, while in the second case, low resistance will result in a small $I^2 R$ product. In practise, satisfactory heating is obtained at 5000 cycles per second when the resistivity of the material to be heated lies between the approximate limits of 50 and 1000 microhms per centimeter cube and when the pitch of the coil and the current through it are such as to give approximately 500 ampere-turns per inch as a minimum. The efficiency of the furnace will increase as the rate of heating is increased because as the time required to reach a given temperature is reduced, the heat lost by conduction becomes a smaller proportion of the total amount supplied.

As in the case of the ordinary transformer, the closer the electromagnetic coupling between the primary and secondary, the higher the power factor and electrical efficiency. In the case of the furnace, however, close coupling requires close approach of inductor and charge, and a point is reached at which the gain in electrical efficiency due to improving coupling is counterbalanced by the loss in thermal efficiency resulting from decreasing thermal insulation. The optimum coupling is not a constant but depends upon the rate of energy supply, the temperature to be reached and the nature of the temperature cycle. The coupling coefficient will be denoted by ϕ and is defined as the fraction of the total magnetic flux produced by the coil which is linked with the charge. Roughly it is proportional to the ratio of the square of the diameter of the charge to the square of the diameter of the coil. For most high-temperature melting operations satisfactory performance is obtained when this ratio lies between the approximate limits of 0.5 and 0.7, and a usual value is 0.6. In a general way, the coupling giving the best results will approach the lower limit when it is desired to reach the maximum temperature with a given amount of power, and will approach the upper limit when a given temperature is to be quickly reached by generous application of energy.

The accurate calculation of the electrical characteristics of a given combination of inductor and charge is a matter of considerable difficulty, not only because of the purely mathematical problems of determining the effective resistances and reactances of the coil and the charge, but also because of our ignorance of the electrical and thermal properties of conductors and refractories at high temperatures. Northrup* has developed approximate formulas which are found to be sufficiently accurate for most engineering purposes when the frequencies are high enough to justify the assumptions:

1. That the effective ohmic resistance of the charge is equal to its reactance.

2. That the resistance of the inductor coil is negligible compared to its reactance.

Two of these formulas are particularly useful in designing furnaces to operate on given voltage and frequency, and are given below.

$$P = \frac{2\,\phi\,E^2}{2\,\pi^2 f L\,(\phi^4 + 2 - 2\,\phi^2)} \tag{1}$$

$$P = \frac{0.45\,\phi\,E\,I}{\sqrt{\phi^4 + 2 - 2\,\phi^2}} \tag{2}$$

Here, P is the power absorbed by the furnace: ϕ is the fraction of the total flux produced by the coil which is linked with the charge; E is the root-mean-square voltage across the coil; I is the current through it and L is its inductance.

In designing the furnaces for the plant here described, we have used somewhat different design methods, as outlined below.

1. Given: An ingot of a certain size and material to be melted.

2. Required: An estimate of the length, diameter, number of turns of the inductor, and the range of condenser capacity and kv-a. required for operation

*Electric Heating by Ironless Induction, by E. F. Northrup: *General Electric Review*, Nov. 1922, Vol. XXV, No. 11, p. 656-666.

*Principles of Inductive Heating by High Frequency Induction, by E. F. Northrup: *Transactions Amer. Electrochem. Society*, Vol. XXXV, 1919, p. 69.

with a power supply of which the voltage, current and frequency are given.

3. Experience was drawn upon to make a plausible estimate of the ampere turns per unit length of the inductor, and also to select a reasonable ratio for the diameters of inductor and charge.

4. The axial length of the inductor coil is determined by the length of the charge, and it has been our practise to make it somewhat greater than that of the charge, the excess in general not exceeding the diameter of the charge.

5. From (3) and (4) the dimensions of a trial coil are found. Its inductance is calculated, and from this and the given values of current and frequency, its reactive voltage and kv-a. are found.

6. The electrostatic capacity required to resonate at the assigned frequency with the inductance determined in (5) is calculated, using the formula,

$$C = \frac{1}{4\,\pi^2 f^2 L}$$

where C is the capacity in farads: f, the frequency in cycles per second: and L the inductance of the coil. This establishes the maximum voltage and kv-a. rating for the condenser and the minimum value for its electrostatic capacity.

7. The effective resistance of the inductor is calculated from its direct-current resistance in the light of test results. Test data are available which show that for frequencies between 5000 and 10,000 cycles per second the high-frequency resistance of the usual furnace coils will be from 5 to 25 times the direct-current resistance. For ½ inch (1.27 cm.) by ¾ inch (1.9 cm.) copper tubing flattened to 0.45 inch (1.14 cm.) and edge-wound with a pitch of two turns per inch (0.79 turns per cm.) the a-c. resistance is approximately 25 times the d-c. resistance for coils having proportions usually encountered in furnaces, the length-diameter ratio being of the order of two to three.

8. The resistance of the charge is calculated on the assumption that it is a thin cylindrical shell of which the length and outside diameter are those of the charge, and the thickness is given by Steinmetz's* formula for the depth of penetration of current in a conductor,

$$L_p = \frac{5030}{\sqrt{\lambda\,\mu\,f}}$$

where

L_p is the effective depth of penetration in centimeters:

λ the conductivity of the material in reciprocal ohms per cm.^{3}:

μ the magnetic permeability of the material and

f, the frequency in cycles per second.

9. The inductance of the charge is calculated by assuming that it is a very thin cylindrical shell whose mean length and mean diameter are those of the shell given by (8).

10. The mutual inductance of coil and charge are calculated by means of the approximate formula,

$$M = \frac{2\pi^2 A_2^2\, n_1\, n_2}{d \times 10^9} \quad \text{and}$$

$$d = X\sqrt{1 + \left(\frac{A_1}{X}\right)^2}$$

where

M is the mutual inductance in henries:

A_2 the means radius of effective current zone in charge in centimeters:

n_1, the total turns on coil;

n_2, the total turns on charge (= 1);

X, the half length of the coil, and A_1 the effective radius of the coil in centimeters.

11. The effective inductance of the coil when the charge is in place will be less than that of the coil alone, and is calculated from the formula given by Morecroft,*

$$L_1^1 = L_1 - \left(\frac{\omega M}{Z_2}\right)^2 L_2$$

where

L_1^1 is the effective inductance of coil with charge;

L_1, the inductance of the coil alone;

ω, the product $2\,\pi \times$ frequency in cycles per second;

M, the mutual inductance of coil and charge;

L_2, the inductance of the charge and

Z_2 the impedance ($\sqrt{R_2^2 + L_2^2}$) of the charge.

12. The effective resistance of the coil will be increased by the introduction of the charge because of energy absorption by the latter. The effective resistance of the coil when surrounding the charge is calculated by a formula given by Morecroft.†

$$R_1^1 = R_1 + \left(\frac{\omega M}{Z_2}\right)^2 R_2$$

where

R_1^1 is the effective resistance of the combination of coil and charge:

R_1, the high frequency resistance of the coil alone:

R_2, the resistance of the charge as calculated in (8).

13. The minimum values of the reactive kv-a. and voltage of the coil and hence of the condenser, and the maximum electrostatic capacity required, are determined by the effective inductance of coil and charge as calculated under (11) on the assumption that the condenser capacity will be adjusted to give resonance at the chosen frequency.

14. The effective resistance of the condenser is calculated from a knowledge of its power factor as

*Transient Electric Phenomena and Oscillations, by C. P. Steinmetz: 1909 Edition, p. 376.

*Principles of Radio Communication: Morecroft, p. 87.

† loc. cit.

determined by test, and the kv-a. corresponding to a given current.

15. The maximum power and current which will be taken by the furnace at the given generator voltage is then calculated by summing the resistances given by (12) and (14), and any circuit resistance which may enter, and applying Ohms' law, assuming operation at resonant frequency so that the inductive reactance of the furnace circuit is balanced by the capacitive reactance of the condenser, and hence that the apparent resistance between the terminals of the condenser-furnace circuit is equal to the true ohmic resistance.

16. The power input to the charge is found by subtracting the copper losses in the coil (determined from its high-frequency resistance and the current) from the total power as determined by (15). The maximum temperature obtainable can be found approximately by calculating the thermal resistance of the refractories separating charge and coil, and from this the temperature drop from charge to coil required to transfer the thermal equivalent of the power input to the charge.

17. Having thus arrived at a tentative design for the inductor coil and an approximate estimate of its performance, the final design can usually be obtained by a second approximation with sufficient accuracy.

In practise, it has been found that the method outlined above gives very good results so far as the determination of condenser capacity and coil voltage are concerned. The results for maximum temperature obtainable and the effective resistance of the coil with charge are less accurate. This is due to the approximations necessary in the calculation of the copper losses in the coil and the effective resistance and inductance of the charge (hence the effective resistance of the coil with charge) and to uncertainty as to the true values of the electrical and thermal properties of materials at high temperatures. Table IV gives a comparison of the results of calculation and test for a certain melting furnace.

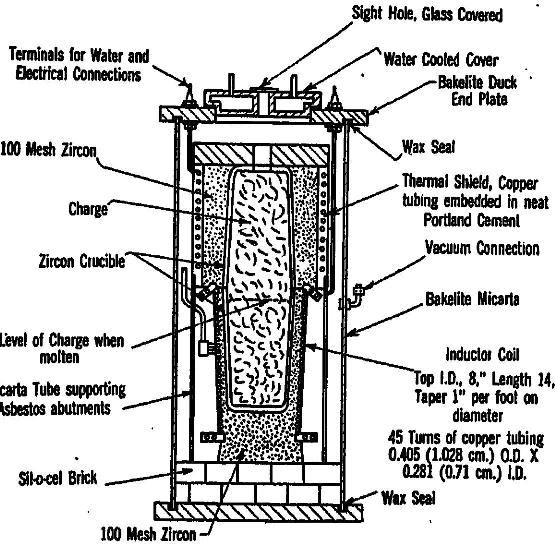

FIG. 7—50-LB. VACUUM FURNACE

The actual construction of two types of furnace now in use is shown by Figs. 7 and 8.

Fig. 7 is a vacuum furnace designed to melt 50-to 60 lb. charges of iron. The vacuum jacket enclosing the furnace proper consists of a micarta tube to which micarta duck-end plates are sealed by means of a special wax. The furnace proper consists of a slightly tapered helix of copper tubing supported on radial asbestos abutments carried within a second micarta tube. Water and electrical terminals are brought out from both ends and the middle of the coil. Above the coil is a water-cooled cylindrical shield formed by casting a shell of neat Portland cement around a helix of copper tubing. This shield supports the thermal insulation around the upper end of the furnace chamber and protects the micarta casing of the furnace against heat from the charge. The top end-plate is provided with an opening through which the furnace is filled. When the furnace is in operation, this opening is closed with a water-cooled cover provided with a glass observation window. A rubber gasket and stopcock grease form a vacuum-tight joint between the cover and the end plate.

TABLE IV.
Comparison of Calculation and Test Data for 50-lb. Vacuum Furnace

	Resonant Frequency (with full charge)	Furnace Current with full charge	Coil voltage (for 184 amperes)	Power Factor	Input kw.
Calculated	6200	300	735	6.5	23.8
Found	6100	184	740	10.7	14.5

The melting chamber is formed by placing a crucible within the coil and inverting a second one over it. A hole is cut through the bottom of the second crucible to allow for charging and for observation of the occurrences within. Zirconium silicate, ground to a uniform size of approximately 100 mesh, has been found a very satisfactory material for providing the necessary refractory thermal insulation around the furnace chamber. All the space between the crucibles and the coil and thermal shield is packed with this material, and the furnace is then ready for charging. The whole volume of the melting chamber is available for containing the ingredients of the charge because as melting proceeds in the bottom crucible fresh material settles down from the top.

With the furnace charged and the cover in place, evacuation is next in order. We have used No. 2 Trimount rotary oil pumps, exhausting into a system whose pressure is kept at approximately ½ inch (10-12 mm.) of mercury by a reciprocating vacuum pump. When the furnace is cold, the pressure within it can be reduced to a few hundredths of a millimeter of mercury, but it is usually impossible to get much below five millimeters of mercury when the furnace contains a molten 50-lb. charge of iron, for example, be-

cause of the evolution of gases from the charge and the hot refractories.

With the furnace exhausted and water flowing through the coils, it is ready for operation. It is connected to the busbars and the alternator is started and allowed to speed up with small field excitation. At first the current is imperceptible but it soon rises sharply to a maximum as the resonant frequency is passed. When the resonant frequency has been found, the alternator speed is reduced to give a slightly lower frequency and the field excitation adjusted to give the desired furnace current. Stable operating conditions are obtained by working slightly below resonance because tendency to increasing speed is counteracted by the increased load on the generator due to increases in both furnace current and power factor at the generator terminals which take place as resonance is approached.

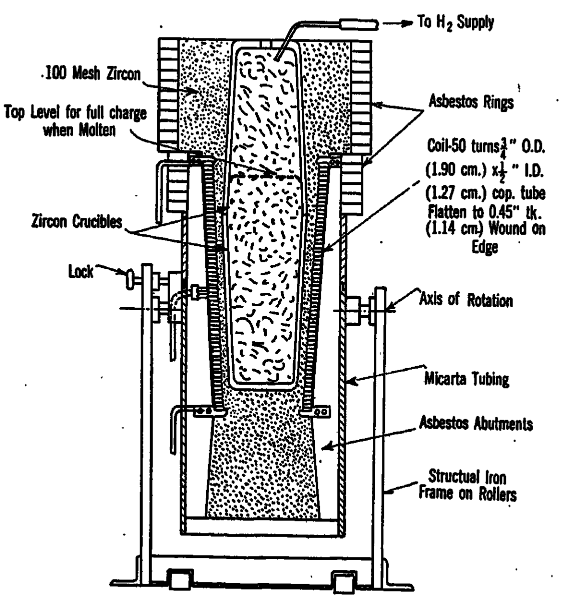

FIG. 8

After the melt has been brought to the proper condition, it is cooled by decreasing the power input and bringing the temperature of the charge down until it is close to the solidification point, and then cutting off the power, allowing it to freeze. The cooling schedule has an important bearing on the soundness of the ingot and is determined by experience. By using only the top half of the coil during cooling, the solidification of the top of the ingot can be retarded. This practise aids considerably in getting ingots which are free from shrinkage cavities.

The log of a typical run of one of these vacuum furnaces is given in Table V.

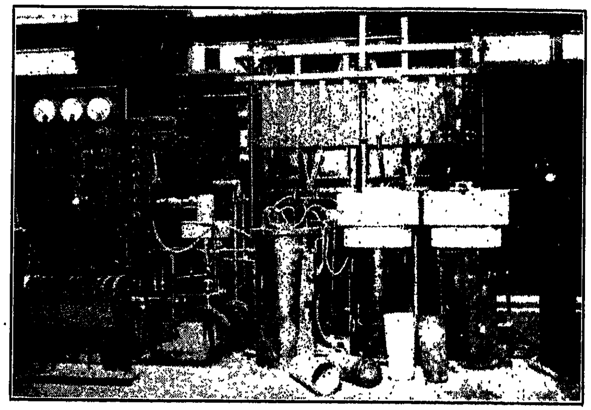

FIG. 9—HIGH-FREQUENCY FURNACES, 225-LB. (100 KG.) CAPACITY. HIGH-FREQUENCY MOTOR-GENERATOR SET AND CONDENSER BANK IN BACKGROUND

The variations in the frequency are due to the changes in the inductance of the furnace caused by the changes in the coupling coefficient and the resistance of the charge which occur as the latter is converted from a stack of irregularly shaped pieces of metal to a cylindrical molten mass.

When the ingot has cooled sufficiently, the vacuum is released, the zircon scooped out and the crucibles and contents lifted out with a pair of specially designed tongs. The taper of the furnace coil facilitates removal of the charge.

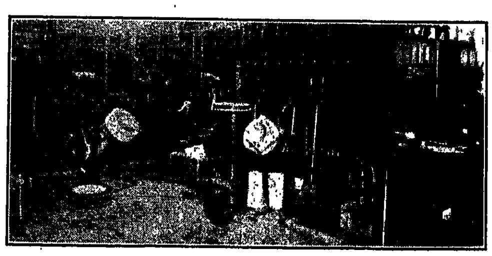

FIG. 10—HIGH-FREQUENCY FURNACES. FROM LEFT TO RIGHT; CONTROL PANEL, VACUUM PUMP, 50-LB. VACUUM FURNACE, TWO 225-LB. (100 KG.) FURNACES, HYDROGEN TANK. CRUCIBLES AND INGOTS IN THE FOREGROUND

The bottom crucible is used but once, but the top one usually lasts through five or six heats. The zircon is used repeatedly although there is some loss due to its

caking on the outside of the lower crucible, and being discarded.

Fig. 8 is a diagrammatic cross section of a furnace designed to melt 225-lb. charges of iron. The general appearance of some furnaces of this type is shown in Fig. 9. They are carried by structural iron frames mounted on rollers so that they may be easily moved about, and trunnions are provided so that they can be tilted for discharging. The melting chamber is formed by two crucibles, one inverted above the other as in the vacuum furnace. The hydrogen, or other protecting gas, is led in through a small side opening near the top end of the upper crucible. Zirconium silicate is packed between crucibles and coil and rings of asbestos lumber retain it around the upper crucible, above the end of the coil.

The necessity for using copper tubing of such large radial width may be questioned, but experience with some of the first furnaces built shows that the inductor coil must possess considerable mechanical strength if it is to resist the stresses caused by the expansion of the crucible. The zircon packing between the crucible and coil does not seem to possess a great deal of resilience, and water leaks in two coils were definitely traced to stretching due to the thermal expansion of the crucible and refractory packing.

The operating routine of these furnaces is not greatly different from that of the vacuum furnace just described. Melting is done at atmospheric pressure, usually under the protection of a suitable gas. Hydrogen is convenient and has been used in the majority of cases. The gas is supplied from a tank of compressed gas through a regulating valve. A typical log of a furnace run on a 225-lb. charge of iron-nickel alloy is shown by Table VI.

Fig. 10 gives a good idea of the general appearance of a portion of the melting floor as seen when looking toward the control panel and high-frequency motor-generator set. In the center is seen one of the vacuum furnaces described above, and between it and the control panel may be seen the vacuum piping and the oil pump. The mercury manometer and vacuum connection to the furnace appear on the right side of the furnace. The two right-hand furnaces are the 225-lb. type, shown diagrammatically in Fig. 8. The one next to the vacuum furnace was in operation when the photograph was taken. In the foreground are two ingots from the large furnaces and two of the crucibles used to make them.

In the early stages of our high-frequency furnace work the problem of refractory thermal insulation and of crucibles and furnace linings gave us much concern. Zirconium silicate is now used almost exclusively for thermal insulation, and the same material bonded with a small percentage of refractory clay is used to make furnace linings and crucibles. The process for making these crucibles was worked out by A. A. Frey, of the Research Department of the Westinghouse Electric & Manufacturing Company, and the crucibles are now being manufactured regularly at a cost which makes it economical to allow the ingots to solidify in the crucibles and use the crucibles but once. Thus, we avoid the pouring of ingots and the attendant complication and expense, eliminating the need for skilled personnel which would otherwise be required for this work.

Because of the unusual character of some of the processes and much of the equipment used in this plant, it might appear that it is nothing more than an overgrown laboratory, burdened with all the complications and expense usually associated with laboratory operations. A laboratory might be defined as a place where results are obtained without regard to cost or output, while the plant must produce the same results without regard to anything but cost and output.

When the plant is operating on a production schedule, there is one furnace connected to the power supply at all times, while others are being charged or emptied. The maximum output which has been required in any

TABLE VII.
Analysis of Production Costs based on Monthly Output of 30,000 lb. (13,500 kg.) (Costs in cents per pound)

	Electrolytic Iron	Iron-Nickel Alloy (ingots)
Labor	1.96	1.51
Incidental factory expense	10.36	6.81
Material	4.23	28.3
	.....	.....
Totals	16.55	36.62

one month was slightly more than 30,000 pounds, and this figure was reached without difficulty.

The operations of this plant have been subject to the same cost analysis and accounting procedure as other works departments of the Westinghouse Electric & Manufacturing Company, and the figures given by Table VII are believed to be trustworthy. The item "Incidental Factory Expense" covers capital charges, amortization, rental, supervision and all other overhead charges.

These figures are very satisfactory for they indicate that, by the extension of laboratory methods, it has been possible to produce a highly specialized material of great purity which meets very stringent specifications, at a cost not far different from the market price of ordinary commercial material having the same nominal composition but very much inferior properties.

Discussion

H. N. Shaw: I should like to ask what the over-all efficiency of that high-frequency induction furnace really is? That is, the ratio of the B. t. u. put into the motor to the B. t. u. actually developed in the iron of the furnace. It seems to me that there would be other applications if that efficiency is at all high. Offhand, it would seem to me to be quite low.

P. H. Brace: In reply to Mr. Shaw's question as to the over-all thermal efficiency of the high-frequency furnace and generator installation, I should say that for an input of approximately 150 kw. to the motor we get slightly more than 100 kw. out of the generator. Twenty kw. are lost in the copper of the inductor coil of the furnace and five kw. in the condensers, thus leaving a balance of about 75 kw., which is converted into heat in the charge. This is not a particularly high thermal efficiency as compared with that obtained with large arc furnaces, but with the present type of furnace we can easily do things that are not practicable with other types. We have complete control of our furnace atmosphere and in our particular design of furnace we have avoided all the troubles due to the casting of ingots and done away with all of the heavy labor. The use of electrolytic metals has eliminated the fire refining steps required in ordinary steel-making processes and we have attained a product which we were unable to secure in any other way. I might emphasize the fact that this plant is more than a plaything; we are producing approximately 40,000 lb. per month of one particular material.

Synchronous Motor Drive for Rubber Mills

With Special Reference to Dynamic Braking Control for Safety Stopping

BY C. W. DRAKE[1]

Member, A. I. E. E.

Synopsis.—Since wound-rotor induction motors with clutch brakes have been very commonly used for this application, a review of the operating conditions and safety requirements is given, in order to show why synchronous motors without clutches may be used for the same application.

* * * * *

DURING 1920, the Rubber Subcommittee of the Industrial and Domestic Power Committee of the A. I. E. E. collected and prepared considerable data relative to the choice and selection of motors for mill-line drives (paper presented January 14, 1921 at the Akron-Cleveland meeting). It was mentioned in this report that synchronous motors had certain desirable characteristics for mill-line drives and that there were a few in operation which had given very satisfactory service. The real demand for synchronous motors, however, has come only since the interest in power-factor improvement has been given thoughtful consideration.

Mill-line drives may be divided into two groups; namely, the geared type, in which gear units with high or moderate speed motors are used, and the gearless type, in which the motors operate at the speed of the mill line or about 100 rev. per min. For the latter group, synchronous motors have been used principally on account of their lower cost and better performance as compared with induction motors, while those synchronous motors which have been used for gear drive were undoubtedly installed primarily for power factor purposes, since there is little advantage in efficiency or difference in cost as compared with the induction motor.

Rubber mill drives impose two severe conditions upon the motor equipment, first, a high starting torque when the mills are started with rubber in the rolls, and second, a quick stopping in case of accident or emergency. The risk and danger involved in the milling of rubber has been appreciated ever since the industry started, and these factors have always had an important bearing on the type of driving equipment used. In other words, the question of safety to employees has had, as it rightly should have had, preference over other factors in the layout of mill drives. A knowledge of these conditions explains why the wound-rotor induction motor, which has been most extensively used for mill drives, has in most cases been equipped with a clutch brake. From the standpoint of starting and running the clutch is unnecessary, as such motors have ample starting torque. However, since most of the stored energy of the system is in the rotor of the motor, it is not surprising to find that one of the first methods of obtaining quicker stopping was to disconnect the motor and then apply a brake on the remaining load. Although clutch brakes have been quite generally used, it has been found in many cases that it is the practise in starting to close the clutch first and then start the motor, thus using the clutch only as a safety feature and saving the wear which would be occasioned during starting to the clutch lining.

In view of the established or common practise employed in the installation of wound-rotor motors, it was to be expected that synchronous motors which had lower starting torque and, as a rule, more stored energy, would be equipped with similar clutch brakes, and that these would be used both during starting and stopping. Thus equipped, the synchronous motor should give service identical to that of the induction motor, since each may be designed for the same maximum torque, although the fact that the induction motor slows down considerably before reaching its maximum torque may sometimes give sufficient warning to prevent its pulling out and stalling. Many of the early installations of synchronous motors were of the gearless type, and since motors as slow as this have a low starting torque, the clutches were undoubtedly needed to obtain a starting torque comparable with that developed by the wound-rotor motors. Synchronous motors used with gear units have much higher starting torque but the question is just how much torque is required to start a mill line.

Under normal conditions the mills are started empty, since the rubber is always removed before shutting down at the end of each shift. The torque required to start an empty mill line is so low that it may be entirely neglected. If the mill line is shut down by accidentally pulling the safety switch or by loss of voltage, the torque required to start the mills will depend upon the condition of the rubber in the mills at that time, and that may take from 50 per cent to 150 per cent of full-load torque. If the motor is shut down due to pulling out or the opening of the overload relay, which is usually set at about 200 per cent load, it is evident that if the motor cannot carry the load at synchronous speed, it cannot start it from rest, and one must resort to other means in order to reduce the load. The most usual method is to reverse the motor, thus backing up the rubber in the mills. Depending on conditions, the rubber may

1. Westinghouse Elec. & Mfg. Co. East Pittsburgh, Pa.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925.

either be removed if very stiff and cold, or, after again starting the motor in the normal direction, the rubber may be forced through the rolls, since by this method the motor gets a start before the rubber enters the wedge of the rolls. Experience has proven that with a motor of correct capacity for a given mill line the shut downs with loaded mills are not numerous, and consequently the question of starting torque should not unduly affect the rating or design of the motor. Synchronous motors designed to operate at 80 per cent power factor and at a speed of about 600 rev. per min., which is commonly used for geared drive, have a starting torque on full voltage varying from about 1.5 times full load torque for motors of 100 h. p. up to about 2.5 times full load torque for motors of 400 or 500 h. p. capacity. When started on the 80 per cent voltage tap of the starting transformer a torque varying from 1.0 to 1.5 times full-load torque will actually be obtained, and although this is not as high as could be obtained by a wound-rotor motor or by a clutch, it has been found sufficient to meet all requirements.

As long as a clutch was thought necessary to obtain sufficient starting torque, the simplest, and probably the cheapest, method of obtaining safety stopping was by means of a brake on the mill side of the clutch. The

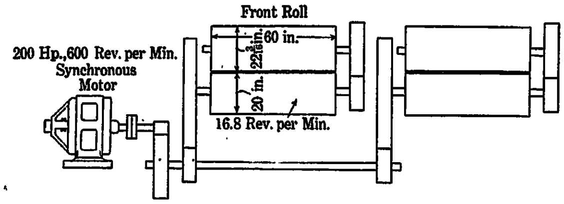

FIG. 1—SCHEMATIC ARRANGEMENT OF TWO 60-IN. MILLS WITH COUPLED-TYPE SYNCHRONOUS MOTOR

elimination of the clutch gave opportunity for other methods of braking, and electrical engineers naturally considered first the possibilities of electrical systems. Tests conducted a number of years ago on synchronous motors proved conclusively that very quick and uniform stopping could be accomplished by disconnecting the motor armature from the a-c. supply, and connecting it to a resistance of suitable value, while the field circuit of the motor is left energized at its normal full load value. Although the above facts and principles were known many years ago, it is only during the last two or three years that practical application has been made of them in the rubber industry, and to the best of the author's knowledge, no other industry has attempted a similar application.

Fig. 1 shows a characteristic layout of two 60 in. mills, which, in this case, are driven by a 200-h. p., 80 per cent power factor, synchronous motor, three-phase, 440-volt, 60-cycle, 600 rev. per min. This motor is connected to the gear unit by means of a flexible coupling and when delivering 200 b. h. p. will have a leading reactive component of 124 kv-a., while a wound-rotor induction motor of similar rating would have a lagging reactive component of 106 kv-a. Consequently the replacement of an induction motor by a synchronous motor in this case effects a reduction of 124 plus 106 or 230 reactive kv-a. in the total plant load.

The details of a control equipment for a synchronous motor with dynamic braking will vary considerably

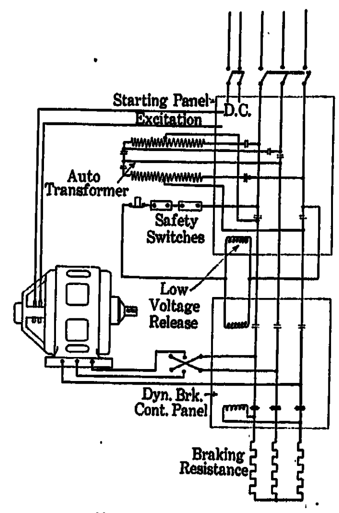

FIG. 2—SCHEMATIC DIAGRAM OF SYNCHRONOUS MOTOR CONTROL SHOWING STARTING PANEL, DYNAMIC BRAKING PANEL AND REVERSING SWITCH

with the size and voltage of the motor, also with the desires of the rubber company, but the fundamentals are the same in all cases. For instance, one company may desire the simplest type of manual starter while another desires a full automatic starter in order to install it in some remote location. Consequently the

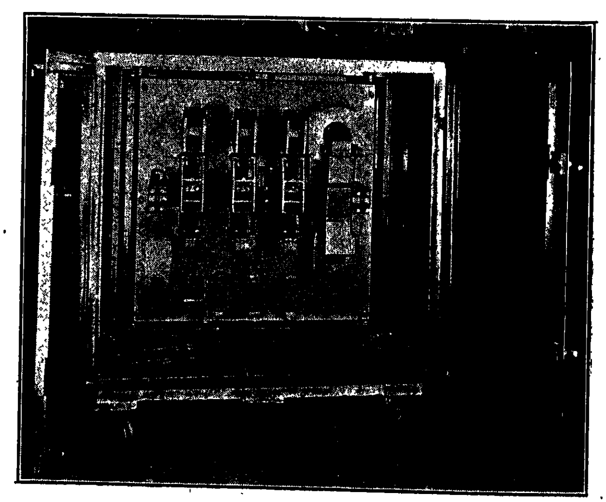

FIG. 3—GRAVITY-OPERATED DYNAMIC BRAKING CONTACTOR WITH REVERSING KNIFE SWITCH

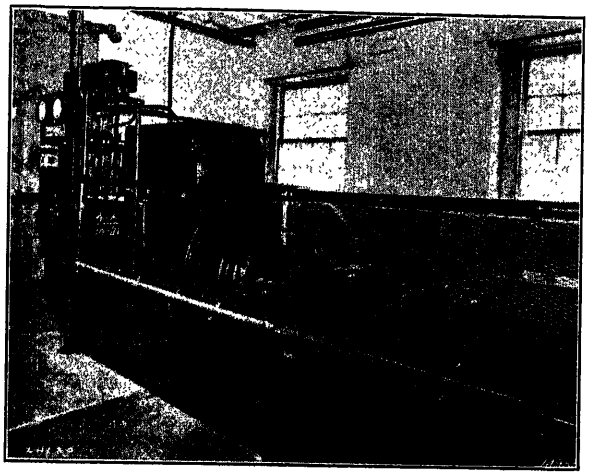
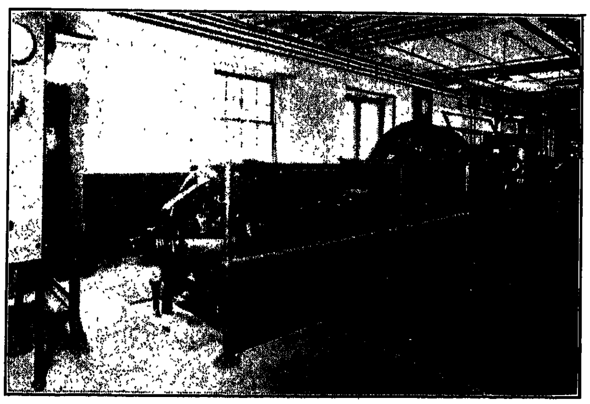
dynamic braking contactor has been designed as a separate unit which may be used with any type of starting equipment. Fig. 2 is a schematic or simplified diagram of the control in which the motor starter may be either manual or automatic. The three-pole, double-throw, dynamic braking contactor is really the

heart of the system, for the stopping of the mills in case of emergency is entirely dependent on this and is independent of the rest of the control. As seen from the diagram, also from the photograph of this contactor in Fig. 3, the upper contacts open the circuit to the motor in series with those of the main controller thus introducing a double break and insuring opening the circuit even though the main circuit breaker or contactor does not open. The safety switches, of which there is at least one for each mill, are connected in series and upon the opening of any of these, the circuit is opened to the low-voltage release coil of the starter





Figs. 4 and 5—Installation of a 200-H.P. Synchronous Motor with Dynamic Braking Control Driving Two 60-in. Mills

and to the upper magnet coil of the dynamic braking contactor. Upon the opening of this circuit the upper contacts open and the lower contacts are instantly closed by the action of gravity aided by the spring pressure of the upper contacts. The closing of these lower contacts connects the motor armature to the dynamic braking resistance, and since the field circuit has not been opened, the voltage generated produces a current, the value of which may be regulated by the value of resistance used. The voltage generated during braking is also utilized to energize the lower magnet and hold the lower contacts firmly together until the motor stops.

The two-pole double-throw knife switch located below the three-pole contactor is used to reverse the direction of rotation of the motor when necessary and this switch is intended to be opened only when the motor is shut down. To provide against opening power current on this switch auxiliary contacts are provided which open the main circuit breaker or contactor of the starting equipment, also the dynamic braking contactor before the knife blades leave the jaws. Fig. 4 and 5 show installation views of a 200-h. p. synchronous motor mill line drive as shown diagrammatically in Fig. 1, together with the starting equipment. The starter is of the manual type panel-mounted consisting of a double-throw oil-immersed starting switch with separate mounting auto-transformers, the dynamic braking contactor, reversing knife switch and braking resistance are mounted in the cabinet at the rear of the starting panel.

To obtain the maximum possible safety on a rubber mill drive, the dynamic braking control should:

1. Operate by gravity and not depend upon closing a contactor electrically.

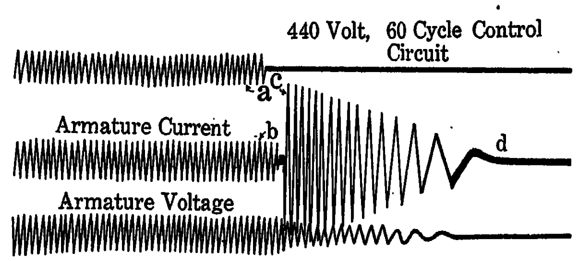


Fig. 6

2. Operate at high speed, in order to obtain as short a stop as possible. The special contactors developed for this work operate upon failure of the control circuit by any cause and, due to the method of construction used, a very high speed is obtained. Tests upon a 500-ampere contactor show a total time from the opening of the control circuit of the upper magnet coil to the closing of the lower contacts of about 1/20 of a second. High speed at this point is of great importance, for until the lower contacts are made, the rubber mills are traveling at full speed. The average speed of the front roll in the present case was about 100 ft. per min. or 20 in. per sec., so that the roll travel from the opening of the safety switch to the close of the dynamic braking curcuit of the motor would be about one inch.

A committee of the National Safety Council has been gathering data regarding the stopping distances of mill lines with a view of eventually preparing a safety code for rubber mills. No conclusions have as yet been reached but the Department of Labor of the State of New Jersey, in a tentative code, has decided upon 18 in. as a maximum travel for group-driven mills with roll diameters from 16 to 24 in. The travel is to be meas-

ured with the mills empty on the surface of the front roll by means of an electrical device which operates when the safety switch circuit is broken. This method of measuring the travel, although it gives the results desired by the safety engineers and the rubber engineers, does not allow the electrical engineer to analyze the entire operation. Consequently, oscillograph records have been taken using three elements and a characteristic film is reproduced in Fig. 6. The upper element indicates the current through the safety switch, the center element the current in the motor armature and the lower one the voltage at the motor terminals. At point *a* the safety switch opened, while the motor current was not interrupted until point *b* was reached. The small gap between *b* and *c* represents the time required by the contactor passing from the upper to the lower position. The distance from *c* to *d* indicates the time for the motor to stop after the braking current is completed, and by counting the number of cycles, it is possible to determine just how many revolutions the motor made. For instance, in this case there are 16 cycles, and since the motor has 12 poles or six cycles per revolution, the total number of revolutions is 16/6 or 2⅔ revolutions. On the mill line under consideration the ratio between the motor speed and the roll travel is approximately 600 rev. per min., to 100 ft. per min., or 10 revolutions equal 20 in. travel. Consequently 2⅔ revolutions represents about 5⅓ inch travel, to which it is necessary to add about one inch for travel during the operation of the controller, making a total travel of approximately 6⅓ in. The time required for the motor to stop can be adjusted to the maximum torque obtainable by adjusting the braking resistance. Probably the limiting condition in all cases will be the gears and mechanical parts of the mill drive, since the stresses in the motor when stopping in the minimum distance are not greater than those obtained when the motor is pulled out of step, due to overload. As a roll travel of about 10 in. with mills empty, is considered amply safe by motor engineers on mills of large diameter, there is little need of subjecting the equipment to unnecessary strain, and especially since every safety device should be operated and checked at least once a day to see that it is in satisfactory operating condition.

When stopping in a given distance, the dynamic braking will always be easier on the equipment than mechanical braking, since the torque developed in the motor is transmitted to the revolving field through the flexible medium of a magnetic field as compared with brake lining and mechanical friction in the latter case. Tests have also shown that the current values in the primary winding, when braking, are materially less than when starting under average conditions, so that as far as the motor is concerned, if it is of sufficient capacity to start and operate the mill line satisfactorily, those functions will be more severe than those encountered in stopping by dynamic braking.

Discussion

S. H. Mortensen: Mr. Drake's paper recognizes the importance of the application of dynamic braking to motors driving rubber mills and similar industrial installations where quick stops are necessary for safety reasons. The importance of this was brought to the speaker's attention in 1918, in connection with the design and operation of a 500-h. p., 450-rev. per min., self-starting synchronous motor, geared to a four-roll rubber-mill drive in the plant of the B. F. Goodrich Company in Akron, Ohio. This motor was installed for power-factor improvement and as it replaced a wound-rotor induction motor, it was connected to the mill by means of the magnetic clutch which formed part of the original motor drive, together with a solenoid-operated brake for stopping the mill in case of accident. As this installation was a novelty at that time, extensive tests were made on this motor. These proved not only its suitability for this type of drive but

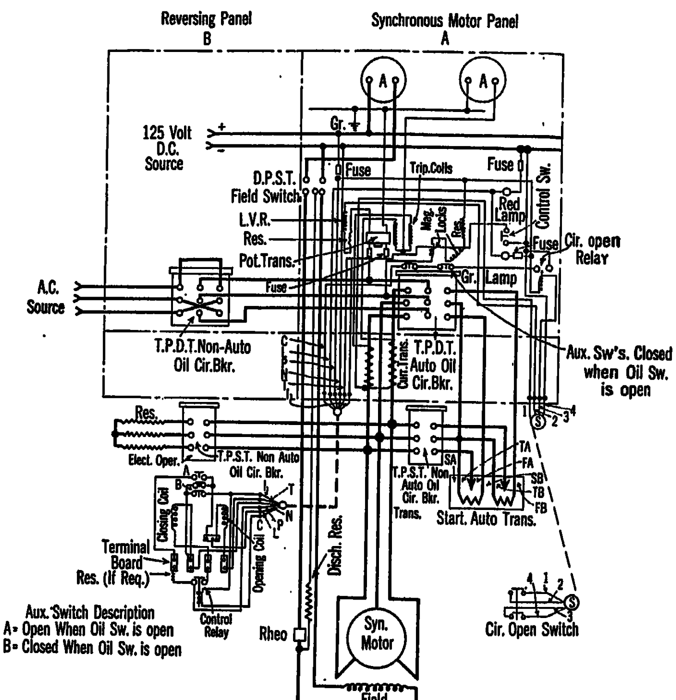

Fig. 1—Diagram of Connections as Seen from Rear of Panel. All Secondary Wire No. 12 R. I. F. P.

also that it did have ample starting torque to bring the mill up to speed with the clutch energized. Its pull-out was beyond any load that could be put upon it by overloading the mills with the toughest rubber available.

The first opportunity for applying dynamic braking in conjunction with a synchronous-motor rubber-mill installation occurred in 1920, when two 500-h. p., 450-rev. per min. synchronous motors were designed for direct gearing to two four-roll, rubber-grinding mills in the plant of the Fisk Rubber Company, Cudahy, Wis. In this installation the magnetic clutch was omitted from the mill drive, together with the mechanical brake, the motors being designed with a heavy squirrel-cage winding proportioned to develop a starting torque of 2.3 times full-load torque which enables it to start the fully loaded mills from rest and bring them up to synchronous speed. The motor was designed for dynamic braking. To stop the mills a safety switch located over the rolls is tripped and this automatically disconnects the fully excited motor from the power supply and short circuits its armature winding through a resistance, thereby producing the braking effect. The type of control used is shown in Fig. 1, herewith. This installation is to the best of the speaker's knowledge the first where the driving motor is geared

direct to the mill and dynamic braking is used for emergency stopping. After these motors had been in service for a considerable length of time they were subjected to a number of tests and the result of these tests together with a description of the general installation was written by the speaker and published in the August 4th, 1923, number of the *Electrical World*.

Fig. 2 is an oscillographic record of the voltage and currents obtained at the terminals of this motor during the period of dynamic braking. The upper records show that the time re-

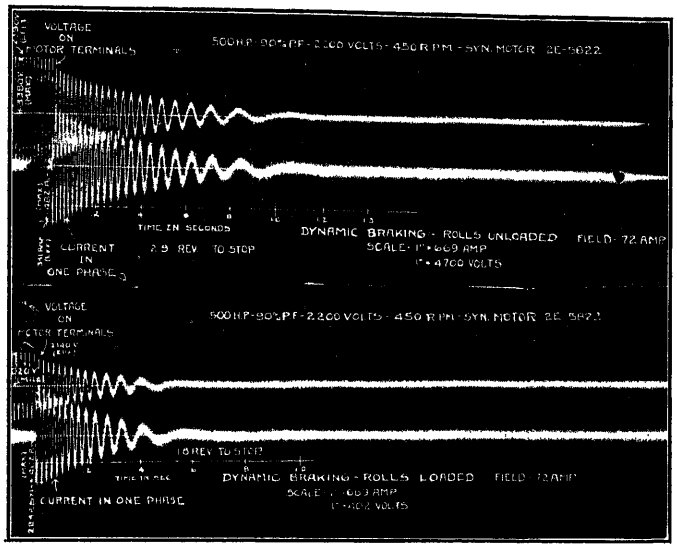

Fig. 2

quired from the instant the safety switch was operated to the time the empty mill came to a stop corresponds to 2.9 revolutions on the 450-rev. per min. motor. As the gear ratio on this mill is 1 to 20, the mill rolls actually came to a stop in 0.145 revolutions. The lower record of Fig. 2 shows the same condition as the upper part except that the mills were loaded when this test was made. Under these conditions the motor came to a stop in 1.8 revolutions. By making simple adjustments this stopping time could be further reduced.

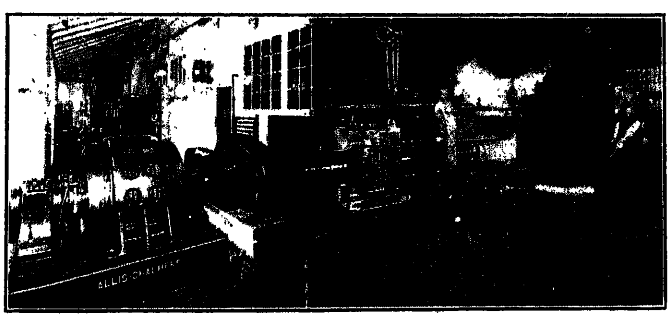

Fig. 3

Comparative tests were made on mills similar to the one described above, except that they were driven by induction motors through a magnetic clutch and stopped by disconnecting the magnetic clutch and setting the mechanical brake on the mill side of the drive. In all cases it was found that the dynamic braking was superior to the mechanical braking. It is consistent in value and acts more quickly than the mechanical brake and with less mechanical shock to the mill parts. The rapidity with which the rolls of a mill can be stopped by means of dynamic braking depends upon the stored energy of its rotating parts, the time elements of the switches, the characteristics of the motor and the amount of resistance connected in the armature circuits during braking. When the resistance is adjusted to give a maximum braking effect, the initial torque during dynamic braking is comparable to the pull-out torque of the motor with unchanged excitation. On the high-speed, gear-type synchronous motors the braking effect is as a rule ample to stop the mills in as short a time as the strain in the mechanical parts involved will permit, but where slow-speed direct-connected synchronous motors are involved the dynamic braking torque may not be sufficient to stop the mill in the desired time. In such installations the braking effect can be further increased by increasing the motor excitation simultaneously with its being disconnected from the line.

In connection with the installation described in Mr. Drake's paper, I should like to ask how this mill is stopped in case it becomes necessary to bring it to a sudden stop during the starting period, prior to the time when excitation is supplied to its fields.

In conclusion it may be of interest to the members of the American Institute of Electrical Engineers to know that dynamic braking has found successful application in connection with synchronous-motor-driven steel-rolling mills. An installation of this kind is shown in Fig. 3, which depicts a synchronous-motor-driven roughing mill. In this installation the dynamic-braking feature has proven its value as a safety measure and the rapid stops which it insures have, in several instances, either eliminated or minimized accidents which otherwise might have proven fatal to human life.

E. A. Hoener: The writer is connected with the Firestone Tire & Rubber Company; as engineer, also chairman of the Engineering Committee, Rubber Section, National Safety Council. We are collating data with reference to stopping distances on rubber mills and I am, therefore, very much interested in this discussion. In this connection I have come in contact with state commissions and have discussed with them the merits of the magnetic clutch brake and synchronous motors for stopping mill lines. One item which the synchronous-motor manufacturers have overlooked and which the state officials are giving not a little consideration is, what happens when the power goes off? We have had accidents due to power interruption on the part of the public utility or trouble in our own main power house causing power and lights to go off at the same time and mill men working on mills have been caught in the bite of the rolls. In cases of this kind dynamic braking does not do much good. We realize this is a very remote accident hazard, however state industrial boards think along these lines.

Another item to be considered is the changing over of existing equipment. I am interested in getting some of the rubber manufacturers in the United States to change their present equipment in such a way that it will become reasonably safe. It is hard to realize that there are rubber mills in existence which have only a motor direct-connected to the mill line without a brake or other safety device. This results in the line coasting to a stop after the power has been shut off. We also realize that when the manufacturer is making a new installation, he will seriously consider the installation of a synchronous drive on account of power-factor correction. However, this does not help out the manufacturer who desires to change over existing equipment in order to cut down the length of stop.

We have in Akron, particularly at Firestone, some very large mill lines direct-connected to 800-h. p. induction motors by means of magnetic clutch brakes. I shall grant that the stopping distances so far obtained on these lines have not been very good. The chief trouble has been in demagnetizing the clutch. In other words, the mechanical brake has to help overcome the magnetization that stays in the clutch. We, along with the manufacturers of equipment, have been working for some time to overcome this trouble.

A great deal has been done in correcting faulty equipment although there is a great deal still to be done. Mills, in my opinion, offer one of the greatest hazards in the rubber industry

because it is impossible to guard the bite of the rolls and still have them do the job for which they were installed.

Quentin Graham: The performance of a synchronous motor when used for dynamic braking, as described by Mr. Drake, can be predicted with reasonable accuracy in a fairly simple manner. During the braking period, the motor becomes a generator feeding a non-inductive load. The energy of rotation of the machine and its load is converted into heat which is dissipated mainly in the external braking resistor. Since the

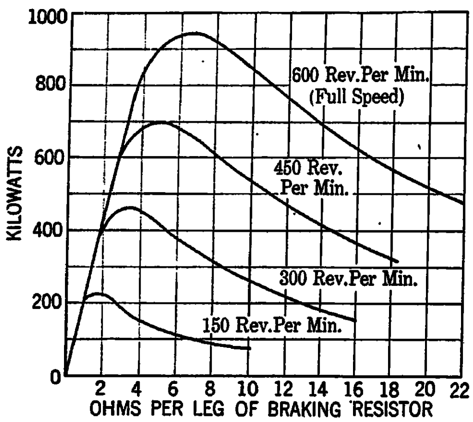

Fig. 4

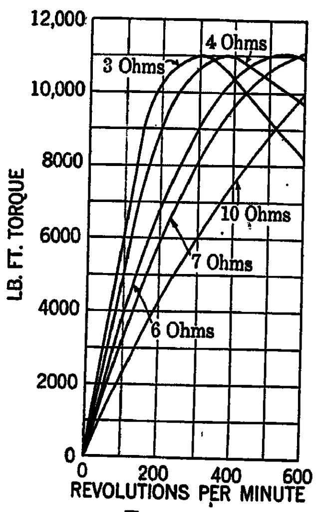

Fig. 5

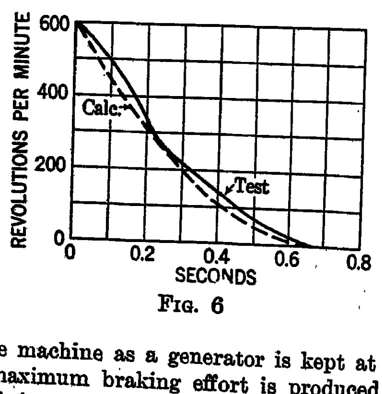

Fig. 6

output of the machine as a generator is kept at unity power factor, the maximum braking effort is produced for a given current. This is a decided contrast to the braking performance obtained with induction motors when reversed voltage is applied and the power factor and torque per ampere are quite low.

It is interesting to note the effect of changes in the ohmic value of the braking resistor. The curves in Fig. 4 show the variation in kilowatt output with changes in the braking resistance for a particular motor. Fig. 5 shows the corresponding values of braking torque determined from the kilowatt output curves. The losses within the motor, which also have a retarding effect, were neglected in plotting these curves since they are relatively unimportant. An inspection of the curves in Fig. 5 shows that at about 4 ohms per leg the braking torque would be most effective. Fig. 6 gives calculated and test curves showing the rate of retardation of the motor. For the case shown here the maximum braking torque was between two and a half and three times full-load torque.

For the retardation of heavy inertia loads which require much longer periods of time, there are two refinements of control which are used. First, the field current is increased to the maximum value so as to give the greatest possible output of the motor. Secondly, the braking resistance is varied as the speed decreases so as to obtain maximum output at all speeds. For most applications of dynamic braking, however, the retardation is too rapid to justify the use of these added complications.

P. C. Jones (communicated after adjournment): Mr. Drake's paper brings up a subject which should have been given more attention before, not only because it pertains to a distinct change in industrial drives but because the general use of such a method would vitally affect the entire central station industry by its decided affect on system power factor.

Thus, while there are any number of phases of the subject that could well be discussed, there are just two points I wish to bring up—both of them referring to the use of synchronous motors for dynamic braking.

It has always been recognized that braking equipment, particularly if used for emergency purposes, should be independent of any external source of energy. For this reason electrically operated brakes have been arranged so that the magnet, solenoid, or motor as the case may be, holds the brake released and a spring or weight sets the brake. Thus, even though the power should fail at the time the safety bar was pulled there would be no failure to stop. This principle is violated to some extent in the use of a synchronous motor as a dynamic brake. Where a direct-connected exciter is used the issue is met part way but not completely.

Of course, the chances of a power outage occurring at the time of braking are remote and generally will not be a sufficiently strong counter argument to have any appreciable weight in the ultimate conclusion, but they should always be considered if for no other purpose than to insure reliable excitation.

The second weakness I want to point out is inherent in all dynamic braking schemes. The stopping of a motor under a purely dynamic effect follows an exponential curve and is asymptotic to the axis of zero speed. Under pure dynamic effect, therefore, a motor will never stop. The expression for velocity is,

$$v = v_0 e^{-\frac{KT}{IZ}} \qquad \text{(a)}$$

where v is the speed of the motor at any moment, v_0 its initial speed, K a constant, I the moment of inertia of the system, and Z the impedance of the braking circuit.

In any actual case, however, in addition to the dynamic action there is a certain amount of line and motor friction and windage. Under this influence the velocity expression changes to the form below:

$$N v_0 = (N v_0 + 1) e^{-\frac{KT}{IZ}} - M \qquad \text{(b)}$$

If the expression (a) is integrated to obtain the distance traveled before stopping, the result will be infinity, but the expression (b) may be so integrated and yields a result in the form below:

$$s = (P I / Z) - Q \qquad \text{(c)}$$

P and Q are constants, s the distance traveled before stopping, and I and Z bearing the same significance as above. Actually both (b) and (c) are modified by armature reaction which cuts

down the initial torque and thus decreases the initial rate of deceleration, and, in the case of an a-c. generator, here being discussed, by the decreasing frequency which, by decreasing the reactance drop, has an opposite affect.

There is never any question as to the satisfactory stopping of a synchronous motor-driven mill line by dynamic braking under load conditions. Under unloaded conditions, however, where the friction load is low and the moment of inertia is high, and a very quick stop for safety purposes is desired, the conditions should be carefully checked.

Hans Weichsel (communicated after adjournment): It appears that the great number of applications to which the synchronous motor has proved to be useful, contradict the statement made by one gentleman that the synchronous motor cannot be considered as a machine of the future but rather one of the past.

It is interesting indeed to see from Mr. Drake's paper that the synchronous motor has been successfully used to replace induction motors with wound secondary, which, up to the introduction of the synchronous motor, had been used for this class of service on account of its superior starting characteristics. The operating results have shown that the synchronous motor can perform this work not only as well as an induction motor but has proved to be, in many respects, superior to it. There are two pronounced advantages obtained by the application of the synchronous motor, viz:

1. The power-factor correction
2. The possibility of applying dynamic braking

Referring to power-factor correction, the author properly calls attention to the fact that the obtainable correction is not equal to the leading component of the synchronous motor but equal to the sum of the lagging component of the replaced induction motor and the leading component of the replacing synchronous motor. This is a fact which quite often seems to have been overlooked in considering the field of usefulness of synchronous motors.

Referring more particularly to the contactor arrangement for obtaining the dynamic braking, the author states that the "voltage generated during braking is utilized to energize the lower magnet and hold the lower contacts together until the motor stops." No reason is given by the author why the voltage and not the current is used for this retaining action. I should think that in all possibility the decision was based on the following two points:

1. Mechanically, it is easier to arrange for a voltage coil than for a current coil.

2. Under the conditions existing during the braking period, the magnetism produced by a voltage coil is nearly constant for all speed conditions, while the magnetism produced by a current coil would decrease approximately proportionally with the decreasing speed.

It will be interesting to hear from Mr. Drake if these are the reasons which governed him in deciding for a voltage coil.

There are a few other questions which I should like to ask in this connection. A statement is made that, for maximum possible safety, the dynamic braking control should be "operated by gravity and not depend upon closing a contactor electrically." It would be interesting to have this statement explained more in detail. It appears to me that an electrically operated contactor is just as safe as a contactor operated by gravity as long as electric supply is in existence, but if the electric supply gives out, the dynamic braking effect fails no matter whether the contactor is operated by gravity or by electric means, because the possibility is very great that, with failure of the a-c. supply voltage, the d-c. supply voltage for exciting the synchronous motor also fails. Therefore, the braking effect in such an abnormal case would be zero no matter whether gravity or electric control is used for the contactor.

This reasoning assumes that the d-c. exciter is not directly connected to the synchronous motor, but is driven by an auxiliary unit. From the photographs and oscillograms given in the paper, it appears that this assumption is justified.

The very short time required for bringing these mills to a rest by aid of this dynamic braking equipment is extremely interesting, especially in connection with the fact that the current values in the primary winding when braking are materially less than when starting under average conditions. Naturally this is readily explained, because in starting, the motor has to overcome the inertia torque plus the torque necessary to move the rubber through the mills, while during the braking period, the generator torque plus the torque to move the rubber through the mill is equal to the inertia torque. It would be interesting to hear from Mr. Drake how often, under average working conditions, use is made of this dynamic braking equipment. It would seem that the number of braking periods during a day are so few and the time required for the actual braking so short that the braking conditions can be entirely neglected in selecting the frame size of the synchronous motor for a given horse power capacity.

E. W. Pilgrim (communicated after adjournment): It is my belief that dynamic braking of synchronous motors is by far the best method of emergency stopping for this type of motor. Tests we have made check with the data submitted in Mr. Drakes's paper and indicate that there are no severe strains imposed upon the motor or machine and I believe that this system which as far as I know is employed only in rubber mills, will become more or less the universal method in other industries.

Stopping by dynamic braking is always of the same value, whereas stopping by means of mechanical brakes is not, due to the fact that the brakes are not always in perfect adjustment. There is a definite resistance value for stopping the motor in the shortest time, and by varying this resistance, the time can be lengthened. We have found from experiments that increasing the resistance will lengthen the time and also decreasing the resistance over this definite value will also increase the length of time required for stopping.

I much prefer the automatic control as I believe that the mechanical control does not include all the features that should be included, and is not nearly so fool-proof. With hand control, if the operator throws the starting compensator into the starting position and the motor does not start, he is very apt to pull the compensator back to the "off" position which will cause severe arcing on the switch and perhaps its total destruction. The equipment should embrace a relay operated by the field current of the motor so that if the motor loses its field, it will stop. This would indicate to the operator that something was wrong and the trouble could be corrected. Otherwise, an emergency stop might be required when there is no field on the motor, in which case the dynamic braking would not be affective.

I do not think that it is absolutely necessary to operate the dynamic-braking contactors by gravity inasmuch as an electrically operated contactor functions fully as well and I can see no objections to this type of contactor, but the control should have other safety relays for stopping the motor in case of loss in field or loss in voltage. The chances that emergency stopping would be required at an instant when voltage fails, are very remote and I do not feel that it should be considered serious.

Dynamic braking of synchronous motors will, no doubt, be used very extensively now that experiments conducted by various electrical manufacturers have proven its reliability.

A. S. Rufsvold: The early synchronous motor dynamic braking installations described by Mr. Mortensen, are of considerable historical interest. Like any other electrical development, the scheme of control for dynamic braking has been considerably improved since it was first used.

In explaining the oscillograph records which he presented, Mr. Mortensen stated that the time required for the operation of the control immediately preceding the braking action was "very

short." The length of this time interval is of vital importance, because during the preliminary functioning of the control, the motor is traveling at full speed. In the apparatus described by Mr. Drake, this time interval is reduced to a minimum value of about 1/20 sec. by the use of a specially constructed contactor. This is an improvement over that type of control which depends upon the opening of one contactor and the closing of another by the use of relays, all of which takes up a considerable interval of time, and is less safe.

Mr. Mortensen has asked what provision has been made in the control described by Mr. Drake for dynamic braking during the starting period, before the excitation has been applied. On the latest type of control, this has been taken care of by arranging the control to automatically apply the excitation when a safety switch is opened during the starting period.

Mr. Hoener mentioned the possibility of the failure of power at the same instant a man is caught in the mill rolls. Although this is an exceedingly remote possibility, yet it is a point which is considered by safety committees. In the control described by Mr. Drake, since the dynamic braking contactor operates by gravity, failure of the a-c. power would not interfere with its operation. Of course, the braking action depends upon maintaining the field excitation, but should the main plant circuit breaker open, there is sufficient energy stored in the rotating parts of the motor-generator set supplying the direct current to maintain excitation during the brief dynamic braking operation. This brings up the question of what would happen in case a direct-connected exciter were used with the motor. On first thought it might be expected that no braking would be obtained, but tests have shown stopping distances quite comparable to those obtained by using separate excitation.

C. W. Drake: Mr. Hoener, Mr. Jones and Mr. Weichsel seem to be under the impression that no dynamic braking is obtained if the a-c. supply fails. This may be true with some types of control, but with the construction described, the failure of a-c. voltage automatically releases the upper contactors and the lower ones are closed by gravity. The d-c. field is maintained because any rotating d-c. machine, such as a motor-generator set or a synchronous converter, will, upon the failure of the a-c. supply, maintain its d-c. voltage for a sufficient length of time to give dynamic braking.

Mr. Jones, in his mathematical discussion, indicates that the synchronous motor losses and friction may materially affect the results of the various equations. He also states that for a quick stop with no load, such calculations should be carefully checked. Tests made on the stopping of synchronous motors in the factory with no load whatsoever indicate that there is no tendency for the motors to coast or drift at low speed. Fig. 6 in Mr. Graham's discussion shows a retardation curve under such conditions and it will be readily appreciated that the addition of a gear unit and mill line will add friction which will still further tend to eliminate drift.

Mr. Weichsel asks why a voltage, instead of a current coil, is used on the lower contactor for holding it closed during braking. The principal advantages of a voltage coil are as follows:

1. Easier to wind and connect
2. Fewer coil designs required to cover all applications
3. Gives more nearly uniform pull, since the impressed voltage and frequency decrease in proportion

Mr. Weichsel also questions the advantages of the gravity-operated contactor and quite definitely states there would be no braking in case of power failure. We have already explained why braking is obtained under these conditions and practise has proven it. Another advantage of the gravity-operated contactor is that any break in the control wiring immediately shuts down the mills, while if any circuit has to be made during the braking cycle, a failure in that wiring would remain unnoticed until it was required to operate.

Purchased Power as Applied to Plate Glass Manufacture

BY A. L. HARRINGTON[1]
Associate, A. I. E. E.

Synopsis:—The paper gives some general statistics on plate-glass manufacture, and estimates that the present total electrical requirements of the industry in the United States, are about 350,000,000 kw-hr. per annum.

About 60 per cent of this energy is purchased and is considered a very desirable load from the central station point of view, as the plants generally run almost continuously and shut down only a short time on Sundays, giving a very desirable load factor.

The paper briefly describes the manufacturing processes, and shows the different operations requiring the application of power. Specifically, it describes the 110-kv. station built for the Crystal City plant. This is designed along very simple lines to take the place of an isolated plant.

General Statistics, Plate Glass Manufacture

A SEARCH of the TRANSACTIONS of the Institute for quite a number of years back fails to show any papers presented on this subject, or, in fact, the application of electric power in any way to the manufacture of plate glass. In consequence of this, it might be well to present to the Society the general magnitude of the business as it affects central stations; then go into details.

It appears that the first attempt at plate-glass making in the United States dates back to about 1850. Nothing came of this and, in fact, various companies were formed and failed. Until 1883 no company seemed to be successful commercially. From that time on, plants have been built in small numbers until, at the present time, there are about sixteen separate factories operating.

In 1884 approximately one and one-half million square feet of glass were produced; now the American production is about one hundred million feet while approximately twenty-five million feet are imported.

Raw Materials Affecting Plant Location

Large amounts of very high grade silica sand, natural gas or coal and considerable quantities of water are required in the business, and most of the plants are located in a rough rectangle with Pittsburgh, Buffalo, Chicago and St. Louis as the four corners. In nearly all of this territory the supply of natural gas was plentiful and as it was particularly desirable as compared with producer gas which is now generally used, and as the melting end of the manufacture required about one-half of the total fuel used, a cheap and plentiful supply of natural gas largely dictated the location of the plant.

Previous Sources of Power

In the early plants most of the work was done by hand and most of the product was of relatively small dimensions. Gradually, however, individual high-speed engines were used for the grinding and polishing processes, to be later supplanted by Corliss engines, driving line shafts, from which principal units were driven through friction clutches. This later development required that the machines be driven at constant speed and about this time a development in the machinery itself made that feature possible. Line-shaft driving attained its maximum when 5000-h. p. engines were put in use.

Natural- and producer-gas engines were the next development, driving generators, many of which were 25-cycle, the principal units of the load being operated by means of belted motors. Overhead cranes and industrial locomotives were usually operated by 250 volts d-c., obtained by smaller gas engines or motor-generator sets.

Total Kilowatt-Hour Required

The present total requirements of the industry probably call for something like 350,000,000 kw-hr. per annum in the United States and an increasing percentage of this is being transferred to central station systems. At the present time, about 50 per cent of this is used in completely electrified plants and at least 60 per cent of this energy is purchased. In several of the larger plants, new power houses were built fifteen to twenty years ago and the normal depreciation of these plants has brought their life to an end within the last few years. So the question of changing over to central-station power has recently become a very important one.

Load Factors

Plants usually run continuously, shutting down only from eight to sixteen hours on Sundays during which time maybe 15 or 20 per cent of average power is required for operating machine shops, pump houses, cranes and locomotives. The annual shut-down, due to the necessity of making certain repairs about the furnaces, may decrease the demand on the power system to 10 or 15 per cent for two or three weeks, but in the event that a stock of semi-finished glass is available, the machinery part of the plant may be continued in operation, which makes a very desirable load from the central station man's point of view.

1. Pittsburgh Plate Glass Company, Pittsburgh, Pa.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925.

Central Station Power Applied to Particular Plant

It so happens that at the present time one of the larger plants of the country, located within transmission distance of St. Louis,—namely, the Crystal City, Mo. plant of the Pittsburgh Plate Glass Company,—is being changed over to central station power and, as certain features of this change-over may be of interest to electrical engineers, this paper is prepared to make such information available.

In order to give a clearer understanding of the detailed application of power, we might describe briefly the process of plate glass manufacturing.

Detail of Manufacturing Process

The raw materials are chiefly a high grade silica sand, soda ash, limestone, together with a very small amount of sodium sulphate charcoal and arsenious oxide. The proper mixture of this raw material in a perfectly dry state is accomplished in a manner similar to that used with concrete. It is placed in fire-clay pots, which are, in turn, placed in the equivalent of an open-hearth furnace. The temperature is gradually raised until melting is complete. This is followed by a few hours of refining, after which the furnace is allowed to cool down so that the glass attains the consistency of "cold molasses." The pot is then removed from the furnace by an overhead crane and dumped on a water-cooled cast-iron table, somewhat larger than the largest plate desired to make. This is done by means of a special crane giving a motion to the pot very similar to a mason placing a trowelful of mortar on the brick.

A water-cooled cast-iron roller is then rolled over the hot glass, the thickness of the finished sheet being determined by flat strips of metal put under the ends of the roller. After the plate is cooled sufficiently to be capable of being pushed by its cold edge, it is forced into an annealing oven and is, by various mechanical methods, moved through a series of annealing ovens so that eventually it comes out at atmospheric temperature.

The "rough glass," approximately ½ in. thick, is roughly examined and cut in such a way as to remove defects, and stocked.

The next part of the cycle consists of grinding and polishing. The first step is to secure a sheet of rough glass to the approximately true top of a circular table which, when placed in the grinding or polishing machine, is in effect the same as a table of a boring mill. This attaching of the glass to the table is done by plaster of Paris so that but little time is consumed and yet the attachment is not so good but that it can later be quite easily separated.

Referring to illustration, Fig. 1, which is a vertical cross-section taken through the grinding or polishing machine, it will be seen that the table which is provided with four wheels to operate on a system of tracks around the works, is supported by and revolves with the circular casting at the top of the large shaft, which casting at all times remains secured to the shaft. It is evident that relative vertical motion of some part of the machine is necessary to place the table on the "spider" and this is usually accomplished in either one of two ways:

First, the tracks over the machine may be lowered by hydraulic jacks or equivalent, so that the table comes down on top of and rests on the spider, the rails going downward a sufficient amount to clear the wheel flanges: Second, the rails may be kept permanently in position and the shaft, together with the spider on the top, may be raised by a hydraulic jack until it lifts the table from the rails.

In the plant in question the last method is the one in use and the hydraulic jack at the bottom of the shaft,

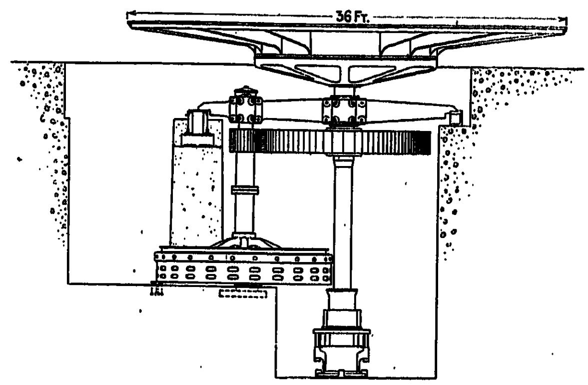

Fig. 1—General Cross-Section, Grinding and Polishing Machine

together with a safety lock or wedge, is introduced after the operation is completed, is shown at the bottom of the pit.

Grinding is accomplished with sand and water applied between the glass and iron blocks. These blocks are usually secured to disks, two or more of which are in contact with the top of the glass, with axes parallel but not in line with the main shaft. It is evident that rotation of the table produces a torque on these "runners," which revolve freely in their bearings, and pick up a speed intermediate to the table.

After coarse grades of sand have been applied, finer grades are usually followed by several grades of emery until the glass is as smooth as it is possible to make it. The table is then stopped, removed from the spider, transferred to another machine which is similar so far as the driving mechanism is concerned, but having in place of the cast iron blocks, pieces of felt saturated with iron oxide—"rouge"—and the glass is thus brought to a polish by the operation of the machine.

After one side of the glass is ground and polished, it is necessary to turn the plates over, bed them in plaster again, and repeat the cycle, after which the glass is removed from the table, washed with acid to remove the plaster, and, when dry, cut up into desired sizes and placed in stock.

In considering the application of electric power to the complete process of manufacture, we might first give consideration to the handling of the raw material. This is a proposition for handling raw material in which the usual methods are used and the only thing to be considered in applying a motor relates to the fact that the principal component, dry sand, is very highly abrasive. The other components, being alkaline, will attack certain parts of the equipment, particularly in the presence of moisture, and as a final item to look out for it is necessary to use every precaution to keep stray iron out of the batch material, which calls more or less for the use of magnetic separators,—usually pulleys.

The manufacture of the clay pots and other large amounts of fire-clay products is more or less similar to brick manufacture except that the clays are in a greater state of purity and must be kept so, and must be far more thoroughly mixed. The machinery consists of extra long pug mills in which the clay is mixed with water to the proper consistency, with rock crushers to crush up the raw clay, as well as fragments of previously burned clay, and chaser mills which grind the mixture of the different clays into powder.

Induction motors seem to be the proper driving medium and gear boxes, or similar devices taking up as little room as possible and closed against the entrance of dust, should be the connecting medium. As most of these machines either start up under load regularly or accidentally, they should be provided with slip-ring or double-wound rotor motors, 40- or 50-h. p. motors being about the limit as to size.

The entire melting or manufacture of the rough glass does not represent any features of interest to the electrical man, except in one or two small details. One of these is the "teeming crane" that pours the pots on the casting table. This teeming crane must move horizontally not more than twenty feet in two seconds, starting and stopping within this distance; and the motion must be combined with the pouring motion which occupies even less distance in this period. This power problem is usually met by applying a direct-current crane, or better still, mill motors and control that has practically no current or time limits.

The other item of interest is the considerable number of electric pyrometers required to follow the temperature of the glass throughout the various parts of the cycle.

The grinding and polishing part of the manufacturing process is the largest and by far the most important application of power as these machines consume upwards of 85 per cent of the entire power requirements. They also require the largest motors and are usually the only drives outside the ordinary daily applications.

Consideration of Main Drive

In the plant under consideration, 36-ft. tables are in use, a well-recognized maximum general size at many of the larger plants; and this size table requires upwards of 700 h. p. for the polishers, the speed of rotation being somewhere from 10 to 15 rev. per min., and the grinders require upwards of 500 h. p. at approximately double these speeds. We, therefore, have the problem of applying electric power to a vertical shaft running at very low speeds, and of course the first scheme would be a direct motor application. There are no examples of this kind of drive in use but it has commercial possibility.

The next solution is using a higher speed motor with a single gear reduction; if the machine in general is of the type in which the rails are lowered to permit the revolution of the table, then the high-speed shaft may be connected to the low-speed by either bevel gears, when the shaft would be horizontal, or, if the machine is of a type with fixed rails and the main shaft requires to be raised and lowered to permit the revolution of the table, then bevel gears are impossible and a high-speed vertical shaft with spur gears is necessary. With ordinary gear ratios, this will give a vertical shaft speed of somewhere from 50 to 150 revolutions and a vertical motor can be considered, as in the installation which we are describing.

The third scheme would be to apply bevel gears to the high-speed vertical shaft and on the horizontal shaft revolving at, say, 200 or more revolutions, the motor could be direct connected. Machines of this type are in successful operation.

Another scheme is to use a belted motor driving the last mentioned horizontal shaft, when, due to the motor being belted there are no particular limits as to the motor speed required. This last plan has been in use in this plant for some fifteen years and is in fact in quite general use in all plants.

In changing over this plant from 25 cycles produced locally to the 60-cycle central station power, (the 25-cycle system having been installed something over fifteen years ago) it was particularly necessary to consider the use of new motors rather than the use of the old motors with a frequency changer. This being the case, any type of motor could be selected; but due to mechanical troubles with belts, pulleys, bearings and bevel gears, which originally were designed for 300 and 500 h. p. but now with improved methods of manufacture, were loaded to peaks of 500 and 700 h. p., it was considered necessary to use a drive which would eliminate all bevel gears and belting. This decision reduced the methods of driving to the first two mentioned.

It is needless to point out that a motor revolving at 10 revolutions is a very large and expensive machine and nearly impossible at 60 cycles, although quite practical with the aid of a lower number of cycles and a frequency changer. Some of the saving due to a motor of this kind would be the reduction in size of the large pits required under the machines, formerly necessary to house the belted motors and various arrangements of gearings. Such a saving, however, could not be obtained except in a new plant designed particularly for motors of this kind and as it would also involve the

complete redesigning and rebuilding of the machine itself, it would mean a large loss in production; the machine being in use 144 hours per week. It was, therefore considered unfit for this case.

The second scheme of the vertical motor revolving at somewhere between 50 and 150 revolutions was found to be very satisfactory, if synchronous motors were used, both from an efficiency and a financial point of view.

Following is the problem which the motor manufacturers were called upon to meet:

Motors were to be three-phase, 60-cycle, 2200-volt, one rated 700 h. p. at 68 revolutions, and the other 500-h. p. at 106 revolutions; temperature rise being 50 deg. cent. and continuously loaded. Mechanically the motors were required to fit present pits and, specifically, not to exceed a certain diameter, approximately 15 ft. on account of their striking the main shaft or necessitating excessive cutting away of the concrete pillars supporting the upper part of the machinery. The stators were to overhang the pit without support. One bottom combined guide and thrust bearing was called for, this to be attached in the simplest possible manner to what remained of the concrete

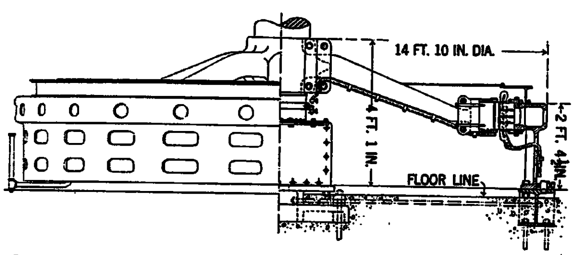

Fig. 2—Cross-Section, Synchronous Motor for Polishing Machine

after the block supporting the vertical shaft had been cut off to a level with the floor. The motors would be synchronous with 250-volt external excitation, self-starting and, when thrown directly across the line, were to develop sufficient torque to start. Due to the load at this plant being practically 95 per cent synchronous, unity power factor only was required.

Referring to the illustration, in Fig. 1, may be seen the manner in which the above specifications were carried out. The tooth reaction on the large motor is on the order of 45,000 pounds, which required the use of an 18-in. shaft to avoid excessive deflection causing unsatisfactory operation of the pinion and gear, or possible rubbing in the gap. The shaft is in two pieces, the idea being that pinion trouble, which has occurred in the past, could be quickly overcome by removing the top half of the shaft. The stator frame (Fig. 2) was made sufficiently deep to act as a girder in a vertical direction to take care of the overhang. The thrust bearing of the spring type (Fig. 3), was set upon a sole plate imbedded in the concrete floor, with arrangements to shift the bearing sideways and allow a lining-up of the gear teeth and similar arrangements provided on the stator frame to adjust the air-gap. The resultant side-pull at the bottom of the shaft due to reaction at the pinion, while not great because of the relative ratio of the lever arms, was, nevertheless, a considerable amount to be added to by variations in air-gap, and this side thrust was brought quite low on the bearing due to the fact that the thrust bearing is vertically rather thin.

The rotor spokes were made in umbrella type, bring-

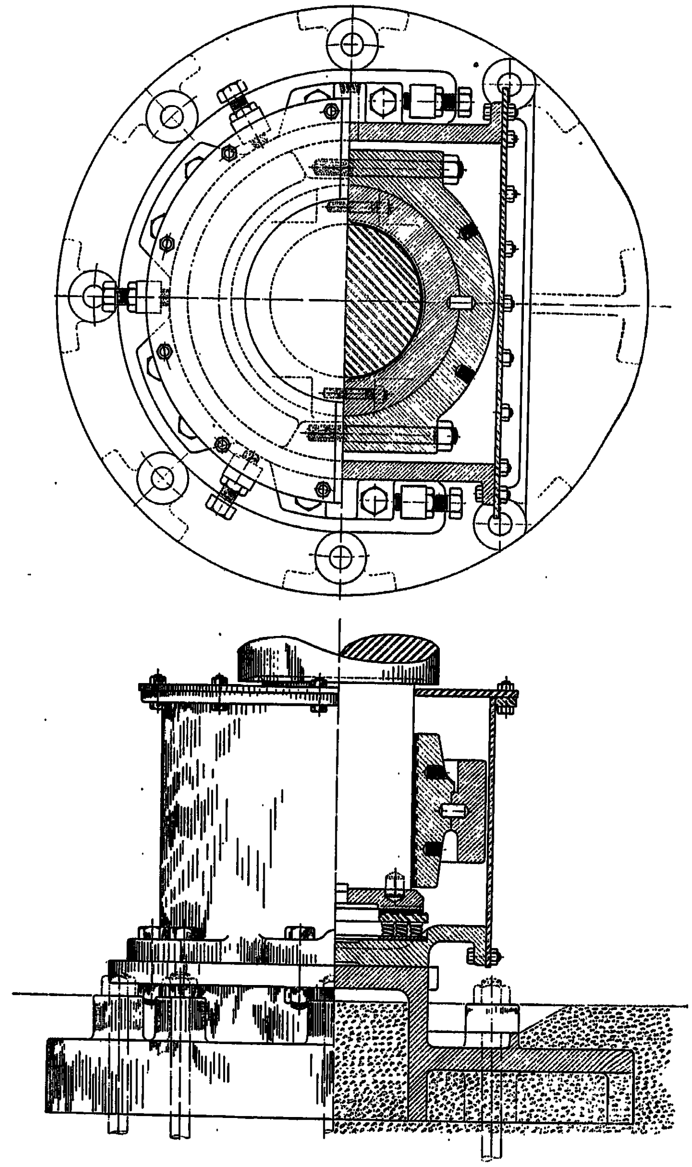

Fig. 3—Enlarged Views of Bearing of Motor Shown in Fig. 2

ing the center line of the active part of the motor down nearer the floor and quite close to the center of the lower bearing, the effect of this being that even considerable wear of the upper bearing would not cause any material change in the air-gap.

It will be seen from Fig. 3 that by taking the front plate off the bearing and raising the shaft slightly by means of jacks under the rotor rim, the bearing plates can if necessary, be very quickly removed and replaced.

These motors have been unusually successful in operation being put into regular continuous service within an hour or two after first being started. They show very high efficiency in spite of the low speed, the 700 h. p. being 92.3 per cent and 92.8 per cent for the 500 h. p. The motors are thrown directly across the line by means of a special contactor which is designed to have approximately 15,000-amperes rupturing capacity in the event of a short circuit; but this is sufficiently rapid in operation to permit of a jogging motion being given, so that the table may be slightly turned to bring the wheels above the track. The field is automatically closed by a definite time limit relay, set at something less than thirty seconds and put into operation by the throwing on of the stator current. The starting current, while not a limiting feature, is quite satisfactory, being less than the guaranteed 280 per cent of normal for the 700 h. p. and 250 per cent for the 500 h. p.

In conclusion, it might be stated that we are unable to locate any similar slow speed vertically geared synchronous motors in the United States, and that apparently those described herein are unique in several particulars.

High-Tension Substation

With reference to the central station power supply, the Union Electric Light and Power Company, of St. Louis, has built a double-circuit steel tower line, operating at approximately 115,000 volts from the Cahoka Power Plant to Crystal City, a transmission distance of 34 miles.

The power being purchased at 110,000 volts, the glass plant was required to build a complete receiving and transforming substation and other parts of the system required to receive this power from either or both of the transmission lines, the step-down transformer banks to be considered as a unit with the line. In other words, there were no cross connections.

The high-tension oil switches were required to have upwards of a million and a half-kv-a. rupturing capacity and their bushings, as well as the transformer bushings, were required to have at least leakage surface equivalent to that supplied on 132,000-volt equipment, because of the prevalence of coal smoke and similar dirty conditions of the atmosphere. The power factor of the load had to be above a certain amount, but this was more than met in that the bulk of the load consisted of synchronous apparatus.

From the consumers' viewpoint, in designing the high-tension substation the problem was presented of locating the station on a limited piece of ground adjacent to other high buildings and railroad tracks, compelling the transmission line to make a span of over 1600 feet across a number of the railroad yards of the company on which locomotive cranes were in constant use. This requirement in itself forced the use of a dead-ending tower approximately 135 ft. above the ground.

The peak load of the plant, amounting to 7500 kw. or more, together with some possible extensions, called for the consideration of 10,000 kv-a. banks. With these fundamental requirements in view, the substation shown in Fig. 4, was designed and built.

It will be seen that the two transmission lines are dead-ended on the upper platform of the tower and the

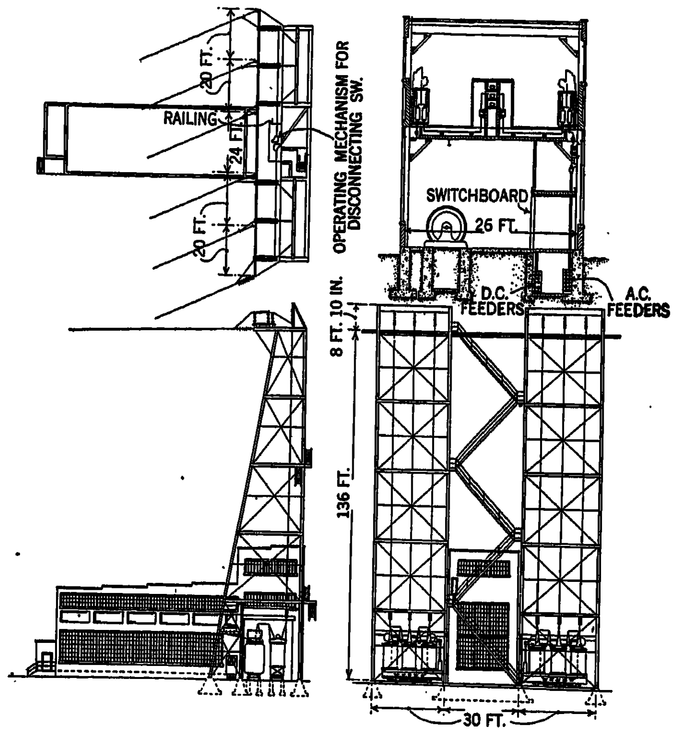

Fig. 3 A—High-Tension Transformer, with Four-Row Tubular Tank

wires are 20 feet apart. The circuit is then carried through motor-operated pole top switches having a single break six ft. long. The circuit continues down the inside of each of the outside sections of the tower, the wires being eight ft. apart, and having some five-ft. clearance to ground, supported at the upper end by strain disks, and at the lower end by a rigid insulator

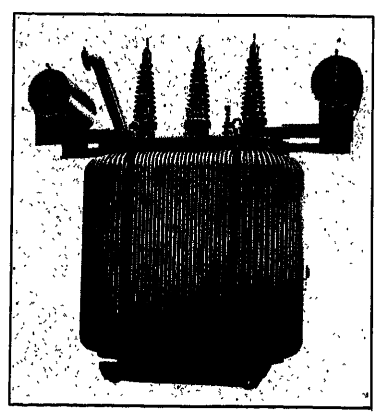

Fig. 4—View of 110-Kv., 20,000-Kw. Substation

hinged on the steelwork of the tower to swing in a vertical direction and clamped to the wire on the outside end. A weight of approximately a thousand pounds is attached to the head of the insulator, to put sufficient tension in the vertical wire to prevent side motion.

Running through the base of the tower are two standard gage tracks, on one of which are two 130,000-volt oil switches and on the other two 10,000-kw. three-phase, circular-coil core type transformers, provided with conservators and two-in. tubes for cooling. It will be noticed that the line side of the oil switch is within a few feet of the steadying insulator before mentioned, the relative arrangement being such that if the line should burn off at the upper end, the insulator and the weight are expected to swing downward and thus prevent damage to the oil-switch bushing. The oil switch and the transformer are as close together as possible so that no high-tension insulators are required between the two. The 2300-volt secondaries are connected to the leads going into the building by short lengths of flexible cable.

The central part of the tower, approximately 28 ft. square and 50 ft. high, constitutes the repair shed. Roll-up doors, 20 ft. wide and 23 ft. high, admit both the oil switch and the transformer to the building, where a 25-ton trolley of the standard type used on overhead cranes, operates on a fixed track at right angles to the transformer track. This crane is provided with a motor for the lift and hand motion for the cross travel. The lifting speed is approximately two feet per minute, which is very handy for transformer repair work.

The outstanding points of the high-tension part of the substation lie in the fact that only twelve high-tension insulators are in use outside of the apparatus bushings; 20,000 kw. with switching and repair facilities is located on approximately 2000 sq. ft. of ground; and the transformers, we understand, are the largest, or among the largest, provided with tubes, that have ever been shipped filled with oil.

The low-tension part of the substation is a two-story building on the second floor of which is the 2300-volt bus structure consisting of the usual concrete and brick arrangements, with disconnecting switches connected to the H-type oil switches, arranged along each side of the building by one-quarter by four bars run under the removable steel floor and above the four in. concrete ceiling. On the first floor, two 1200-kw. motor generators, with space for a third, are installed.

Along one entire side of the building is the remote control a-c. and the hand-operated d-c. switchboard of the usual design. A mezzanine floor located back of the panels and slightly above them, is provided to give access to the outgoing disconnecting switches and to cover part of the control conduit. There is also a partition wall running from the top of the switchboard panels to the ceiling which contains the balance of the control conduit and also protects the balance of the station in the event of a cable pothead or a current transformer blowing up. At the top of the panels is located a pull box, about 4 in. by 12 in. and extending the entire length.

In this connection it will be seen that considerable expense has been incurred to place barriers throughout the low-tension busbar system, as it was considered that short circuits of about 250,000 kv-a. might occur.

The outgoing a-c. feeders, in three-conductor leaded cable, go down the side of the building from above the mezzanine floor and, in fiber ducts encased in concrete, into the pit underneath the switchboard. The d-c. cables of the same general description enter the ducts on the other side of this pit immediately under the switchboard panels.

Substation Equipment

High-tension disconnecting switches:
- 2—L G 119—154 kv. on 135-kv. insulators, motor operated.

High-tension oil switches:
- 2—F H K O—72 C—135,000-volt, 400-amperes, solenoid operated.

High-tension transformers:
- 2—Type H. circular coil 10,000-kv-a.—110,000-2300-volt, three-phase, 60-cycles, air-cooled by 2 in. tubes, with conservators.

High-tension oil storage and treating system:
- 2—12,000 gal.
- 1—7 in. filter press.

High-tension repair shop:
- 1—25-ton crane.

Low-tension oil switches:
- 2—3000 amperes, 15,000 volt.
- 2—1200 " "
- 4— 800 " "
- 8— 500 " "
- Type H-206 and 203.
- 6—Motor-generator starting switches,—F. K. 132-A & B.

Bus insulators, 15,000 volt, heavy duty.

Motor generators:
- 2—1200-kw. 250-volt, with synchronous motors.

Switchboard:
- 12—A-c. remote control panels,
- 21—D-c., manual.

Above electric equipment by General Electric Company,

Substation peak, 10,000 kw. annual kw-hr., 50,000,000.

Plant Equipment:
- 8—700-h. p. synchronous motors, G. E. Co.
- 8—500-h. p. synchronous motors, G. E. Co.
- 1—500-h. p. synchronous motors for air compressors, G. E. Co.
  - Control for above.
  - 675-h. p. induction motors—for pumps—G. E. Co.
  - 950-h. p. motors various uses,
  - 500-motors, (approx) 250-volt, d-c. for all other uses.
  - 500-kw. total lighting transformer.
- Main distributing system—7 miles 3-conductor lead cable mostly underground.

Discussion

C. W. Fick (communicated after adjournment): Mr. Harrington's very interesting paper may raise the question of why this arrangement of vertical synchronous-motor drive is not universally adopted by the plate-glass manufacturers. There are some twenty plate-glass plants in this country with a total of 100 to 125 grinding and polishing machines. Of this number a majority must operate for a short time at slow speed at the beginning of each operating cycle, due to the method of lowering the grinder and polishing disks onto the glass. Thus, the synchronous motor is eliminated for these cases, unless a frequency changer and double bus arrangement is used.

A wound-rotor induction motor arranged as were the synchronous motors described by Mr. Harrington would have a power factor of between 65 and 68 per cent and would be more costly and require more control equipment.

However, there is no reason why the belts and ropes which are at present used on perhaps 75 per cent of these tables, cannot be eliminated by the use of horizontal slip-ring motors (as new motors are required) of 200 to 250 rev. per min. coupled to the bevel-gear shaft, with a saving of maintenance and power, and in some cases of first cost.

A. L. Harrington: The question has been asked why high-tension lightning arresters have been omitted from this substation. It was our privilege to be connected with a power system having some of the earliest outdoor substations. This system was in a locality subject to lightning any day of the year. Although the original main and substations were equipped with arresters, business increased so rapidly that it came about that transformers (in some cases) were on hand for new customers but no lightning arresters. A comparison was then available between protected and unprotected stations. Such failures as were experienced were never from line to ground but rather from turn to turn or coil to coil in the transformer. Much evidence was present to show that the dangerous disturbances were often of low potential but high frequency. In many cases results did not seem to justify the cost of lightning arresters.

With the greatly improved design of some modern transformers, we feel that they do not need the assistance of arresters. Recently these conclusions have been proven true in the Pittsburgh territory, but at a lower voltage than the substation under discussion. It is possible to add arresters to this job later if conditions of actual service seem to warrant them.

Sleet and Ice Troubles on Transmission Lines in New England

C. R. OLIVER[1]
Associate, A. I. E. E.

Synopsis.—This paper deals with the troubles one of the large power companies in New England has encountered from sleet and ice on transmission lines. The experience of this company should bring home to the transmission line designer the fact that in certain parts of the country sleet is a very serious problem and should be taken into account in designing all new transmission lines. It also shows the necessity for looking over the existing transmission systems with a view to providing some quick and easy method of thawing sleet from the lines already constructed.

* * * * *

UNTIL recent years, New England was not thought of as a section of country particularly susceptible to sleet; in fact, no serious trouble had been experienced by any of the communication or power companies before the storms of recent years, and outside of the usual one-half inch of ice and 8-lb. wind pressure, no particular attention was given by the designing engineer to the possibility of trouble from this source, either in the tower or in the conductor. Our recent experience has convinced us that there is no single tower line in New England built before 1922 that would stand up under the excessive loads that they may be called upon to carry. The only reason that any of them are standing today is that they have been fortunate enough to escape the sleet.

THE NEW ENGLAND COMPANY POWER SYSTEM

In describing the sleet troubles, the author will confine himself to those experienced by the New England Company Power System lines, with which he is most familiar.

This system, with its connections, extends from the New York State line across the State of Massachusetts to Boston, down into Rhode Island to Providence, and across to Fall River. In the northern section it extends half-way through Vermont, into New Hampshire and across the State of Connecticut to New London and Stafford Springs. Its main trunk lines are towers built in 1908 to 1914. Within recent years wooden pole lines have been constructed instead of tower lines. All of these lines operate at 66,000 volts. Last year a new double-circuit tower line was completed, 75 miles long across the center of Massachusetts, designed to operate at 110,000 volts. There are 240 miles of 66,000-volt, double-circuit tower line; 70 miles of 66,000-volt, double-circuit pole line; 275 miles of 66,000-volt, single-circuit, pole line; 75 miles of 110,000-volt, double-circuit, tower line, and approximately 75 miles of 22,000- and 13,000-volt feeder lines.

TROUBLE OF 1916

The first serious trouble on the system, due to sleet, came on December 22, 1916, on the tower line that connects the station near Hoosac Tunnel, Massachusetts, with the substation at North Adams, Massachusetts. This line was built in 1913, and consists entirely of 75-ft. standard square towers weighing approximately 5000 lb. each, with two circuits of No. 1 copper conductor, each circuit being arranged in a vertical plane, and with a ground wire at the peak of the towers. It is only 8.3 miles long, but in this length it crosses a section of country varying in elevation from 1000 to 2300 ft. above sea level. During the first winter of service on this line it was observed that quite frequently a slight sleet formation took place on the wires, and the engineers of the company thought that the No. 1 copper was too light to carry the sleet load. In the following summer, the No. 1 copper on five towers over the highest peak was replaced with ⅜-in. crucible steel conductors, and all of the towers over this peak were dead-ended.

This decision was very unwise, for two years later, in 1916, this section of the country was visited by a very heavy sleet storm, and ice of three to four inch diameter was sticking to the wires. All five of these towers on which the heavier conductors had been installed were completely wrecked. This failure occurred without a single break in the conductor, showing conclusively that had the towers been designed for the stronger conductor, no interruption would have occurred.

Only temporary repairs could be made, using low wooden structures, as the whole mountain side was frozen and covered with glare ice. Later, in the summer, the wooden structures were replaced with ten low towers, placing all wires in a horizontal plane. These towers were designed to withstand the sleet and wind loads for this section, and since their installation no trouble in this particular section has been experienced, although there have been some very heavy sleet storms on this line.

Fig. 1 shows the replacement towers which have been very satisfactory.

TROUBLE OF NOVEMBER, 1920

During Thanksgiving week of 1920 another sleet storm swept over this line, affecting a four-mile section varying in elevation from 1500 to 2300 ft. The sleet was

1. Assistant General Manager, New England Power Co., Worcester, Mass.

Presented at the Regional Meeting of the A. I. E. E., Swampscott, Mass., May 7, 1925.

again three and one-half in. to four in. thick, and although there was no tower failure, there were many span-wires broken; so many in fact, that later in the summer this whole section had to be resagged. The storm lasted five days and no headway could be made toward getting the line back into service, for as fast as breaks were repaired in one section trouble would develop in other spans. In desperation some 2300/220-volt transformers were borrowed from one of the manufacturers and, by a temporary connection, were so arranged that it was possible to secure approximately 6000 volts;

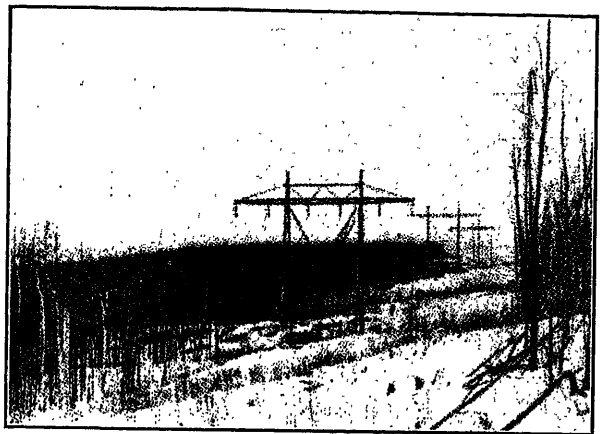

Fig. 1—A Section of the Line Showing Type of Replacement Towers

and with this pressure, using about 300 amperes, the sleet was cleared from the line by heat. During all this time the customers supplied from the North Adams substation were without power.

After the storm a careful examination of the line showed no signs of any of the towers being overstressed, nor were the wires stretched beyond their elastic limit. The only apparent damage was the broken conductors due to the overloading of the ice.

Fig. 2 shows the profile of the line from Hoosac Tunnel station to Adams substation, and the extent of ice trouble is indicated by the shaded part of the line.

Trouble in 1921

The most disastrous sleet storm on record in this section of the country started December 28, 1921. There was a steady, drizzling rain for three days with a temperature of around 32 deg. fahr. This froze as soon as it struck, thus accumulating ice three and four inches in diameter on wires, towers and trees. There was also a wind of about thirty miles an hour accompanying this storm, which appeared to have three distinct paths; one across the mountains between Shelbourne Falls and North Adams, one in the hills between Leverett and Ware, and one from Gardner east to the coast, the storm being heaviest within a 30-mi. radius of the city of Worcester, Massachusetts. Down the Connecticut Valley and in other sections of the system there was snow and very little damage to power and lines of communication. On the mountains around Hoosac Tunnel, where for years there had been so much trouble from sleet, the ice was just as heavy as in previous years but during this whole time service was maintained on two circuits 66,000-volt tower line without interruption. This was due entirely to the sleet-thawing method previously worked out. The telephone trunk-line over this mountain had, in early years, successfully withstood the sleet but was now completely wiped out. Lines affected in the company system were as follows:

1. Over 55 miles of double-circuit, 2/0 copper on 75-ft., square towers, weighing approximately 5000 lb. each, with the wires in a vertical plane and the ground wire at the peak: This line was built in 1913-1914 and extends from Shelbourne Falls to Millbury and Pawtucket. There were 69 tower failures, five towers with broken peaks and four with damaged crossarms. The tower failures consisted of broken masts, crippled legs, broken crossarms, damaged footings, both in tension and compression, and a number of towers was completely wrecked.

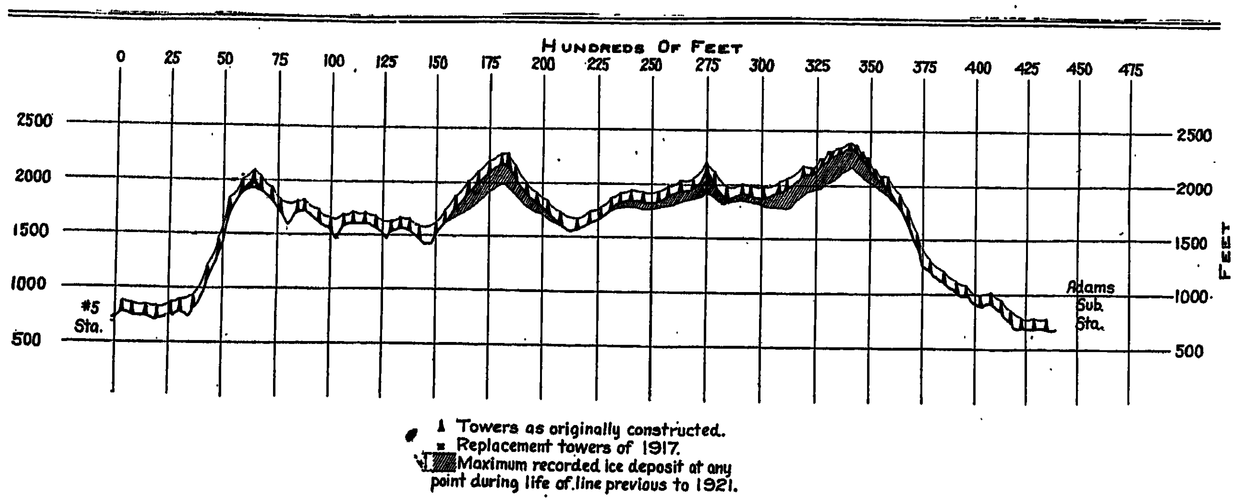

Fig. 2—Profile of Nos. 9-10 Lines from No. 5 Station to Adams Substation

Approximately 75 per cent of the damage was at

dead-end points, and in addition to the tower failures, there were many hundreds of broken spans on both power and ground wires.

Temporary repairs were made by building a 66,000-volt, single-circuit pole line along the edge of the right of way, and later, the good parts of the damaged towers were salvaged, the towers being replaced with new material purchased.

2. Over 40 miles of double-circuit, No. 2/0 and No. 2 copper line, with bayonet type towers, 50 ft. high, with pins, insulators and wires arranged in a triangular position: This line was constructed in 1908 and extends from Vernon, Vermont, to Worcester, Massachusetts, and all towers had been designed to break the conductor. Only three towers failed on this line, two being at angle points of over 45 deg., and the third tower was pulled down by the failure of the other two. Between Worcester and Gardner there were many

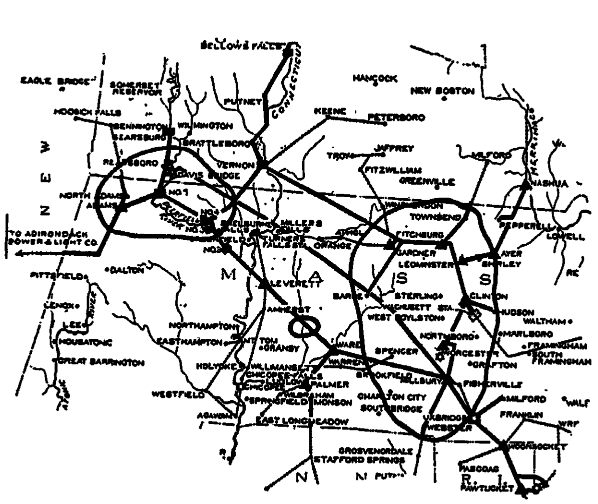

Fig. 3—Enclosures Show Sections Most Seriously Affected by Sleet

hundreds of broken spans, and damaged insulators and pins.

3. Over ten miles of "A" frame, double-circuit tower line with No. 2 copper in a vertical plane and ½-in., copper-clad ground wire at the peak of the tower: This line passes around the city of Worcester on a very crooked right of way, with many large angles. Among the "A" frames were mixed a few 75-ft., square towers at heavy angles and guyed to take the expected loading. Due to the excessive sleet loading, however, some of the angle towers gave way and 78 towers were completely wrecked. On the remaining towers a number of span wires were broken and the whole line was so completely wrecked that it was necessary to replace all of the damaged towers with two-pole structures.

4. Over 50 miles of wooden pole line with wishbone crossarms and suspension insulators: These poles were substantially guyed and double-pole construction used on all dead-end points. Four or five crossarms were broken and a number of poles was thrown out of the line, but there were no broken poles; there were also a few broken conductor spans of No. 2 copper, but it was a comparatively easy job to put these pole lines back in service.

5. In addition to the high-tension trouble, there were many miles of 13,000- and 22,000- volt feeder lines running along city streets carrying No. 2/0 copper and smaller. There were many broken span wires, but this was caused primarily by the trees, overloaded with ice, falling on the feeder lines and carrying them down. There was very little pole damage, and these lines were quickly put back into service as soon as the sleet was cleared.

Fig. 3 shows the area most affected by sleet during this storm.

Troubles of March, 1924

On the 11th of March, 1924, during a heavy snowstorm, the system began to experience trouble in the southern section, centering around Worcester and Providence. The wet snow packed around the insulators and stuck to the wires. By night it became so serious that Millbury, Mass., and Woonsocket and Warren, R. I., substations were completely isolated from the system. The storm centered in Rhode Island, and its effect on the balance of the system around Worcester was not so serious.

The trouble was caused by the very wet snow, sticking to the wires and towers, becoming solidified due to a drop in the temperature and this combination of snow load and a 60-mile wind completed the damage. In Rhode Island, snow accumulated to a diameter of four inches and actual measurements showed that it weighed 48 lb. per cubic foot. Around Worcester the snow was not so wet, and although the snowfall there was greater, the accumulation on the wires was much less. On lines north of Worcester there were very few broken spans on any of the circuits, and these circuits were all back in condition within a short while.

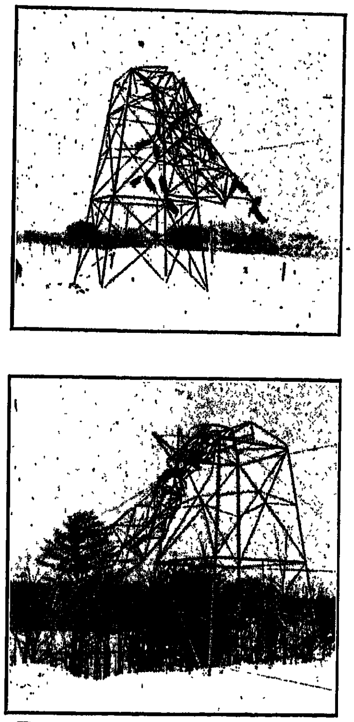
Between Worcester and Pawtucket, R. I., a distance of thirty miles, there were 36 broken span wires, 21 of them occuring in the last ten miles; but there was no structure damage. All of the towers in this section were standard 75-ft. square towers, weighing approximately 5000 lb., with the wires in a vertical plane.

The heaviest damage centered around Providence and on the transmission line to Fall River, (16.5 miles), 94 out of a total of 147 towers were damaged. This damage varied from broken masts to completely wrecked structures. The line consisted of 75-ft. standard square towers with the wires in the vertical plane and weighing about 3500 lb. Being lighter than the other 75-ft. towers on the system, the effect of the storm on these was much more disastrous. Temporary repairs were made by building a double-circuit, wooden-pole line along the edge of the right of way.

Figs. 4 and 5 show typical tower failures, illustrating how completely the towers were wrecked, and Fig. 6

is a photo of solidified snow on the wire, four inches in diameter.

An interesting thing developed during this storm; a 66,000-volt, double-pole, double circuit of No. 2/0 copper, wooden pole line with all wires in a horizontal plane runs around the north side of Pawtucket to East Providence. This pole line for quite a distance is on an adjacent right of way with a standard 75-ft. tower line. The ten miles of wooden pole line came through the storm with only three broken conductors and a few unhooked insulator strings, while the tower line had several towers completely wrecked and a great many broken span wires. One of these towers, due to the heavy load of ice, fell across the pole line and caused one of the above mentioned broken spans. The pole line had no broken or damaged structures and was put back in condition in one day's time.



Figs. 4-5—Tower Failures

Fig. 7 is a photograph of the 75-ft. tower which, in falling, put the wooden-pole line out of service.

Sleet Thawing

The first experience of sleet thawing on the company's system was during the storm of 1920. The lines were cleared of ice in western Massachusetts by using a group of 2300/220-volt transformers connected in series and paralleled, to secure from 6000 to 8000 volts at 300 amperes. This was only a temporary connection made up after six days of ineffective work trying to clear the lines, and much to the surprise of all it worked amazingly well. These were retained in the plant during the remainder of the winter. Plans were then made to provide the Hoosac Tunnel Station with permanent means of thawing the ice from the two No. 1 copper lines running over the mountain to North Adams, eight miles, and the two No. 1 circuits running over the mountains to Shelbourne Falls,—14 miles. Equipment in this station consisted of two 11,000-volt, 25-cycle generators, and two 2300-volt, 60-cycle generators; five 3000-kv-a., three-phase, 66,000- to 2300-volt transformers.

From many tests made in the field, it was evident

Fig. 6—Solidified-Snow-Covered Cable

that from 250 to 300 amperes at 6600 to 8000 volts would be required to clear in an hour the No. 1 copper of sleet. The engineers of the company were in favor of providing a separate auto-transformer for this service only, but on receiving the proposal from the manufacturers, the proposition was abandoned as too excessive in cost. Further study was made and it was finally discovered that by opening the delta on the low-tension side of one of the three-phase transformers and connecting the individual coils in series with the delta of a second three-phase transformer and

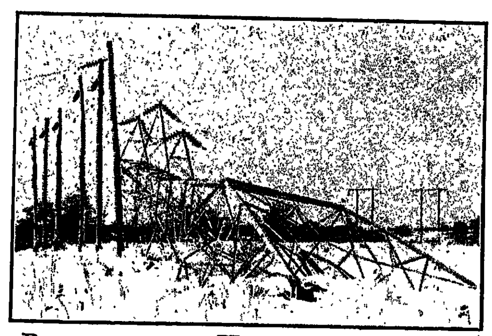


Fig. 7—Destruction of Wooden-Pole Line by Fall of 75-Ft. Tower

with the two high-tension sides connected in multiple, an extended delta could be secured, giving the desired voltage.

Fig. 8 shows the diagram of connection and the method of connecting the two deltas.

In order to make use of this combination for sleet thawing and still keep the transformers available for ordinary service during the other times of the year, all six secondary leads were brought out of one of the

three-phase transformers to disconnecting switches mounted on the ceiling overhead the unit. These switches were so arranged that the special combination for thawing could be made very quickly, and special cables were run from the extended delta up to the roof of the building, where a flexible connection of a hundred feet of three-phase cable was provided, by means of which connections could be made to any of the four lines on the roof to be thawed. The total apparatus tied up for sleet thawing consisted of one 60-cycle,

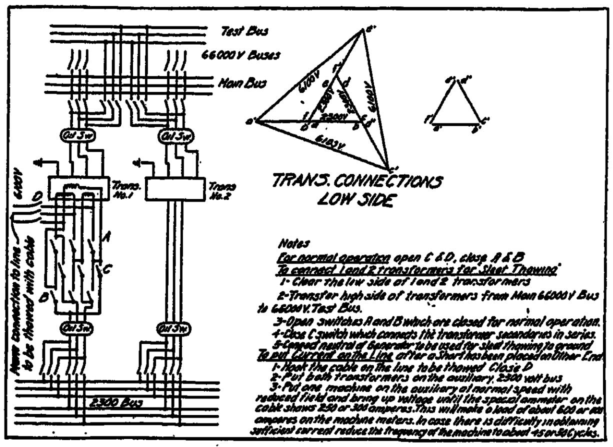

FIG. 8

2300-volt generator, and two three-phase transformers. This equipment, with a separate exciter, could be operated independent of the balance of the equipment in the station. The total cost of the sleet thawing outfit was, therefore, very moderate, and the only new equipment required was a few sets of 6600-volt, disconnecting switches and some cables. A test made under actual operating condition on the line to North Adams, (8.3 miles long and of No. 1 copper), showed the following result at 60 cycles.

Line Amperes	Generator Volts	Line Volts
200	1170	3150
250	1460	3930
300	1740	4760
390	2300	6150

A test on the line to Shelbourne Falls, (14.7 miles and of No. 1 copper), showed the following results:

Line Amperes	60 Cycle Generator Volts	Line Volts
200	2290	5600
250	2600	6970
	40 Cycle	
200	1670	4470
250	2090	5590
275	2300	6120
300	2500	6700

Within the last year, the third 25-cycle, 11,000-volt generator has been installed, and this will also be available for sleet thawing.

The success of the sleet-thawing arrangement depends entirely upon complete cooperation between the generating station at Hoosac Tunnel and the stations at the end of the line to be thawed. This cooperation normally requires telephone connection between the stations, but during sleet trouble, the telephone lines are usually the first ones to be put out of commission, so it was necessary to devise a means of working the sleet thawing device absolutely independent of telephone. Accordingly, a definite schedule was worked out for 24 hours, whereby sleet could be thawed on any or all of the four lines radiating from this station. This schedule is independent of dispatchers' orders or telephone, and it functions even when all telephone connections have been completely wiped out.

The sleet thawing is always started and carried on in accordance with this schedule regardless of the time of day and the number of lines to be thawed, so that the crews at both ends of the lines are thoroughly familiar with the routine of operation. A complete cycle of the schedule is given as follows:

Time	Shel. Falls Sta.	Hoosac Tunnel Station	North Adams Substa.
2:45 p.m.	Remove short from No. 7 Line	Start heat on No. 10 Line	..
3:00 p.m.	Close No. 7 Line when alive	Energize No. 7 Line at 66,000 volts	..
3:15 p.m.	Open and switch No. 8 Line	Open and switch No. 8 Line	..
3:30 p.m.	Attach short to No. 8 Line if dead	Stop heat on No. 10 Line	..
3:45 p.m.	..	Start heat on No. 8 Line	Remove short from No. 10 Line
4:00 p.m.	..	Energize No. 10 Line at 66,000 volts	Close No. 10 switch when alive
4:30 p.m.	..	Open and switch No. 9 Line	Open and switch No. 9 Line
4:45 p.m.	..	Stop heat on No. 8 Line	Attach short on No. 9 Line if dead
5:00 p.m.	Remove short from No. 8 Line	Start heat on No. 9 Line	..
5:15 p.m.	Close No. 8 Line switch when alive	Energize No. 8 Line at 66,000 volts	..
5:30 p.m.	Open and switch No. 7 Line	Open and switch No. 7 Line	..
5:45 p.m.	Attach short to No. 7 Line if dead	Stop heat on No. 9	..
6:00 p.m.	..	Start heat on No. 7 Line	Remove short from No. 9 Line
6:15 p.m.	..	Energize No. 9 Line at 66,000 volts	Close No. 9 Line switch when alive
6:45 p.m.	..	Open and switch No. 10 Line	Open and switch No. 10 Line
7:00 p.m.	..	Stop heat on No. 7 Line	Attach short on No. 10 Line if dead
7:15 p.m.	Remove short from No. 7 Line	Start heat on No. 10 Line	..
7:30 p.m.	Close No. 7 Line switch when alive	Energize No. 7 Line at 66,000 volts	..

The sleet thawing equipment was completed several weeks before the storm of 1921, but the crews at the station had not become proficient in its use, and when the sleet storm struck, it was not deemed wise to attempt to keep all four lines free from ice. All energy was devoted to keeping the lines over Florida Mountain

clear. As a result, these two lines came through the storm with a clean record and service was maintained to the customer during the whole time, in spite of the fact that all other communications and telephone lines in this part of the country were very seriously affected by the storm. This test thoroughly convinced the organization of the efficiency of the device, and since that time, sleet-thawing devices have been installed in several other points on the system.

Conclusions

The lessons learned during the past few years have been very expensive, but it is hoped that the future will benefit by so designing the lines of the system that they will come through a storm with a clean record. The following facts have been discovered:

1. That towers should be designed to stand regardless of the load on the conductors. A conductor failure is bad, but a structure failure is positively disastrous.

2. That earth footings fail very often in compression and this failure has wrecked many towers. There are also some failures of footings in tension.

3. That guying towers at angle points instead of using a heavy structure is very poor makeshift. The tower usually fails before the guy has a chance to do any work.

4. That "A" frame towers are not an ideal combination for sleet conditions even when all points are reinforced with heavy square towers installed every half mile in tangent and with a heavy ground wire overhead.

5. That vertical spacing of conductors will never prove satisfactory for sleet condition, not even with the middle crossarm extended.

6. That the so-called 75-ft. standard square towers as used in this section of the country for years will not withstand the sleet and wind load.

7. That wooden pole lines have suffered less damage and are easier to put back into service than light tower lines.

8. That in building important high-tension lines there is no half-way ground. To withstand the sleet it should be either a double-pole construction with steel crossarms or a steel tower with suitable factors of safety and with all wires in a horizontal plane.

9. That wherever possible it is advisable to install a thawing device if it can be done at a reasonable figure. This is a very desirable addition in New England, and will pay for itself many times on transmission lines thus protected from the sleet storm.

10. That over 60 per cent of trouble occurs at dead-end towers. These should be self supporting and not guyed, and as many angles as possible eliminated.

It is quite evident that ideas have had to be revised about transmission line design for this section of the country. During the past two years, the Company has constructed over 125 miles of 110,000-volt transmission lines and these lines have been designed with the thought that it was possible to build one that would withstand even the severe sleet storms of New England. Advantage has been taken of the lesson we have learned from the other sleet storms, and it is believed that the present transmission line will prove satisfactory.

Discussion

L. W. W. Morrow: The Pennsylvania Power & Light System, as well as other companies in central Pennsylvania, have encountered this sleet problem for several years, and have introduced a method of combating sleet which I think will prove of interest. It is somewhat along the same lines as the method used by the New England Power Company.

The method is based on the premise of catching sleet before it forms. In other words, we all know that it takes a large amount of heat to melt ice once formed. Down there most of their sleet occurs only in the high-altitude territory, so they have organized a system whereby, after studying all weather maps and close observation of approaching storms, all patrolmen are concentrated into the sleet areas to be on the job to start immediately if there is any chance whatsoever of sleet forming on any line.

If a report comes in that a sleet storm is approaching, they immediately organize to combat the sleet. This is done by isolating generators in stations sectionalizing lines as much as possible, improvising equipment that can short-circuit any line, and attempting to heat the lines before the sleet forms. It doesn't take much heat in a line to keep sleet from forming, but it takes an immense amount of heat to melt ice off the line once it is formed. So their method is sectionalization and crowding loads into lines, utilizing generators in stations, putting energy into the lines they are trying to warm to keep sleet from forming. It is a scheduled proposition, definitely arranged, with all men on the whole system alert to prevent sleet from damaging the system.

The result of their experience has been that in the last year or two they have had very little trouble and have been able to combat sleet very successfully.

J. Roubicek: I think it interesting to see how the sleet melting is effected in one of the recent additions to the New England Power Systems. I am referring to the Montauk plant in Fall River.

There is a 32,000-kw. generator operating on a bank of transformers temporarily connected to give 66,000 volts on the high-tension side. The generator cables are led to a small cable house in the outdoor switchyard, from which point bare copper connections are made to the transformer. A double-throw, disconnecting switch is located in the top of the cable house, by means of which it is possible to throw the generator output either on the transformer bank, or directly on the outgoing high-tension line, (hereby bridging switches, transformers and high-tension apparatus in the outdoor switchyard), and subject the high-tension lines to the passage of the heavy generator current. Lamps in the cable house indicate whether the transformer oil switches are closed or opened, so that the operator can make no mistakes in interrupting the transformer circuit while the breakers are in. The connection of the 14,000-volt sleet-melting cable to the high-tension line is made by solderless connectors which are disconnected when not in use.

H. S. Knowlton: The cost of modern transmission lines for high-voltage service is rapidly approaching a figure per mile

comparable with the cost of building steam railroads perhaps a generation ago, and it is certainly pretty nearly one-fourth of the cost of building steam railroads per mile through some of the canyons of the Far West. I think it would be very interesting if Mr. Oliver would say just a few words about what range of costs per mile have been encountered in his practise.

R. E. Argersinger: Some twelve years ago, before much trouble of sleet on transmission lines had been experienced in New England the company with which I am connected built a transmission line in Connecticut. This was a two-circuit line with No. 2 copper wires, each circuit in a vertical plane on one side of the tower.

Considerable sleet trouble was experienced, but a large portion of it was eliminated by extending the middle crossarm. However, it was later decided to attempt to melt the sleet from the wires and this was done successfully over a length of line approximating 20 mi., by short-circuiting one end of the circuit and applying voltage at the other end. A current of 175 amperes will melt sleet on these No. 2 wires with the air at about 32 deg. fahr. However, if there is a breeze and the temperature gets down to 20 deg. fahr., it will take nearly 300 amperes to obtain satisfactory results.

I did not clearly understand from Mr. Oliver the size of wire in the case to which he referred.

C. R. Oliver: It is our experience that 300 amperes will thaw the sleet if it is taken in time. The size of which I was speaking is No. 1.

R. E. Argersinger: If you start as soon as sleet begins to form, considerably less current is required to prevent further sleet formation than would be necessary to free the wire from a considerable thickness of sleet after definite formation.

I believe that in view of sleet troubles which have occurred in New England in recent years, more attention should be paid to the design of the line towers. In too many cases towers are purchased without sufficient attention to stresses allowed in the design and the compression formula employed; also to the proper factor of safety.

Last winter St. Louis experienced a very severe sleet storm and a great deal of damage was done throughout the district to overhead work. As reported to us the Keokuk-St. Louis steel tower line "stood like a rock,"—the result of careful structural analysis in the design and an ample factor of safety.

J. A. Johnson: Some years ago I had occasion to design a transmission line and carried out that old practise of going into the market and buying a standard product from a manufacturer. During the construction of the line, a heavy sleet storm occurred and several towers were wrecked before the line was ever put in service. The point I wish to bring out is that this sleet-thawing device ought to be the first thing provided when building a transmission line, and one should not wait until the line has been built and in service several months before beginning to think of sleet protection.

C. R. Oliver: It has been our experience that in the two or three hours between the time we stop thawing a line and get back to it, the sleet forms a little but not seriously. The whole trick that we have learned in sleet thawing is to get at it quickly. With very light sleet we have no trouble, but once the sleet gets two inches thick, you have real trouble on your hands, because your conductors sag down in the old vertical spacing and one span will unload before the other span does and a burned-off conductor results. We try to get to thawing the minute we find there is any sleet.

It has been true that there has not been as much thought put into the transmission-line tower design as we have put into our substation design or power house design.

We build a substation structure, and the structural engineer will calculate every member in that structure and all the stresses, and then add one hundred per cent in order to play safe. And by the time he gets through he adds another hundred per cent. We don't put that factor of safety into transmission lines; at least we haven't in the past. Very few men can actually calculate stresses in the mast of the tower, particularly in the old type of tower. A footing designed with delightful intention very often crumbles in compression, and if just one member crumbles in a particular footing a damaged tower results.

On the line that we finished just last year, we tried to put as much thought into the building of these individual towers as we did into the building of a structure of any kind. When the footings were excavated an engineer was there with a transit, and he stayed with the footing crew the whole time, and that footing was set just as carefully and just as much to grade as if we were setting the footing of a building.

Regarding the question of single-pole construction, this has been a standard on our system now for about six years; that is, up to angles of 15 deg. we use a so-called double-pole construction with a single crossarm, but over angles of 15 deg., we take an individual pole and dead-end of the wire with a pull-off construction for each phase.

Regarding the Moloney-type footing, we haven't used any of these. We know nothing about them except what some of our friends who have tested them have told us, but we hope to try some of them out in test if not in actual use.

Mr. Knowlton asked about the cost of transmission lines. Well, that depends much on the designing engineer, the type of country you are going through, the type of service you have to give. There are many indeterminate figures in the problem. We can give you what a 110,000-volt line costs, but it is dangerous to use it on any other section of the country; in fact, it is dangerous to use it in any way except as a guide.

We had that illustrated some time ago with one of our financial men. We were talking to some of the Southern fellows about building transmission lines, and had just put in an estimate of $15,000 a mile. He said, "We build that kind of lines for $8000 a mile," and we have had a very difficult time explaining to our people why we can't build them for $8000 a mile. But it is due to the character of the country, to the loadings we get, to the care we try to put into the lines, and it makes your cost go up. We have seen some recent estimates of 220,000 volt, running about $40,000 a mile for double circuit. On the 110,000, so-called flat construction with six wires in one plane, we run about $25,000 a mile, including the right of way and the fees.

Mr. Morrow spoke about sleet-thawing down in Pennsylvania. They have an ideal condition with their load at one point and power station at another part of the system, and can bunch their load therefore on one line. But we have a condition in New England quite different from that, that is, we have a 66,000-volt distribution system in effect, and there is no way that we can bunch the load over one line and keep the sleet off.

Transformer Tap Changing Under Load

BY H. C. ALBRECHT[1]

Associate, A. I. E. E.

Synopsis.—Attention is called to the need for voltage and power-factor regulating equipment on lines used for tying together large generating stations and for interconnection of systems. Such lines must be capable not only of transferring large amounts of energy in either direction, but must also be suitable for connecting generating sources operating at essentially equal voltages.

The important characteristics of the three principal methods for voltage regulation on interconnecting lines,—namely, synchronous condensers, tap changing under load, and induction regulators,—are presented, discussed and compared. The comparison includes such factors as first cost (including installation) reliability, ease of operation, losses, effect on system power factor and losses, maintenance, adaptability to reversible energy transfer and ability to give close voltage regulation.

The requirements of regulating equipment, particularly from the operator's standpoint, are discussed with the idea of bringing out the necessity of obtaining a high degree of reliability, ease of operation and flexibility to meet the various operating conditions.

The fields of application of various methods of regulation are discussed, showing the advantages of each for different requirements and pointing out that in some cases the best solution of the problem lies in the application of a combination of two different methods of regulation to secure the best over-all results.

Brief descriptions of three installations (two of tap changing under load, and one of induction regulators) for voltage regulation and power-factor control on lines of The Philadelphia Electric Company are included.

* * * * *

IN an effort to obtain satisfactory voltage regulation more economically for certain transmission requirements involving step-up transformation during the past two or three years, methods and equipment have been developed by which the voltage ratio of large power transformers can be changed while in service without interrupting the load. Changing taps by any such method is commonly referred to as "Tap Changing under Load."

The purpose of this paper is to indicate, so far as possible, the field in which transformers provided with tap-changing equipment might be economically and satisfactorily applied, comparing their characteristics, advantages and disadvantages with those of the other better-known types of regulating equipment, such as synchronous condensers and induction regulators. The development of equipment for tap changing and the various schemes by which this may be accomplished will be but briefly referred to, as this is to be the subject of other papers. As a result of experience in a recent installation of four 20,000-kv-a., 66-kv. transformers of this type on tie lines between two important generating stations of The Philadelphia Electric Company system, however, some suggestions will be made from the standpoint of the operating company relating to their design, construction and installation.

Where step-up transformation is involved, voltage regulation requirements have usually been those relating to one way transmission, but the tremendous growth in capacity of individual systems in the last decade, and the decided trend toward interconnection of systems, has brought with it another somewhat different problem of controlling voltage and transferring reactive kilovolt-amperes with reversible energy flow. The time is not long past when there were scarcely any ties between neighboring systems and but few of any considerable capacity between generating stations of the same system, since most companies could boast of but one large plant. The greatly increased demand for energy has resulted in the building of many large capacity generating stations, which, for economic operation, are tied together in any one system. In the past few years considerable progress has been made in the interconnection of adjacent systems to secure even greater economies. With the general spread of the "superpower" idea through the country and the consequent increase in the number of such ties, this newer problem of regulation, where energy transfer may be in either direction, is of growing importance.

Except for the induction regulator which has been applied only to a limited extent, until the recent development of tap-changing equipment; the synchronous condenser has been practically the only means of obtaining the voltage regulation to meet the requirements discussed in this paper. With tap-changing equipment available, however, the best solution of many problems may be a combination of this equipment with synchronous condensers, or, in certain cases, of tap-changing equipment alone where its range is sufficient. Of course, there are many cases in which bulk power is supplied to distant points, where it is practicable to obtain some or all of the required regulation by variation of voltage at the generating station, particularly when there is no local distribution from that point.

Application of the three above-mentioned types of equipment, for obtaining voltage regulation where step-up transformation is involved, may be commented on as follows:

SYNCHRONOUS CONDENSERS

This type of equipment has been extensively used for voltage regulation, particularly for one-way transmission, and has the following characteristics:

1. Engineer, Station Elec. Design & Const. Philadelphia Electric Co.

Presented at the Regional Meeting of the A. I. E. E., Swampscott, Mass., May 7, 1925.

a. Very important advantage of ability to carry reactive kilovolt-amperes, thus minimizing system losses and permitting best utilization of system capacity.

b. Ability to obtain smooth voltage regulation and, when necessary in cases where the charging kilovolt-amperes of the line is high, to prevent voltage rise at light loads.

c. Ability to maintain level-voltage transmission which may be of advantage where loads are tapped off along the line.

d. High cost of complete condenser installation, due not only to cost of the apparatus in the capacities required but also to the necessity of providing foundations and building.

e. Comparatively high operating and maintenance costs and losses; the latter, however, generally being more than balanced by savings in system losses.

f. Extremely high cost of installations to take care of reversible energy transfer, as duplicate equipment must be installed at each end of the line with possibly little appreciable additional saving in system capacity or losses to offset charges on the additional investment.

g. Units may be taken out of service purposely or accidentally without necessarily causing a serious disturbance.

Tap-Changing Transformers

This type of equipment of recent development, so far installed chiefly on tie lines between generating stations, is possessed of the following characteristics:

a. Very low cost, since the only amount involved is practically the difference between transformers provided with tap-changing equipment and those not so provided.

b. Adaptability to reversible energy transfer where line power factor is high or distances are relatively short.

c. Inability to improve system power factor and thus decrease losses and increase system capacity.

d. Inability to give smooth voltage regulation, changes being made in steps.

Induction Regulators

Induction regulators have been used, to a limited extent, on the low-tension side of transformers connected with high-voltage transmission lines and have the following characteristics:

a. Moderate cost.

b. Adaptability to reversible energy transfer.

c. Ability to give smooth voltage-regulation.

d. Inability to improve system power factor and thus decrease losses and increase system capacity.

e. Moderate losses.

f. Introduction of phase angle between line and bus voltage by polyphase regulators.

Comparisons

In considering these three types of regulating equipment, it will be seen that induction regulators and tap changers perform very much the same function—they vary the voltage, but have no beneficial effect on power factor, as in the case of synchronous condensers. Of these two equipments, tap changing is considerably cheaper, more efficient and occupies less space. For instance, a 7½ per cent buck-and-boost, polyphase, induction regulator, in series with the low-tension side of a 20,000-kv-a., 66-kv., three-phase transformer, would probably cost almost as much as the transformer itself, while a transformer of the same capacity provided with tap-changing equipment to give the same voltage range, would probably cost less than 150 per cent of the transformer without such equipment. In addition to this advantage in first cost, there would be a considerable annual saving by elimination of the regulator losses. There is also another advantage in favor of the tap-changing equipment; the regulator is almost as large as the transformer itself, requiring special foundations and more space than the tap-changer equipment. The regulator does give a smooth variation of voltage instead of in steps, but in many cases this is not of sufficient importance to overcome the other disadvantages. An application of tap-changing transformers of considerable interest is one in which the voltage change from one tap to the next is accomplished gradually through the use of a small induction regulator which may require an insulating transformer between it and the main transformer.

The polyphase regulator also introduces a phase angle between line voltage and bus voltage, which makes paralleling difficult. When voltage regulation is desired for existing installations, it may be quite difficult and expensive to safely apply tap changing and, in such cases, the induction regulator may work out very satisfactorily. It, therefore, seems that in new installations where step-up transformers are required, tap-changing equipment has decided advantages over regulators.

In a comparison of tap-changing equipment with synchronous condensers for voltage regulation, the two points of outstanding importance are, on one hand, the tremendous advantage of first cost of the tap-changing equipment over the condenser installation, and on the other hand, the ability of the condenser to supply reactive kv-a. in addition to voltage regulation, thus minimizing system losses and permitting best utilization of system capacity. It would seem, however, from an economic standpoint that, in many cases, the advantages of tap-changing equipment would outweigh those of condensers, if the tap changers would give the desired voltage range. As this is perhaps hardly possible, the best solution of many problems would very likely be a combination of tap-changing equipment with a smaller capacity of condensers than would otherwise be required. This compromise would permit of installation of condenser capacity sufficient to bring the power factor to the economical point and obtain the remaining regulation required with tap changing. Where the system power factor is already fairly high,

the desired voltage regulation can be obtained with tap-changing transformers of the maximum, practical voltage range, supplemented by condenser equipment if necessary. The combination of condensers and tap-changing transformers gives the advantages of both types of equipment and overcomes most of the disadvantages.

In many cases where the charging kv-a. of the line at no load is high, there may be no alternative other than the installation of condensers; but, even with this the case, the combination may work to advantage. It is again pointed out that where it is practical to vary the generating station voltage considerably, this, in combination with the use of condensers, may be a better solution than tap changing.

Development of Tap Changing

There has been a growing appreciation of the advantages of taps in transformer windings and a desire to increase their availability, and this even with recognition of the fact that taps do introduce some slight hazard and that the number should be kept down to the minimum advantageous for use. This first took the form of adding a terminal board with links whereby the ratio of transformation could be varied. However, this required the opening of a handhole over the terminal board or the lifting of the cover—an inconvenient procedure at any time and especially undesirable in bad weather. Thus, with the necessity for changing taps frequently to care for seasonal variations in load, this led to the development of ratio adjusters operated from without the transformer tank, with the unit out of service. As the necessity for making these changes became daily rather than seasonal, the next step was naturally towards means of changing taps without interrupting the load.

It may be of interest here to recall that many years ago schemes were developed and applications of small capacity were made in which taps were brought out from transformers to a dial-head and line connections were changed from one tap to another while the section of winding between taps was momentarily short-circuited through reactance.

There are several methods whereby tap changing under load may be accomplished; among them the use of (*a*) two parallel windings which can be cut out of circuit, one at a time, by oil circuit breakers or contactors in order to change taps; (*b*) one winding in which adjoining taps are momentarily tied together through oil circuit breakers or contactors during the change-over with or without "bridging" reactance or small induction regulator; (*c*) one winding in which taps are changed by taking each phase out of service in succession, the load being carried open-delta on the two remaining phases in the meantime.

In cases *a* and *b*, the windings from which the taps are brought out may be either those of the main transformer themselves or those of an auxiliary regulating transformer excited from the main bank. While the former is more compact and cheaper both in first cost and operating losses, it does not provide a means for keeping all the tap-changing equipment outside the main tank. Where regulation is desired on an existing transformer bank, this may be accomplished by the addition of such an auxiliary regulating transformer.

Where the voltage of the circuit is too high to permit the safe installation of tap-changing devices directly, it is possible to accomplish tap changing through insulating transformers, although, of course, this would be at increased cost.

The application of the general principle of tap changing under load presents possibilities for many ingenious arrangements to meet specific requirements, illustrated by the variety in the equipments already in service or on order. Undoubtedly there will be further developments involving new schemes or modification of existing ones.

While this paper treats mainly of tap changing applied to step-up or step-down transformers, it should be pointed out that tap changing can also be applied to series transformers where the line to be regulated includes no voltage transformation.

Philadelphia Electric Installations

It will be of interest to briefly describe an 80,000-kv-a. installation of tap-changing transformers at the Chester Generating Station of The Philadelphia Electric System. This station is fourteen miles from the Schuylkill Generating Station and is connected by two 66-kv. overhead circuits of No. 00 copper. Until recently two 18,750-kv-a. banks were installed at each end of the lines. Although these lines were intended to be for generating station ties only, it was not very long before two important, large customers for special reasons were tapped off not far from the center of the lines. Control of transfer of load and reactive kv-a. for the first two years was obtained by variation of the bus voltage of the Chester generating station, as the local distribution was not extensive and not particularly affected thereby. However, in 1920, this became less practicable and the need for some means of more effectively controlling the lines under various loading conditions was so great that after much consideration two 1750-kv-a., 13,600-volt induction regulators, to give 9 per cent buck-and-boost in a 18,750-kv-a. circuit, were purchased and installed at the Schuylkill end of the lines. These were and probably still are the largest regulators ever built. In 1924, however, it was decided to double the transformer capacity installed at the Chester Station end and extend a 66-kv. tap from the line to a distribution substation with requirement of 20,000 kv-a., the transformers from Chester being transferred to that point. The increased line loading brought a greater voltage drop and it was deemed best to take care of this by making the new transformers at Chester tap changing instead of purchasing additional

induction regulators or installing synchronous condensers. Five per cent buck-and-boost induction regulators were purchased for the tap off substation, as tap changers could be applied to the transformers available only with difficulty. Four 20,000-kv-a., 13.8/69-kv., delta-delta, three-phase, water-cooled transformers were placed in service the first of last November and arranged with six taps in the low-tension winding, to give up to 13 per cent rise at no load in the high-tension winding, or 78,000 volts. The low-tension windings are in two parallel circuits with taps in the middle of each winding, taps being changed on one winding, while the other is temporarily carrying the entire load. A single operation of a control switch carries to completion, the changing from one tap to another, in all three phases. Other papers give description of this equipment and its design problems in detail.

Since their installation these transformers have been operating very satisfactorily. Their control is simple and tap changes of 2.2 per cent cause no noticeable disturbances on the line. While the tap changers at Chester and the regulators at Schuylkill are non-automatic and under the control of the operators, the regulators at the substation are controlled from a contact-making voltmeter, thus insuring the maintenance of a constant voltage at that point irrespective of variations of the voltage of the 66-kv. line, due to direction and amount of energy transferred.

Construction work is well under way on the Richmond Station in Philadelphia, designed to ultimately house twelve turbo-generator units of at least 50,000-kw. capacity each, the first two of which are expected to be in operation by the end of 1925. It is anticipated that about one-half of the minimum ultimate capacity of 600,000 kw. will be distributed at 13.2 kv. and the remainder at 66 kv., and that half of the twelve generators will be connected to the 13.2 buses and the others to the 66-kv. busses through transformers connected directly to the generator leads. Provision is being made to tie the 13.2 and 66-kv. busses together through three 60,000-kv-a. transformer banks. As distribution within the next few years will be considerably greater at 13.2 kv. than at 66 kv., the first few generators will be connected to the 13.2-kv. busses. Two of the three 60,000-kv-a. tie transformer banks, each consisting of three 20,000-kv-a., single-phase, water-cooled units, connected delta-Y, have been ordered and will be placed in service the latter part of this year to provide for the demands for 66-kv. supply. In order to facilitate the ultimate reversible transfer of energy between the 13.2 and 66-kv. busses, these transformers have been ordered with tap-changing equipment of 10 per cent range in four 2½ per cent steps. An interesting feature of this installation will be that individual tap-changing equipments will be furnished with each single-phase transformer, no provision being made to have the taps on the three different phases changed simultaneously.

General Comments

In general, transformers, particularly in large capacities, have a record of high reliability. Tap changing necessarily adds complications to both the transformer itself, and the auxiliary equipment. It is extremely important that the design be developed in all its details so as to minimize any adverse affect upon the over-all reliability of the equipment. Operators are reluctant to add complications to important equipment, but in large capacity units, in which tap changing is of particular advantage, the extra expense to secure exceedingly substantial tap-changing equipment is a very small percentage of the total cost. A requirement of The Philadelphia Electric Company is that the tap-changing equipment inside the transformer tank be built so substantially as to require no attention under the expected duty other than that which would naturally be given on the rare occasions when it is necessary to untank the unit in case of winding failure.

It is true that some hazard is introduced by tap-changing equipment and some operators prefer schemes in which taps are brought outside the tank because of possibility of trouble in the tap-changing mechanism. This, however, brings about other disadvantages, such as the hazard in the additional exposure of important circuits and added first cost. Transformer windings are quite often somewhat special when built for tap-changing service and the design must be carefully worked out to obtain the best balance to meet all requirements; for instance, with schemes involving parallel windings, care must be taken to obtain the best compromise between circulating current and regulation when the load is carried for a short time on one winding during tap changing on the other.

The amount of tap-changing range that is practicable and the affect upon cost and characteristics are interesting subjects for discussion and have important bearing upon its application, particularly for reversible energy transfer. For instance, as previously indicated, the economic solution of many problems may involve a combination of synchronous condensers with tap-changing transformers in proportions determined largely by the maximum practicable range of the tap-changing equipment. It must be appreciated, however, that high ranges impress voltages higher than normal upon transformer, oil circuit breaker and other equipment, and the line itself.

It is of the highest importance that the design and construction of the tap-changing mechanism be such as to insure sturdiness and reliability; and there should be no tendency to skimp in this direction. Whether oil switches or contactors should be used for disconnecting devices, and the relative merits of different types of ratio adjusters, are matters to be carefully looked into for particular applications. Tap-changing equipment is well adapted to remote control and experience has indicated the value of but one operation of a control switch for a complete movement from one tap to

another. Of course, provision must be made for manual operation in case of motor trouble, or failure of control system. The complete movement, whether remotely or manually operated, should be made in the minimum length of time possible without any shock to the mechanism or sacrifice in durability. That portion of the tap-changing mechanism external to the transformer should be properly housed and specially designed to withstand moisture from condensation. The mechanism should be readily accessible for inspection and maintenance.

It is essential that the operator know the tap on which the bank is operating and that any change he desires has actually been completed. Therefore, a position indicator of some kind should be provided on the switchboard and also at the mechanism. It is often desirable to know the voltage on the high-tension side of transformer banks and costly high-voltage potential transformers may be avoided if the voltage is measured on the low-tension side (compensating for drop through the transformer). Since, in the case of tap changing, the actual ratio of transformation is varied, it is necessary to also provide some device such as a small auto-transformer the ratio of which is correspondingly varied by a dial-switch operated from the mechanism. Such a device has been operating satisfactorily in the installation at Chester Station, already described.

In providing the usual differential relay protection, this change in the ratio of transformation must be provided for either by the use of an auto-transformer the ratio of which is varied with that of the main unit or by designing the turns of the relay for the mid position of the tap changer and setting the relay sufficiently high to prevent its operation on through short circuits.

Any failure of the mechanism that may damage the transformer winding thermally should be guarded against, but should one occur, it should be indicated by an alarm. In the case of the double-winding transformers at Chester this is accomplished by relays connected differentially between the two windings which operate when either winding is carrying all the load or when the two windings are in parallel on different taps. These relays in turn operate a definite time limit relay which at the end of one minute gives an alarm.

Conclusion

The author believes that there is a real field for transformer tap changing under load and that this will continue to increase with the expansion of interconnection and superpower. Development will be stimulated as its possibilities are more widely recognized and appreciated.

Acknowledgment is made of the assistance of Messrs. R. A. Hentz, Raymond Bailey, B. E. Hagy and Jos. I. Tabakin, of The Philadelphia Electric Company, in the preparation of this paper.

Discussion

B. G. Jamieson: On the system of the Edison Company in Chicago, there has been built up within the last four years, a 33,000-volt nominal voltage, 60-cycle system of about 360,000 kilowatts. The transformers were generally equipped with the tap-changing system described, the earlier forms with the double winding, and in other cases, a system which involves the step switching scheme with a connected reactor giving the same effect that the last author described.

The operations have been about forty in number, and from the standpoint of the effect on the load, nothing more could have been desired. Changes were made promptly, and we found that with approximately two and a half per cent steps, we got all desired smoothness. It came to our notice, however, very early in the development of these schemes that the complication added to the transformers indicated the desirability of getting the maximum amount of this extra system outside the tank. We are not yet able to take a final position in the matter of requiring this development further than to call to the attention of engineers the many extraordinary things that happen in transformers and the undesirability of having minor troubles or difficulties augmented by the proximity or presence of supplementary internal devices of this character.

As to the schemes of regulation involving the regulator system, this refinement will, I believe, be necessary only in exceptional cases, but where we have used the double winding we are prepared to add the regulator when necessary.

In our committee work in the N. E. L. A., some discussion has arisen regarding the nomenclature, and I must say that there was not complete agreement on this score. The name tap changer and the name *ratio adjustor* were offered for consideration, but the choice seems to be still open. Generally speaking, one associates with the term tap changer a minor piece of equipment and with the term *ratio adjustor* a somewhat more comprehensive system. It would appear from what has been seen that perhaps the term *ratio adjustor* has a little more exact significance.

H. W. Smith: These papers point out the need for some scheme of regulating transformer voltages under load, and mention one solution. I wish to point out, however, that other schemes have been used, and in considering any given problem, these alternatives should be investigated. A tap-changing scheme has been used in which the taps have been brought out of the transformer and changed by oil circuit breakers using an auto-transformer in switching from tap to tap. This also provides a method by which additional voltage points can be obtained half-way between the taps so that, for instance, with five taps, nine voltage steps can be obtained. Four 15,000-kv-a., three-phase transformers using this scheme are in operation in Chicago. This scheme has also been used in connection with air-blast transformers supplying converters. The transformers having a primary voltage of 11,000 and standard contactors were used for changing the taps. This equipment has been in use in San Francisco for several years with satisfactory operation.

Another scheme which is particularly applicable to an interconnection between high-voltage systems, is that of using a combination of transformer with an induction regulator to bridge between the taps of the transformer. This equipment is termed a "step induction regulator." An interesting equipment involving this scheme and rated at 15,000 kv-a. has been used to interconnect the Tacoma Municipal System with the Seattle Municipal System. The Tacoma voltage is 50,000, three-phase, delta-connected, while the Seattle voltage is 57,000 volts, three-phase, star-connected. With the equipment, a voltage variation of 48,000 to 64,000 on the star side is provided. This installation has been described in an article "The Tacoma-Seattle Power Exchange Line," by R. E. Towne in the *Electric Journal* of June 1923. This same scheme has been applied to synchronous

converters to get a large range in voltage for reenergizing a d-c. Edison system when a shut-down occurs.

Another scheme which has been used is that of opening the delta on a bank of transformers, switching the taps on one transformer, then replacing it and doing the same with the remaining transformers. This has been applied to a bank of transformers supplying synchronous converters for obtaining low voltages to reenergize a dead Edison system.

There will be a large field for tap changing on transmission systems supplying scattered areas where the tap-changing equipment must be relatively inexpensive. An experimental installation is being supplied to one property which will use air-break switches with the ordinary type of tap changer. The operator will disconnect one transformer by means of air-break switches, operate the tap changer, close the disconnect switches again, and then carry on this same procedure in the case of the remaining two transformers. The scheme, of course, relies upon the operator to perform the functions in the correct rotation.

A. H. Kehoe: It is important from the operating standpoint that this equipment, which becomes a controlling element in our large capacity lines, should be specified and manufactured in a manner to make it reliable without constant inspection. On the other hand, all operators of such equipment should have regular inspections made until simplified designs have been developed which demonstrate in practise that such inspections are not required.

H. R. Wilson: I believe that we are indebted to C. R. Oliver for inaugurating the idea of changing transformer taps under load by using the scheme of parallel windings. About ten years ago, he installed at Pawtucket, two 18,625-kv-a. three-phase transformers operating in parallel. Each transformer was provided with *ratio adjustors*, and high- and low-tension oil circuit breakers. Tap changes were accomplished by opening the breakers of one bank, changing taps by means of the adjusters, and closing the breakers and the operation being repeated on the second bank.

As regards using disconnecting switches, The Consumers Power Company has had in operation for several years, a scheme whereby switches connected the taps in each leg of the delta so that the taps could be changed in one leg at a time; the transformer operating in open delta during the period the taps were being changed.

Universal Type Motors

BY L. C. PACKER[1]

Associate, A. I. E. E.

Synopsis.—*Heretofore the subject of universal motors has not received very much publicity but the field for these motors has been increasing so rapidly that a great deal more attention is now being given to them.*

The paper endeavors to bring out points of general interest rather than going into the fundamental design and other details.

The term "universal" as applied to this type of motor is defined, together with a description of the operating characteristics in general.

There are two types of universal motors; namely, compensated and non-compensated, both of which are described as to general design, construction and applications.

The question of ratings and limitations of the universal features o both types of motors brings out some interesting points.

Commutation and mechanical balance are questions demanding a great deal of attention due to the comparatively high speeds at which these motors usually operate.

Some of the applications best suited to the universal motor are described, showing the possibilities of this type of motor when properly designed, manufactured and applied.

* * * * *

THE term "universal" is applied to certain small series-wound motors, the performance of which is almost identical when operated on either alternating or direct current. (Alternating current is used in this paper to mean frequencies of 60 cycles and lower.) Universal motors have been in commercial use for fifteen or more years and are still most popular in the two applications in which they were first used in quantities; namely, portable drill and vacuum cleaner drive. However, with improvement in the motors and increase in the number of small motor-driven appliances, a number of new fields for the application of these motors are being found. If a manufacturer's product is sole over a large area, it is obviously to his advantagd to use a motor which will operate equally well on either alternating or direct current, and only the voltage of the circuit need be considered. This advantage has led some appliance manufacturers to modify their machines so that the operating characteristics of universal motors will be satisfactory for driving them.

All of the universal motors on the market are series wound and their performance characteristics are very much like those of the usual type, d-c. series motor. The no-load speed is quite high but seldom high enough to damage the motor, as is the case with larger d-c. series motors. When a load is placed on the motor, the speed decreases and continues to decrease as the load is increased. Although universal motors of several types of construction are manufactured, they all have the varying speed characteristic just mentioned.

Due to the difficulty in obtaining like performance on alternating and direct current from motors designed for operation at low speeds, most universal motors are designed for operation at speeds of 3500 rev. per min. and higher. Motors operating at load speed of 8000 rev. per min. to 10,000 rev. per min. are common. Practically all portable vacuum cleaner motors come within this range. Working speeds above 10,000 rev. per min. are not so common, due to there being few applications where such speeds are desirable and to the manufacturing difficulties in producing motors which will run at such speeds. Small stationary vacuum cleaners, truck-type vacuum cleaners and the larger size of portable tools have motors with operating speeds of 3500 rev. per min. to possibly 8000 rev. per min.

Ratings from zero h. p. to one h. p. are being manufactured. However, it is not possible to obtain the very low h. p. ratings at the lower speeds and get the same performance when operating over the whole range of frequencies from direct current to 60 cycles. In other words, the motors designed for very low horse powers and the lower speeds cease to be universal, for although they will operate on either alternating or direct current their speed for a given load varies over too wide a range with changes in the frequency of the supply circuit.

It is not possible to set a definite limit of difference in speed for a given load, inside of which a motor may be said to be universal and outside of which it would not be designated as universal when motors are operated on direct current or on various frequencies. That is, it cannot be said that when operating at rated load, the variation in speed must not be more than 10 per cent, 15 per cent or 20 per cent, if the supply circuit is changed from 60 cycles to any lower frequency or to direct current. In the usual universal motor applications, such speed variations will probably be found. However, in any application, the motor is considered as being "universal" if it will operate the apparatus satisfactorily when the power supply is varied over the entire range of commercial frequency with rated voltage applied in each case.

Vacuum cleaners and portable drills are two examples of very satisfactory applications for universal motors. In both of these applications, the variation in performance when operating on varying frequencies, can easily be kept within the required limits and it is desirable to have the speed vary with the load. If a vacuum cleaner is used under conditions which decrease the volume of air handled, the load on the motor is decreased and the speed increases. The increase in speed increases the vacuum, causing the cleaner to handle more air than it would if driven by a constant speed motor. Portable drills are almost ideal applications for universal

Presented at the Regional Meeting of the A. I. E. E., Swampscott, Mass., May 7-9, 1925.

motors. The cutting speed is automatically adjusted by the load, since the smaller the size of the drill being used the lighter the load and consequently the higher the speed, and vice versa, when larger drills are used.

The same conditions exist when universal motors are used in small pipe-threading machines and in certain other metal and woodworking machines.

The speed of a universal motor can be adjusted by connecting a resistance of proper value, in series with the motor. Advantage is taken of this characteristic in such applications as motor-driven sewing machines, where it is necessary to operate the motor over a wide range of speed. In such applications adjustable resistances are used and the speed is varied at will.

When considering the use of universal motors to drive any apparatus, the following characteristics of the motor should be considered:

Change in speed with change of load

Change in speed with change in frequency of power supply

Change in speed due to change in applied voltage

The last item has not before been referred to except indirectly in connection with the use of series resistance to adjust the speed. However, a larger percentage of all small motors is connected to lighting circuits and the voltage conditions are not always of the best. This condition must be kept in mind when determining the proper motor to use for any application regardless of type. In general, the speed of a universal motor varies directly as the voltage.

The starting torque of universal motors is usually much more than that required and in most applications does not have to be considered.

There are some motor applications where the motor runs all of the time and the load is connected and disconnected by means of a clutch. On such applications, if the operating characteristics of a universal motor are satisfactory while the load is applied but the no-load

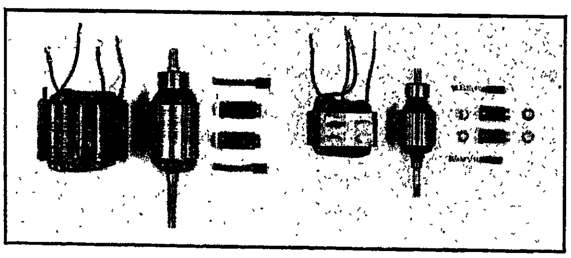

Fig. 1

speed is too high, it is sometimes possible to arrange to have a series resistance connected in the line during the time the clutch is in the position to release the load. The value of this resistance can be made such as to give the desired no-load speed.

Universal motors are applied with two kinds of construction—(1) concentrated-pole, non-compensated and (2) distributed-field, compensated. Most motors of low h-p. rating are of the concentrated-pole, non-compensated type, while those of the higher ratings are of the distributed-field, compensated type. The dividing line is somewhere near 1/4 h. p., but the type of motor to be used is determined by the severity of the service and the performance required. All of the motors have wound armatures of the same construction as the ordinary d-c. motor.

The concentrated-pole, non-compensated motor is exactly the same in construction as a d-c. motor except

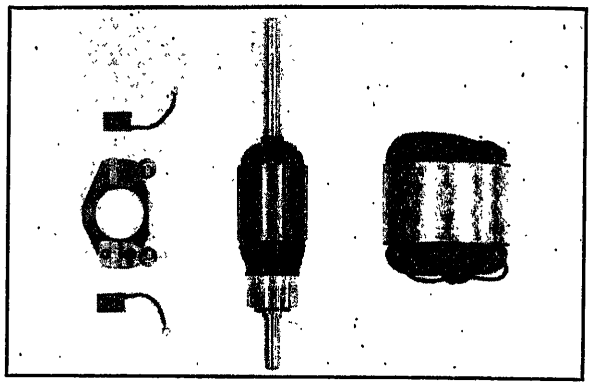

Fig. 2

that the complete magnetic path is made up of laminations. The laminated stator is made necessary because the magnetic field is alternating when the motor is operating on alternating current. The stator laminations are punched with the poles and the yoke in one piece. This makes a very simple construction and one which is very satisfactory to the appliance manufacturers who buy the motor parts as shown in Fig. 1, and assemble them in their apparatus.

The compensated type of motor has stator laminations of the same shape as those in an induction motor. These motors have stator windings of one of two different types. The parts of a compensated motor, as they are supplied to be built into the apparatus, are shown in Fig. 2.

The question might naturally arise as to why it is desirable or necessary to have the non-compensated and the compensated motors and why the ratings are usually limited to fractional horse powers and high speeds. The non-compensated motor is more simple and less expensive than the compensated motor and would be used exclusively over the entire range of ratings if its performance were as good as that of the compensated motor. However, as before stated, the non-compensated motor is used for the higher speeds and lower horse power ratings only. Figs. 3 and 4 show the speed-torque curves for a compensated motor and a non-compensated motor, respectively. It will be noted in Fig. 3 that although the rated speed is relatively low for a universal motor, the speed-torque curves for various frequencies lie very close together up to 50 per cent above the rated torque load. In Fig. 4, the performance of a much higher speed, non-compensated motor is shown. For most universal motor applica-

tions, the variation in speed at rated loads as shown on this curve is satisfactory. However, the speed curves separate rapidly above full load. If this motor had been designed for lower speed, the tendency of the speed-torque curves to separate would have been more pronounced. The chief cause of difficulty in keeping the speeds the same is the reactance voltage which exists when the motors are operated on alternating current. Most of this reactance voltage is produced in the field windings by the main working field. However, in the non-compensated motor some of it is produced in the armature winding by the field pro-

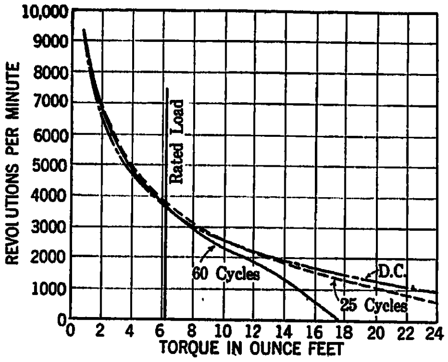

FIG. 3—UNIVERSAL MOTOR COMPENSATED ¼ H. P.—3400 REV. PER MIN.

duced by the armature ampere-turns. The true working voltage is obtained by subtracting the reactance voltage vectorially from the line voltage. If the reactance is high, the performance at a given load will be the same as though there were no reactance

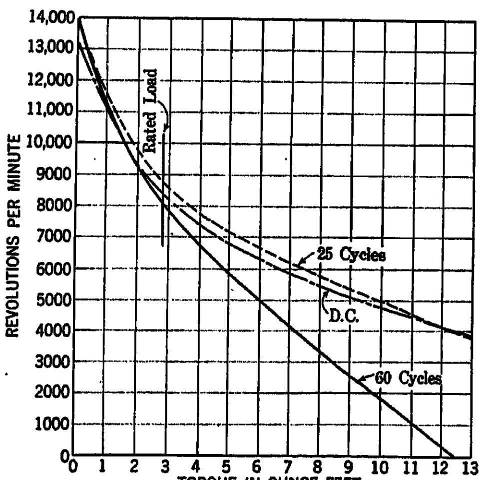

FIG. 4—UNIVERSAL MOTOR NON-COMPENSATED ¼ H. P. 800 REV. PER MIN.

voltage and the applied voltage had been reduced with consequent reduction in speed.

The reactance voltage varies with the frequency and is almost entirely responsible for the difference in performance on the different frequencies of alternating current. However, the difference in performance, when operating on alternating current and when on direct current, is caused not only by reactance voltage but also by the difference in the amount of flux produced by a given value of direct current and by the same value of alternating current. Due to the saturation of the iron in the magnetic path at the time of the maximum value of the alternating-current wave, the alternating current does not produce an effective value of flux equal to that produced by an equal value of direct current. While the reactance voltage reduces the speed, the reduced flux on alternating current increases the speed. The reactance voltage varies with the frequency, but the flux for a given value of alternating current remains constant, regardless of the frequency. When the motor is operated on low frequency the effect of reactance is almost negligible, while the reduction in flux is just as high as for the higher frequencies. The result is that on very low frequencies the speed is always higher than when the motor is operated on direct current. It is even possible to have conditions such that the speed on 60 cycles is higher than that on direct current. However, the latter condition can seldom be obtained in a motor design which is satisfactory in other respects.

It is now apparent that, to get like performance on alternating and direct current, the reactance voltage must be low and the difference between the flux on direct current and alternating current must be decreased wherever possible. The difference in magnetic flux produced by a given value of direct current and that produced by an equal value of alternating current, can be changed only slightly by changes in the material used or in the design of the parts. The reactance voltage can be reduced or increased within certain limits by changes in design. As mentioned before, the major part of the reactance voltage is produced by the field flux passing through the field winding. By keeping the product of the field turns times the flux to a low value, the reactance can be kept proportionally low. This results in what is usually termed a "weak field" motor. Now a weak field in an ordinary d-c. motor permits the field to be distorted by the ampere-turns in the armature, resulting in a tendency towards poor commutation and greater changes in speed with a given change in load. Identical conditions exist in a concentrated pole, non-compensated, universal motor. However, it is necessary to keep the reactance voltage low to prevent the speeds from becoming too low on the higher a-c. frequencies. Within a certain range of speed and h-p. ratings, the reactance voltage can be made low enough to keep the speed variation within reasonable limits and at the same time secure satisfactory performance from the motor. Much has been done in the matter of improving the commutation of weak field motors by improvement in the grades of carbons and by better motor design. When, in a desired rating, the horse power is too high or the speed too low to obtain satisfactory operation with a non-compensated motor a compensated motor is used.

In the compensated motor there is a series winding having a magnetizing force equal and opposite to the magnetizing force of the ampere-turns in the armature. This tends to eliminate field distortion and the resulting bad commutation. When the field distortion has been eliminated, a very weak field can be used with a resultant decrease in reactance voltage and the corresponding decrease in variation in speed for change in frequency. Due to mechanical reasons, it is impossible to distribute the compensated windings so as to exactly compensate for the ampere-turns in the armature. It is this lack of exact compensation which limits the horse power and speed to be obtained in the compensated type of universal motor.

Two types of stator windings are used in the compensated motor: In one type, two distinct field windings are employed. The compensating winding, which has just been referred to, is equal and opposite to the effective ampere-turns in the armature and is distributed to correspond to the armature winding. The main field winding is located 90 electrical degrees from the compensating winding and produces the working field. This winding usually occupies just two slots per pole. In the other type of field winding but one distributed winding is used. By shifting the brushes to the proper position, the armature ampere-turns are opposed by a certain portion of the field ampere-turns and the remaining portion of the field ampere-turns produce the working field.

When the two-winding type of stator winding is used, the brushes are located on the neutral with reference to the main field winding. This permits the direction of rotation to be reversed by reversing the main field. When assembling this type of motor, the brushes can easily be set in the proper position by applying alternating current to the compensating winding and operating the motor as a repulsion motor by short-circuiting the brushes. When the brushes are so set that the armature field is directly opposite the compensating field there will be no tendency in the armature to rotate. When the brushes are moved slightly from this position, the armature will turn in the direction in which the brushes have been moved. The brushes are in the correct position when the armature field is directly opposite the compensating field.

When designing a motor using the one-winding type of stator winding, if certain limiting proportions of field and armature turns are adhered to, it is possible to get exactly the same conditions as to compensation and main field as is obtained when using the two-winding type of stator winding. However, due to the restrictions in regard to relative strength of armature and field, it is difficult to get complete compensation for certain ratings. The fact that the brushes are located off of the neutral of the field winding makes it necessary, in order to get compensation, to shift the brushes when the direction is changed. This makes this type of motor unsatisfactory for reversing service.

The two most difficult problems in the manufacture of these high-speed motors, is that of obtaining good commutation and good mechanical balance. In addition to these, it is necessary to have all parts of the armature well made so that they will withstand the larger centrifugal force which is present when the motor is operating at the high speed to which it will be subjected.

Aside from the usual commutating conditions which are encountered in the ordinary d-c. motor, there is a transformer voltage generated in the short-circuited coil by the alternating main field flux. This transformer voltage is one of the chief causes of commutation trouble, and poor mechanical balance causes sparking at the commutator due to the inability of the brushes to make good contact with the commutator when the armature is vibrating at high frequency. In addition to this it will be realized that, in motors running at speeds around 10,000 rev. per min., the time permitted for the current to reverse in the coil while it is being commutated, is very short. In an ordinary vacuum-cleaner motor, this reversal of current in the coil being commutated must be accomplished in one-half of 1/1000 of a second. The fact that the coil is short-circuited for such a short time determines, to a certain extent, the amount of short-circuit current which exists in the coil.

When considering the mechanical balance, the unusual speed of these motors must be kept in mind. Referring again to the ordinary vacuum-cleaner motor, we find that the centrifugal force acting on an object at the surface of the armature when the motor is operating at normal speed, is approximately two thousand times the weight of the object. As an example, if a piece of No. 20 wire, 1½ in. long, were placed at the top of the armature slot, the centrifugal force acting on the wire would be equal to the total weight of the armature. With this in mind, it is quite obvious that the weights in the armature must be thoroughly balanced or there will be excessive vibration and excessive pressure on the bearings. The usual static balance of armatures improves any unbalance that may exist due to the uneven distribution of the windings or due to there being a slightly heavier coat of armature insulating varnish in one place than in another. However, if when balancing an armature statically the correction of weight is made at the end of the armature opposite that at which the unbalance exists, there is still a very bad condition of dynamic unbalance which will be destructive to bearings and brushes and cause the motor and driven appliance to be noisy. This condition can be eliminated only by very careful dynamic balancing.

The results which may be obtained by using extreme care in designing and manufacturing are shown by tests made on a particular vacuum-cleaner motor. This motor was so designed, electrically, as to get the best commutating conditions, and accurate dynamic balance was obtained. At the end of a 5000-hour endurance run, the indicated total brush life for one set of brushes was 9000 to 10,000 hours. As stated, this motor was very carefully built and such motors could not be produced commercially due to the increased manufacturing

cost. However, the tests on this motor did show the results of careful design and dynamic balance. There is no need in vacuum-cleaner service for a motor such as the one described. If a vacuum cleaner were used continuously two hours per week, which is probably the average, the total hours run per year would be approximately one hundred and the total life of one set of brushes would be 100 years. It is quite obvious that it is not necessary to go to the expense of building a motor of this quality when it is impossible for the driven appliance to remain in service such a great length of time. However, it must be remembered that the brush

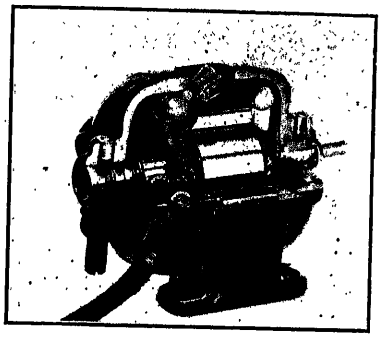

FIG. 5

life which has ordinarily been obtained in vacuum-cleaner motors has not been equal to the life of the vacuum cleaner. The vacuum cleaners being built today are of better quality than those of several years ago and are standing up better, with the result that better motors must be supplied. It is such tests as the one just mentioned which are pointing the way to better motors and are actually bringing about results in the commercial motors now being supplied for vacuum-cleaner service.

Vacuum cleaners and portable drills have already been mentioned as very satisfactory applications for universal motors. In addition to these, there are many other applications in which universal motors are being used. In many cases, the motor parts are supplied to the appliance manufacturer and built into his appliance. In other cases, complete motors, such as the one of which a part cross section view is shown in Fig. 5, are used to drive the appliances. Some of the devices to which these motors have been applied are advertising machines, portable, motion-picture machines, dish washers, hair clippers, sewing machines, drink-mixing machines, small ventilating fans, hair driers, pipe threaders, small grinders and small wood shapers and routers. This is a rather varied list of applications and the variety and number of applications are growing daily.

Discussion

W. L. Smith: I wish to emphasize the fact that on these little motors there is one thing that I believe is very important and that is that the greatest care should be given to perfection in insulation.

H. W. Hills: We can't blame the insulation for all trouble, for, because of the way these machines are used, the insulation becomes oily and hard and even the best insulation, after being subjected to such conditions, will eventually fail. The only thing to do is to provide a good ground on the machine itself. This can easily be done by incorporating a third wire for a ground wire along with the two supply wires. This ground wire can be attached to ground while the machine is in operation.

L. C. Packer: Recently the underwriters have specified insulated brushholder screws for commutator motors. That is a point that the appliance manufacturers have stressed a good bit, and the underwriters have specified certain design points that must be adhered to. Insulation of brush-holder screws is one very important item, especially in vacuum-cleaner and sewing-machine motors.

There is another point about the insulation. Most of the manufacturers of this type of motor test to ground at 1200 or 1400 volts, on a standard 110-volt motor. The motor itself is just as well insulated as higher types of motors. Most of the grounds are caused during the assembly of parts by the appliance manufacturers in grounding the connections against the frame: sometimes the insulation is pinched off the leads in assembly.

C. A. Adams: I should like to ask Mr. Packer how he can get substantially 100 per cent power factor.

L. C. Packer: In the compensated motor the field is usually fairly weak and its reactance voltage comparatively low; that is, from 10 to 20 volts on 25 cycles at rated load. The equivalent values on 60 cycles are 24 to 48 volts. The average motor, of course, will have about the average value between these figures. For illustration in an average design the reactance voltage due to the field is 15 volts on 25 cycles, and 36 volts on 60 cycles. Then suppose we work the motor over a range of load such that the value of reactance voltage would be from 10 to 20 on 25 cycles, and from 24 to 48 on 60 cycles. Since the reactance voltage varies directly with the flux, these values represent considerable change in load.

Since the true working voltage is the vectorial difference between the line and reactance voltages and since the power factor is equal to the true working volts divided by the line volts, it can be seen that it takes quite a material change in reactance voltage to show much change in power factor and it also takes a comparatively large amount of reactance voltage to drop the power factor an appreciable amount below unity.

As a rule, the power factor of the non-compensated type of motor is much lower than that of the compensated type. There is no compensating field; therefore, it is necessary to use as strong a main field as possible to keep down the distortion. This of course results in higher reactance voltage and lower power factor, which varies with different designs. There may be cases where the field may be comparatively weak, resulting in very good power factor, and again in cases of very low horse power rating at low speeds, the power factor may be as low as 70 per cent.

The reactance voltage in the armature is small compared with the reactance of the field of the non-compensated motor, and although larger in proportion to the main field in the compensated motor, in neither type has it much effect upon the ultimate result. For commutation reasons, however, it should be kept as low as possible.

In going through the complete design you would, of course, include all of the reactance voltages, even though some of them were negligible.

The air-gap in these motors is about 0.015 in. to 0.020 in. (single air-gap). The very small motors of cheaper design have from 0.020-in. to 0.025-in. and as much as 0.032-in. single air-gap, due to the fact that the appliances using them, in most cases, must be low in price, thus requiring cheap motors. The large air-gap permits of cheaper bearing design and lowers manufacturing costs.

Oil-Filled Terminals for High-Voltage Cables

BY EUGENE D. EBY[1]

Associate, A. I. E. E.

Synopsis.—Underground cables for transmission of power at 33,000 ft. and above have only recently come into use in America, or received much attention here. In connection with such cables suitable terminals are necessary and present an important problem in high-voltage design.

A marked tendency is noted toward the oil-filling of cable joints; terminal conditions make this procedure both logical and desirable.

Dielectric strength must first be specified, and should exceed that of the cable; flashover should occur without puncture; lightning voltages should be guarded against in the design. Proper d-c. tests are still undetermined for various combinations of solid and liquid dielectrics, and a rigid practise can not yet be established with assurance. At present, high-voltage cable lines are intended for a-c. operation, and safety factors should be determined for that kind of service. High-voltage d-c. operation may come into practise later, and research in d-c. testing should be pushed.

Standard ratings of terminals are proposed, corresponding to the accepted standard ratings for other high voltage apparatus. Consistency with other terminal insulation, such as apparatus bushings and line insulators, is desirable. Cable insulation may eventually experience similar standardization. The method of rating single-conductor and three-conductor cables should be harmonized, and both based on operating-line voltage.

Four typical designs of high-voltage cable terminals are described representing a carefully worked out and effective solution of the problem. These are (a) 37,000-volt three-conductor; (b) 50,000-volt single-conductor; (c) 73,000-volt, single-conductor; and (d). 110,000-volt single-conductor. Flashover tests and time tests, corresponding to breakdown and endurance tests on equivalent cables, are reported to illustrate the ability of the terminals to withstand factory and field tests on the cables, and to show the ample factors of safety under operating conditions. Results of an experimental installation of the 110,000-volt terminals demonstrate the safety of the design, predicted from calculations and confirmed by laboratory tests.

For temporary testing purposes these oil-filled terminals are most convenient and economical, and contribute to the uniformity and reliability of the results in cable testing, which are the factors of greatest importance.

Oil-Filled Terminals for High-Voltage Cables

WITH the introduction of lead-encased cables into the field of high-voltage power transmission, there has arisen the necessity of providing, at the ends of these cable lines, suitable terminals or end-bells, capable of maintaining safe connection between the cable and the apparatus or the overhead line with which it is to operate. Three-conductor, 33,000-volt cables have been used in this country for only a few years, and the number of such installations is still small. Operation of single-conductor cable lines at higher voltages is still more recent. Interest in high-voltage power transmission over cable lines has been rapidly increasing because of the large blocks of power which it is necessary to deliver through congested urban sections, and which cannot be handled on overhead lines. At present there is active interest in cable for 132,000-volt operation and a reasonable prospect of attaining this rating in the not-far-distant future. This rapid increase in cable voltage has led to an intensive effort in the development of the necessary joints and terminals for these higher voltage cables. It is the purpose of this paper to present some of the results of this work as related to the problem of terminals.

Tendency Toward Oil Filling

There is evident in the development of high-tension cable joints a definite tendency toward oil filling, *i. e.*, complete filling of the enclosing shell with a fluid oil under sufficient pressure from auxiliary reservoirs to eliminate all voids or pockets within the joint. The use of hard compounds is accompanied with certain well-known and serious disadvantages, among them being the shrinkage upon cooling which leaves unfilled cavities, separation from the surfaces of the insulating materials thus inviting local breakdown, and incomplete sealing of the joint against entrance of moisture through holes in the shell and the lead wipes. These disadvantages are effectively corrected by the use of a fluid filler under pressure.

The tendency toward the oil-filling of cable joints has already received expression by the substitution of softer compounds as fillers in place of the harder compounds commonly used with the lower voltage joints. Of the soft compounds petrolatum is the most common, while in one or two prominent cases a mixture of transil oil and petrolatum has been employed. Auxiliary pressure reservoirs of several types have been advocated and used to maintain complete filling of the joints. The use of these softer fillers has been fully justified by the results obtained, and these point the way to the oil-filled joint as a logical and promising solution of splicing in high-tension cable lines.

Terminal Conditions

From similar considerations the oil-filled terminal is the logical solution of the problem of insulating the ends of high-tension cables. In two prominent particulars the terminal offers a simpler problem than the joint, in that space limitations are largely removed, and the bared conductor does not have to be enclosed within grounded metal. On the other hand, the terminal presents difficulties not met with in joint design, since it combines the joint problem of insulating the cable end from the sheath by solid and liquid dielectrics, with the further problem of insulating it at the

1. Engineer High Voltage Bushing Eng. Department, General Electric Company, Pittsfield, Mass.

Presented at the Regional Meeting of District No. 1, Swampscott, Mass., May 7-9, 1925.

same time from the sheath through the air. There is also the greater temperature variation, and complete exposure to the elements. In addition to these physical differences, the location of a terminal at the junction point between underground cable and overhead line may at times impose far greater potential strains upon its insulation than most of the cable system is ever called upon to withstand. The cable terminal in general, therefore, is subject not only to those potential stresses originating or developing within the cable system, but also to those stresses occurring in the overhead system as well, including lightning. This latter source of over-voltage stress is usually far more destructive to solid insulations than to liquids. The use of oil in a cable terminal offers the best-known means of dealing with the lightning problem, at the same time contributing very effectively to the quality of the cable near the terminal by serving as an oil reservoir.

Dielectric Tests

The dielectric strength is the first feature of the design to be determined. Obviously the terminal must be able to withstand all tests applied to the cable after installation. This it might do but still be weaker than the cable. Properly, it should be *stronger* than the cable so that it will not fail at any voltage, either momentary or sustained, which the cable can withstand. By failure is meant internal breakdown. The internal strength should be greater than external flashover, the value of which should be consistent with the flashover of bushings on connected apparatus and insulators on connected lines. The desirability of flashover without puncture in the case of bushings and insulators is well established, and the same should be true of cable terminals. The terminal, therefore, should be able to withstand both the short breakdown tests and the longer time tests, it should flashover externally without internal failure at normal frequency, and it should be as nearly lightning proof as possible.

In the foregoing paragraph, alternating voltages have been in mind. Of course, where d-c. testing is employed the terminals must be able to withstand the applied d-c. voltages. Whether this means a greater strength than for a-c. testing will depend largely upon the kind of insulation and the ratio of d-c. to a-c. voltage. The proposed ratio of 2.4 is probably not far from correct for cable paper; for oil a smaller ratio exists, nearer 1.5; and for a combination of oil and paper an intermediate ratio would probably apply, expected to vary with the proportions of these materials. At present, data on the strength of various materials under high direct voltages are too meager to draw definite conclusions or establish a rigid practise. It should be remembered, however, that the terminals and cable are to operate with alternating current, and it is of first importance that they withstand a-c. potentials successfully. The difficulties of applying a-c. tests to long lines of high capacitance will encourage the use of d-c. testing equipment; and some cable lines installed at first for a-c. operation may even experience later on a conversion to d-c. operation. Research in d-c. testing must, therefore, be pushed vigorously, in order that only proper d-c. tests shall be employed. It is not unlikely that both kinds of tests will become a part of the designer's check upon his product.

Standard Ratings

In order that both manufacturer and consumer may benefit by standardization of parts and designs, standard ratings should be adopted and designs developed accordingly. It seems logical that the standard voltage ratings for high-tension apparatus should apply to cable terminals as well. This would harmonize terminal design with that of bushings, insulators, switches, metering transformers and lightning arresters. Standard ratings, as shown in the following tabulation, are already in general accepted use for these devices.

15,000	88,000
25,000	110,000
37,000	132,000
50,000	154,000
73,000	220,000

These ratings, when applied to cable terminals, should represent the practise for both *Y* and delta circuits, grounded and ungrounded, except as modified for other apparatus using terminal insulators. The cable should not be equipped with terminals of lower flashover voltage than that of the bushings of transformers, circuit breakers, and lightning arresters connected thereto.

Intermediate ratings of cable may be found necessary for economic reasons. This will not prevent the use of standard terminals, however, which is highly desirable so that their line-to-ground flashover strength shall not be inferior to other apparatus on the system. It is already generally recognized that the insulation of apparatus located at different points on a high-tension system should have a uniformly high value, even though some of the apparatus is located on a part of the system normally operating at lower voltage than another part. Cable insulation may eventually experience this same standardization.

This proposed standardization of voltage ratings of terminals for high-tension cables emphasizes the desirability of a uniform practise in applying voltage ratings to the cables themselves. Three-conductor cables are rated in terms of line-to-line voltage and their tests determined by this rating. In the case of single-conductor cables, however, it has been the practise to determine their test voltage on the basis of their working voltage between conductor and sheath. This has often resulted in the working voltage from conductor to sheath being used as an expression of the operating voltage, whereas in the case of all other apparatus the operating voltage is understood to be the voltage from line to line. It would appear rather inconsistent to rate single-conductor terminals in terms of the working voltage of

the cables, as this would give the terminal an entirely different rating from the other apparatus to which it will be connected. For example, a single conductor cable for a 50,000-volt system, although its working voltage is 28,900 volts, should have a terminal whose rating is 50,000 volts. Furthermore, if the cable and its terminals are to have their voltage ratings determined on the same basis, both would properly be assigned a rating of 50,000 volts.

Typical Designs

In light of the foregoing considerations, a careful study of the high-voltage cable terminal problem was made, which resulted in certain definite design features, including oil filling. To illustrate the principal features of these oil-filled terminals, four sizes will be described; (*a*) 37,000-volt, three-conductor, corresponding to the highest rated satisfactory three-conductor cable yet produced, viz., 33,000 volts; (*b*) 50,000-volt single-conductor, applicable to the lowest rated single cables above the present three-conductor range; (*c*) 73,000-volt, single-conductor, corresponding to the highest rated single cable in practical operation in this country; and (*d*) 110,000-volt, single-conductor, as now being used in the highest voltage experimental cable installation thus far undertaken. Terminals of this

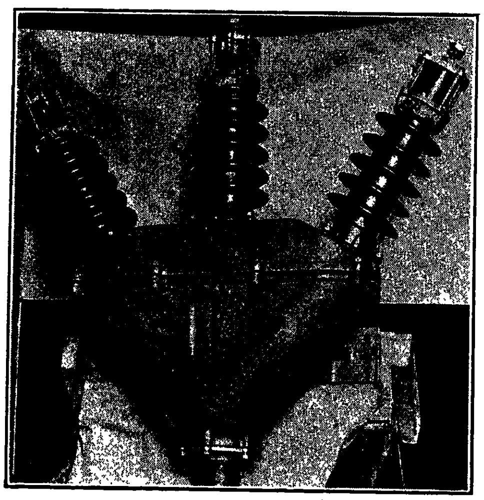

Fig. 1—37,000 Volt, Three-Conductor, Oil-Filled Terminal for Lead-Covered Cable

last rating were used also in the elaborate series of tests conducted by the Electrical Testing Laboratories of New York at the Pittsfield Works of the General Electric Company during the summer of 1924, when several manufacturers contributed samples of their best efforts toward 132,000-volt cable.

37,000-volt three-conductor terminal. This design is illustrated in Fig. 1. The three insulators are in the same plane, an arrangement which makes the tank very much larger than a triangular arrangement, and the spread of the insulators twice as great; but it lends itself readily to wall or pole mounting. Sufficient space in the tank has been allowed for transposition of conductors for phasing, without intermediate link connectors. No side opening in the tank is necessary, as the insulators and cover are removable. The insulators are of wet-process porcelain formed in one piece, with smoothly ground ends, against which bakelized cork gaskets are compressed by means of the metal clamping rings cemented around the ends of the porcelain.

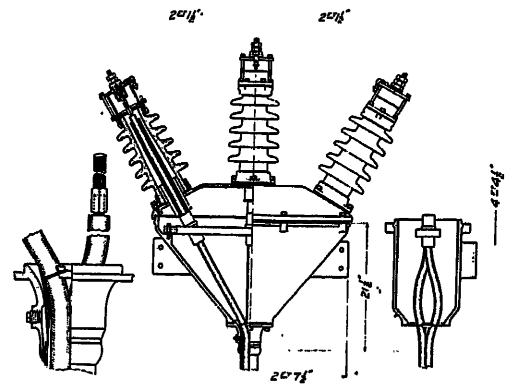

Fig. 2—Drawing Showing Construction of 37,000-Volt, Three-Conductor Oil-Filled Terminal for Lead-Covered Cable

The glass cylinder mounted above each insulator serves as a sight glass registering the level of the oil with which the terminal is filled. An auxiliary reservoir should be provided in connection with a tank of this size, to care for the expansion of the large volume of oil,—in this case about 22 gallons. The lower end of the iron tank is flanged and bolted to the brass-wiping sleeve. The joints here and from tank to cover, as well as at the ends of the porcelain insulators and glass gages, are made oil-tight with treated cork gaskets. Filling and draining is accomplished through a pipe connection to the wiping sleeve.

The internal construction is shown in Fig. 2. The cable sheath terminates just within the wiping sleeve. A thin copper band slipped under the end of the lead protects the paper from sharp edges and damage in soldering. The belt insulation is removed in steps, and the three conductors separated and spaced by a porcelain block. A reenforcement of insulating tape is built up around the outside of the three conductors to give predetermined shape and dimensions, so chosen as to secure a safe distribution of both radial and lateral stresses. Upon the lower portion of this reenforcement is wound an overlay of metal tape, soldered at the lower end to the cable sheath. The upper end of this metal overlay approaches close to the inner surface of the wiping sleeve, which then recedes from the reenforcement and the conductor insulation to meet the lower flange of the tank. The shape of these metal surfaces vitally influences the potential stresses radially and laterally, and largely controls the circumferential stress around the conductor insulation, which seems to be a large factor in so-called *crotch failures.*

Above the reenforcement, the conductors pass in gentle curves to porcelain tubes mounted in a treated wood support, and thence in straight lines to the terminal studs soldered to their bared upper ends. Fairly close fitting paper tubes preserve the concentric alinement of the conductors within the grounded metal shields in the cover. These shields present a smooth, uniform and definite surface to the electric field from the conductors, and also serve to improve the potential distribution on the external surface of the porcelain shells.

The terminal stud at the end of each conductor is locked in place by a double-threaded nut in the recessed depression of the top washer. A terminal cap engages with the stud and seals the top against moisture by an enclosed cork gasket. External connection is made through attachment to the threaded stud extending

Fig. 3—Flashover Test at 170,000 Volts from Cap-to-Cap on 37,000-Volts, Three-Conductor Oil-Filled Terminal for Lead-Covered Cable

from the top of the terminal cap. A drain cock in the top washer above each gage glass permits the escape of air during filling of the terminal with oil.

Samples of this terminal have been tested with three-phase potential to flashover at 170,000 volts, from cap to cap, as shown in Fig. 3. The flashover voltage from cap to case is about 150,000 volts. Time tests have been made at 76,000 volts for seven hours, followed by 100,000 volts for four hours. Subsequent examination failed to disclose any signs of deterioration.

While such terminals for three-conductor cables are perfectly practicable from the standpoint of design, they have some disadvantages in installation, cost, and maintenance, that encourage the use of single-conductor terminals on short single cables spliced to the three-conductor cable, a short distance from the end of the line. This practise is likely to displace the former for sound technical as well as physical reasons. With a length of single cable at the end of the line, extra insulation may be provided against the higher stresses in a connected overhead line, or, due to proximity to reflection points in connected apparatus. Single termi-

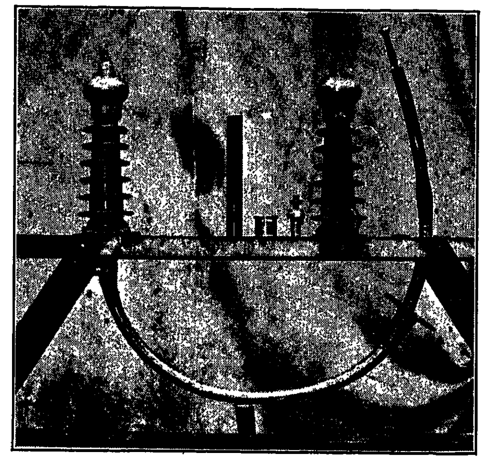

Fig. 4—50,000-Volt Single-Conductor Oil-Filled Cable Terminals with Test Piece of 20/32 In. Paper Insulated Lead-Covered Cable. Right-Hand Terminal Dismantled to Show Construction

nals which can be mounted directly underneath overhead lines of greater spacing than the three-conductor terminal would have, are much smaller and lighter in weight and hence easier to handle, and require much less oil for filling with consequently less expansion

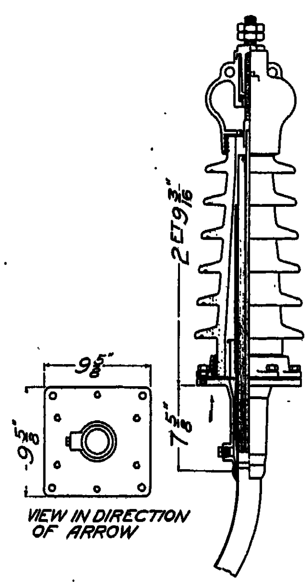

Fig. 5—Drawing Showing Construction of 50,000 Volt Single-Conductor Oil-Filled Terminal for Lead-Covered Cable

capacity in the oil reservoir. The glass gage at the top of the single type of terminal is sufficient for the expansion of the oil in the terminal itself. Single-conductor terminals for higher voltages are described in the following paragraphs. Designs for the lower voltages where

three-conductor cables are used, as at 22,000 volts and 33,000 volts, have been worked out along the same lines.

50,000-Volt Single Terminal

This design is illustrated in Fig. 4. In this case the wiping sleeve and support are in one piece, the latter taking the form of a square flange for bolting to horizontal brackets. The one-piece porcelain shell is cemented into the clamping ring at its lower end, and into the recessed cap at its upper end, with cork gaskets in the joints. The cap shown in the illustrations was designed for petrolatum-filled terminals; for oil-filled terminals a glass gage would be used to give a constantly visible indication of the oil level. The connection details at the top are similar to those described for the 37-kv. terminal.

The internal construction is shown in Fig. 5. The lead sheath terminates, as before, just within the wiping sleeve, and the copper band is inserted under the edge of the lead. A reenforcement of insulating tape is applied directly upon the cable insulation, and the lower end of this reenforcement is overlaid with a metal tape up to its greatest diameter. The reenforcement projects above the support flanges and within the grounded metal shield, with dimensions so chosen as to keep the radial and lateral stresses within safe values. A paper cylinder surrounding the conductor insulation, and spaced from it by means of narrow strips of press-board keeps the conductor straight and concentric within the ground shield, and divides the oil space into cylindrical ducts, thus increasing the insulating value of the oil, and directing its circulation.

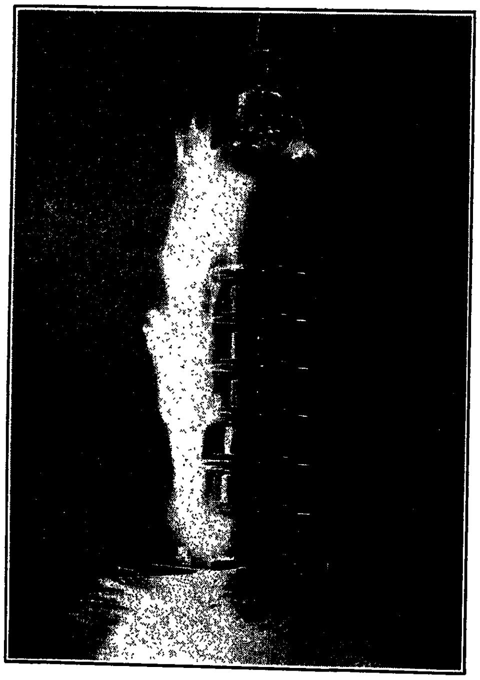

Fig. 6—Flashover Test at 190,000 Volts on a 50,000-Volt Single-Conductor Oil-Filled Terminal for Lead-Covered Cable

Samples of this terminal assembled with 500,000-cir. mils 20/32 in. paper cable[1] have received repeated flash-over tests at an average of 190,000 volts, as shown in Fig. 6, and have subsequently withstood, in consecutive order, the combination of all the several cable tests for 40,000-volt cable taken from the proposed Edison specifications, as follows:

114,000 volt for 5 min.	(breakdown test)
71,000 volt for 15 min.	(full reel test)
57,000 volt for 8 hours	(high voltage time test)

No disturbance of any kind developed during these tests, and no deterioration could be observed upon later examination.

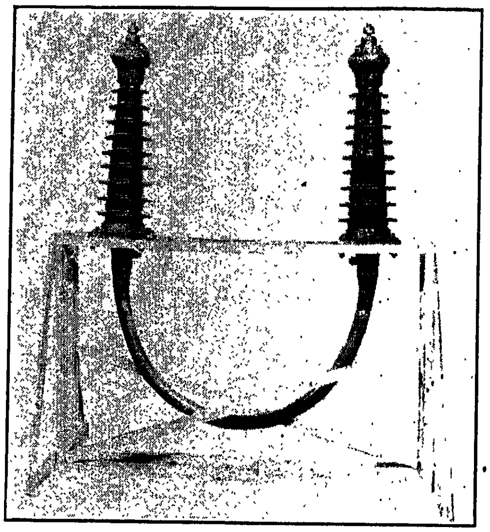

Fig. 7—Two 73,000-Volt Single-Conductor Oil-Filled Terminals for Lead-Covered Cable, Assembled with Test Piece of 66,000 Volt, 30/32-In. Paper Insulated Cable

73,000-Volt Single Terminal

In Fig. 7 there is shown the terminal developed for use with 66,000-volt cable. In external appearance and construction it closely resembles the 50,000-volt terminal just described. Internally, the only prominent difference is in the insulating of the metal ground shield by embedding its upper end in varnished cambric supported directly upon the paper cylinder. Perforations through the flange of the ground shield permit downward flow of the circulating oil in the duct outside of the cylinder. These details and the general construction are illustrated in Fig. 8.

A typical flashover test on this terminal at 290,000 volts is shown in Fig. 9. Time tests on sample terminals have been made at 200,000 volts for several hours. These terminals have also been used with great satisfaction in making time tests on samples of 30/32 in.

1. Cable of this size and insulation is being installed at Columbus, O., for operation at 40,000 volt, three-phase.

paper cables at 200,000 volts and in one instance, a test of 225,000 volts for 36 hours was made on such a cable with no terminal trouble.

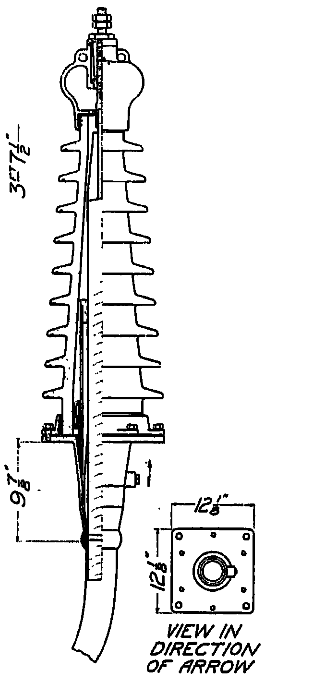

FIG. 8—DRAWING SHOWING CONSTRUCTION OF A 73,000-VOLT SINGLE-CONDUCTOR OIL-FILLED TERMINAL FOR LEAD-COVERED CABLE

110,000-VOLT SINGLE TERMINAL

The terminals shown in Figs. 10, 11 and 12 were developed first for testing of cables having 30/32

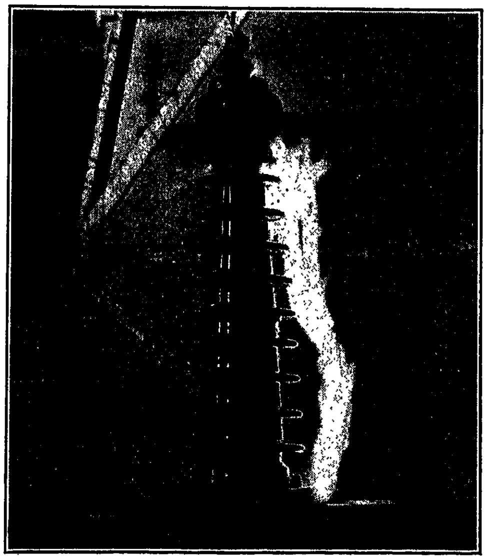

FIG. 9—FLASHOVER TEST AT 290,000 VOLTS ON A 73,000 VOLT SINGLE-CONDUCTOR OIL-FILLED TERMINAL FOR LEAD-COVERED CABLE

in. paper insulation, to determine how near an approach had been made to a safe and reliable 132,000-volt cable. For economy and convenience in assembly, the wiping sleeve is separate from the horn-shaped support casting, with a cork gasket between bolted flanges to form an oil-tight joint. A reenforcement of insulating tape encircles the cable insulation from the termination of the lead sheath to a

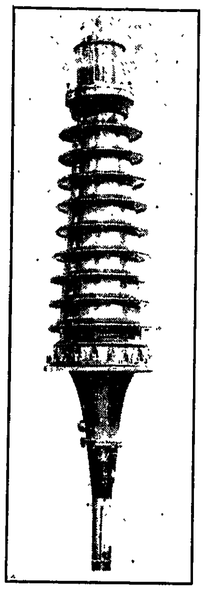

FIG. 10—110,000-VOLT SINGLE-CONDUCTOR OIL-FILLED TERMINAL FOR LEAD-COVERED CABLE

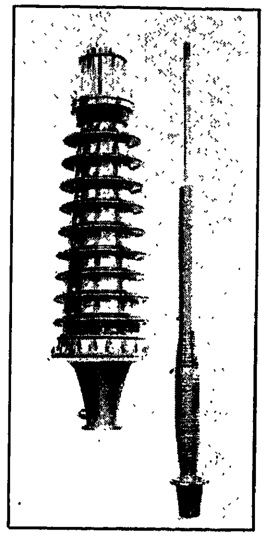

FIG. 11—110,000-VOLT SINGLE-CONDUCTOR OIL-FILLED TERMINAL FOR LEAD-COVERED CABLE, SHOWING TERMINAL REMOVED FROM CABLE, EXPOSING REENFORCEMENT OF CABLE INSULATION

point opposite the top of the ground shield. Radial and lateral stresses are controlled as before by this reenforcement, together with the configuration of the enclosing metal. A bare ground shield is possible by

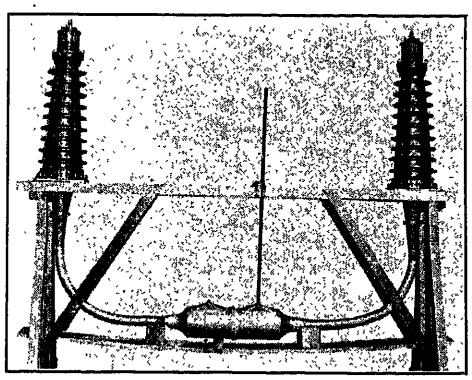

FIG. 12—TWO 110,000-VOLT SINGLE-CONDUCTOR OIL-FILLED TERMINALS FOR LEAD-COVERED CABLE, ASSEMBLED WITH TWO PIECES OF 30/32 IN. PAPER-INSULATED CABLE SPLICED WITH AN OIL-FILLED JOINT

reason of its diameter, and two paper cylinders break up the oil space into vertical ducts. In addition to the ground-shield, a terminal-shield is provided inside the upper end of the porcelain shell to improve the potential distribution along the outside surface of the porcelain.

The porcelain shell and its two clamping rings, and the glass oil-gage and the two adjacent castings are borrowed without change from the standard interchangeable oil-filled bushing for transformers, oil circuit breakers, and lightning arresters, and illustrate again the value, and convenience of standardized

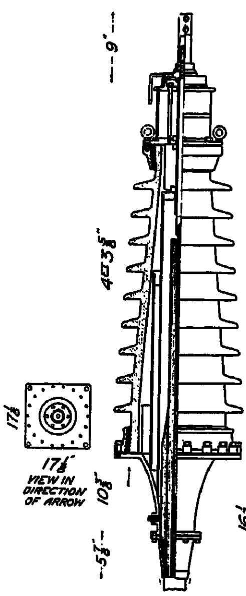

Fig. 13—Drawing Showing Construction of a 110,000-Volt Single-Conductor Oil-Filled Terminal for Lead-Covered Cable

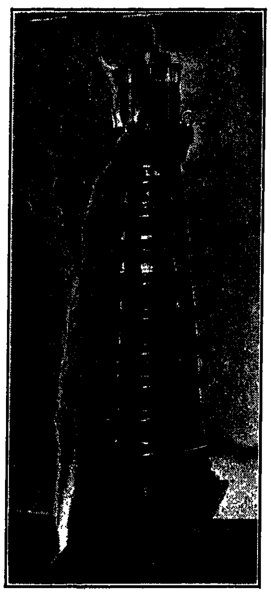

Fig. 14—Flashover Test at 400,000-Volt on a 110,000-Volt Single-Conductor Oil-Filled Terminal for Lead-Covered Cable

material. The details are shown in Fig. 13. The construction is such that, with the exception of the top connector and the wiping sleeve, this terminal may be assembled complete before installing over the prepared end of the cable. This is of great advantage in a terminal of this size and weight, which must be handled with a hoisting tackle of some kind. During installation the long stud, into which the end of the cable is soldered, is passed through the tube in the top of the terminal and secured at the proper elevation by a lock nut above the cover casting. The wiping sleeve is then raised into position, bolted to the support casting, and wiped to the lead sheath.

In the tests on the proposed 132-kv. cable, for which this terminal was first developed, it successfully withstood the breakdown tests up to its flashover voltage of 350,000 volts. These breakdown tests were made, as usual, by starting at some predetermined voltage, and increasing in 10 per cent steps at short intervals. Momentary flashover voltages of 400,000 volts, as shown on Fig. 14, have since been measured on these same terminals, when raising the voltage steadily up to the flashover point. Time tests of six hours at 275,000, and eight hours at 240,000 volts were obtained on some samples of cable, the terminals functioning with complete satisfaction. With sufficiently good cable, it is probable that time tests as high as 300,000 volts for eight hours could be made without trouble developing in these terminals.

It is of very real practical interest, also, that an experimental or trial installation of similar cable equipped with these terminals is receiving a service test on the 110,000-volt system of the Adirondack Power and Light Company, at Albany, N. Y. Fig. 15 shows the installation. This piece of cable is lying exposed on the ground with the ends extending into the terminals, which are mounted on a frame work several feet high. An auxiliary reservoir of oil maintains the oil in the terminals at the proper level, and supplies whatever absorption into the cable there may be. No current is carried by this cable, which fact, coupled with its exposure above ground, imposes a much more severe temperature variation than would be the case with a loaded cable buried in the ground. The test has been running now for four months (to Feb. 1, 1925), and the terminals have given no trouble whatever.

Terminals for Testing Purposes

It may not be inappropriate to say a word about the use of such terminals, as are here described, for temporary or testing purposes. While at low voltages it is usually sufficient to immerse the ends of the cable in

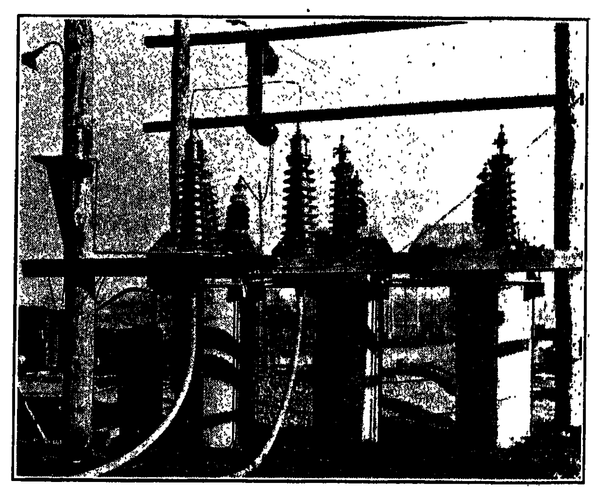

Fig. 15—Experimental 110,000 Volts Cable Undergoing Field Test at North Albany Station of Adirondack Power and Light Corporation, Equipped with 110,000-Volt Single-Conductor Oil-Filled Terminals

oil or compound, either in a tank or by means of cones of metal or paper surrounding the ends of the cable, yet at higher voltages, such as more than 200,000 volts, such temporary methods often become both inconvenient and unsatisfactory in results. The oil-filled type of porcelain terminal, as described above, lends itself most admirably to testing purposes,[2] as well as to permanent

2. See also paper on "Testing High-Tension Impregnated Paper-Insulated, Lead-Covered Cable" by Everett S. Lee, presented at the Midwinter Convention A. I. E. E., New York, Feb. 9-12, 1925.

service installations. The preparation of the cable ends for assembly with the terminal is a simple and rapid process, the terminal parts are easily and accurately adjusted to the cable, the oil filling can be done without delay, and the testing can proceed almost as soon as the filling is completed. With equal facility, the oil can be drained, the terminal removed, and a new piece of cable prepared for test with the same set of terminals. Not only does this method speed up the work, but it makes necessary only a small amount of equipment, avoids the use of large tanks of oil, and saves the loss of much temporary material wasted in some methods of testing. Of even far greater importance are the uniformity and reliability of results obtained, which factors are well nigh indispensible to the value of the test data on the cables themselves.

Discussion

A. O. Austin (by letter): There has apparently been a material improvement in potheads for high-voltage cable. There is no reason why a pothead cannot be made having any desired electrical characteristic, as the problem is not essentially different from making a high-voltage bushing.

The accompanying illustration shows a type of pothead which is quite similar to that shown in Mr. Eby's paper. This pothead was used for running tests on joints and cable for The Cleveland Electric Illuminating Company.

These potheads have an appreciable diameter at the center and form a good reservoir for oil which may be fed into the cable. With potheads of this size it was not possible to flash them over without breakdown of the cable.

In making the tests it was evident that if the cable was free from defects that high frequency had little or no effect. Since high frequency tends to magnify a defect, a much lower voltage may be used and I believe that in the end one of the most valuable cable tests will be that made at high frequency.

If the faulty sections can be eliminated it will be a comparatively easy matter to establish a high degree of reliability. In the potheads shown the stress is reduced to a very low value on the insulation surrounding the cable, as the cable projects up into the bushing. Hence, there is little or no danger of breakdown in the bushing.

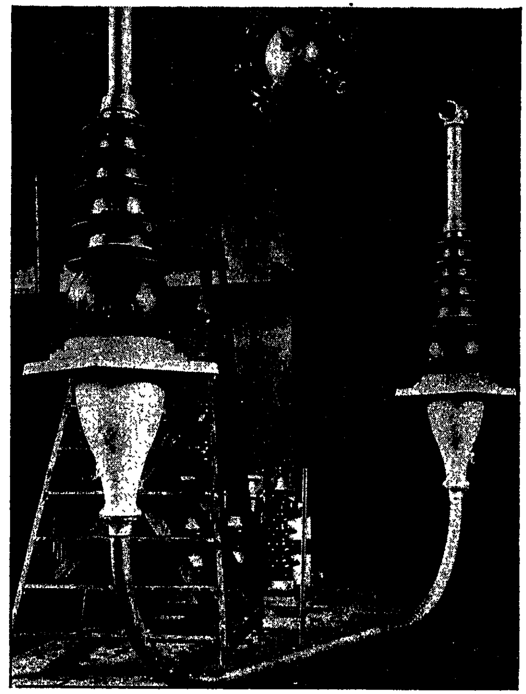

Fig. 1

The potheads were so designed that it is not necessary to use a wiped joint, as a lead sheath may be clamped to the lower end of the pothead bell using a soft gasket. With this arrangement an installation can be made in a few minutes and there is no danger of damaging the insulation from heat. Pin holes caused by the leaking of oil through the wiped joint are also avoidable.

Investigation of High-Tension Cable Joints

BY E. W. DAVIS[1] and G. J. CROWDES[1]
Member, A. I. E. E. Associate, A. I. E. E.

Synopsis.—With suitable cable, the successful operation of a high-tension cable system depends on the joints between consecutive lengths and this phase of high-voltage cable installation must receive considerable attention in the near future.

The essential properties of a good cable joint are:

1. Simplicity of design
2. High dielectric strength
3. Low dielectric loss

The dielectric strength of a joint, assuming proper care and method in assembly, depends upon the materials used. It does not necessarily follow that a joint with high dielectric strength will have low dielectric loss. Low dielectric loss is essential because of the high thermal resistance of the joint.

Data is given from experimental tests carried out on seven different types of joints, four with 25,000-volt cable, and three with 33,000-volt cable.

The joints were made up in the center of a ten foot piece of cable and dielectric loss tests made at various temperatures and voltages. Knowing the loss of the cable itself it was possible to determine the actual loss in the joint. In no case was this loss found to be lower than the loss of an equal length of cable.

The sample of cable with the joint in the center was then tested with high potential at room temperature.

THE demand for cables to operate at high voltages has resulted in much research work being done by cable manufacturers, engineering societies, and operating companies, the result of which has been a material improvement in cables for such service. Dielectric losses have been decreased, dielectric strength increased, and insulating materials developed that are not seriously affected by operating temperatures.

The constants of insulating materials are better known to-day than ever before, and cables can be designed for the normal operating voltages with greater assurance of success than would have been possible a few years ago.

There is, however, one phase of high-voltage cable installation that must receive considerable attention before satisfactory operation of high-tension cable systems can be assured. No matter how complete the design, how low the dielectric loss, or how high the dielectric strength of a cable may be, it is of little value if the joints between consecutive lengths are not equal in quality to the cable itself.

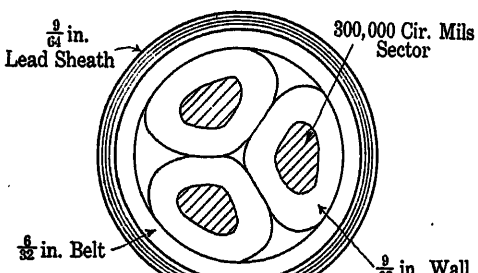

Fig. 1

Three-conductor, 300,000-cir. mil, sector conductor
9/32-in. wall paper on conductors
6/32-in. belt paper over three conductors
9/64-in. lead sheath

We believe that the essential properties of a good cable joint are as follows:

a. Simplicity of design
b. High dielectric strength
c. Low dielectric loss

In this paper, there will be discussions of the last two essential properties of a joint as just named, assuming that the *Simplicity of Design* needs little or no discussion.

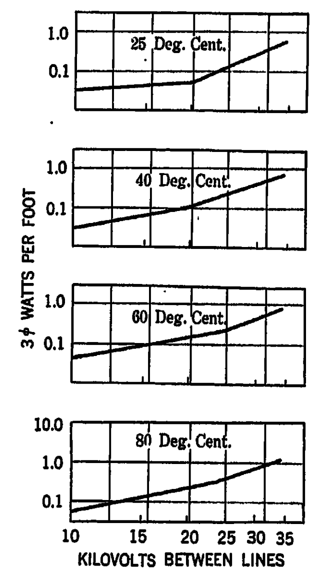

Fig. 2—Dielectric Loss—Three-Phase Watts per Foot vs. Kilovolts

Three-conductor, 300,000-cir. mil, sector, 25,000-volt cable

The dielectric strength and dielectric loss of a cable joint depend upon the insulating materials used, the method of application, and the exercising of extreme care in assembling. Low dielectric loss does not necessarily follow from the fact that a joint has high dielectric strength.

The insulating material on a joint is usually considerably thicker than on the cable itself, which results in a greater thermal resistivity for the joint. Even though the joint has a greater heat dissipating surface than the cable, it can be readily shown that temperature of the joint, with normal copper loss and dielectric loss, would

1. Simplex Wire & Cable Company, Boston, Mass.

Presented at the Regional Meeting of Dist. No. 1, Swampscott, Mass., May 7-9, 1925.

be higher than that of the cable. Hence the necessity of making the dielectric loss of a joint as low as possible.

The following experimental work was carried out on seven different types of joints for cables to operate on 25,000 volts and 33,000 volts working pressure. The first four joints were made on a 25,000-volt cable, a cross section of which is shown in Fig. 1.

voltages as the temperature increases. Assuming that ionization is due to entrapped air, this phenomenon of the ionization point may be accounted for by the fact that the dielectric strength of air increases with increase of temperature and increase of pressure.

The first joint constructed was of varnished cambric insulation with dimensions as shown in Fig. 3.

The varnished cambric used was of the best grade,

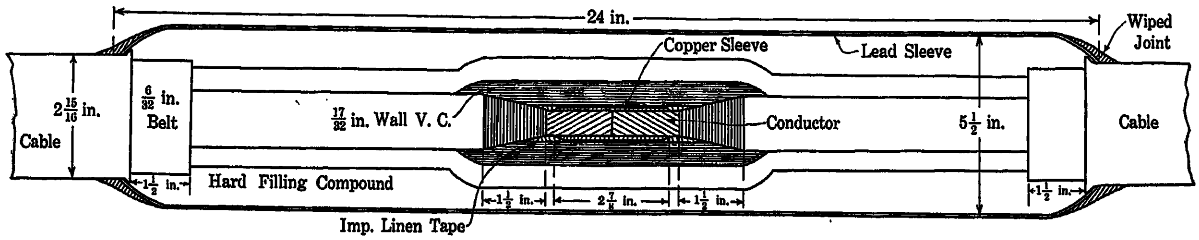

FIG. 3—CONSTRUCTION AND DIMENSIONS OF VARNISHED CAMBRIC JOINT
Three-conductor, 300,000-cir. mils. sector, 25,000-volt cable

A ten-foot length of the cable was placed in a rack, cut in two, and a joint constructed in the center of the length. The length, with the joint, was then put into a heat box and three-phase dielectric loss tests made at various temperatures and voltages. After the dielectric loss tests, the cable was removed from the heat box and dielectric strength tests made at room temperature.

From data of dielectric loss tests of the cable itself

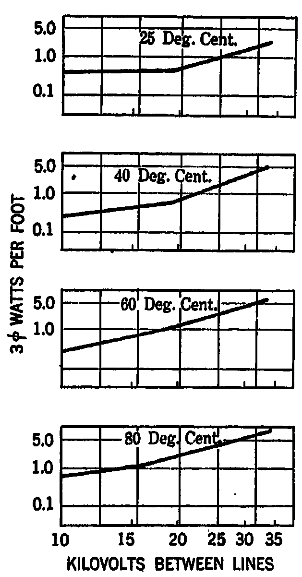

FIG. 4—DIELECTRIC LOSS—THREE-PHASE WATTS PER FOOT VS. KILOVOLTS
Varnished cambric joint—three-conductor, 300,000-cir. mils. sector, conductor 25,000-volt cable

and data of the dielectric loss tests of the cable with the joint, the dielectric loss of the joint only was calculated.

Fig. 2 shows the results of dielectric loss tests on the cable.

The loss curves plotted to logarithmic scale show a definite ionization point, and this point occurs at higher

bias cut, black cloth with an average dielectric strength of 1100 volts per mil. It may be noted in Fig. 3 that a soaked linen tape was applied over the copper sleeve. This tape was of the kind commonly used by cable splicers, boiled out in petrolatum grease. After wiping on the lead sleeve, the joint was filled with a standard high-grade filling compound, sealed, cooled, and made ready for test.

Fig. 4 shows the results of dielectric loss tests on the varnished cambric joint. The dielectric loss is expressed in watts per foot of joint for convenience in comparing the values with similar values for the cable.

It will be noted that while the ionization point of the cable occurred at from twenty to twenty-five thousand volts, (See Fig. 3), the ionization point of the joint occurred at the lower voltage of from fifteen to twenty thousand volts.

Table I gives the ratio of three-phase dielectric loss of the joint and the original cable at 25,000 volts working pressure.

TABLE I

Ratio of Three-Phase Dielectric Loss
Varnished Cambric Joint to that of Original Cable
Three-Conductor, 300,000-Cir. Mil Sector Conductor 25,000-Volt Cable

Temperature Deg. Cent.	Ratio—Three-Phase Dielectric Loss Joint to Cable
25	4/1
40	5/1
60	6.6/1
80	7/1

After the dielectric loss tests, the following dielectric strength test was made at room temperature. (Approximately 25 deg. cent.)

No. 1 Conductor vs. No. 2—No. 3 Conductor and Lead Sheath
75,000 volts—five minutes
100,000 volts—reached by 500-volt steps held 30 seconds at each step.
Return to 75,000 volts—30 minutes
No. 2 Conductor vs. No. 1—No. 3 Conductor and Lead Sheath
75,000 volts—30 minutes
No. 3 Conductor vs. No. 1—No. 2 Conductor and Lead Sheath
75,000 volts—180 minutes.

The dielectric loss of this joint is considerably lower than that of the varnished cambric joint, but still higher than that of the cable itself. The ionization point for this paper joint is higher than that of the varnished cambric joint—in fact, it occurs at practically the same voltage as for the cable.

The ratio of dielectric loss of the impregnated paper joint to that of the cable is shown in Table II.

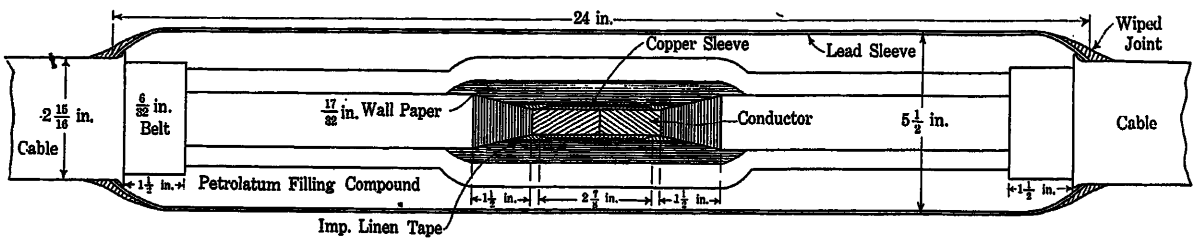

FIG. 5—CONSTRUCTION AND DIMENSIONS OF IMPREGNATED PAPER JOINT
Three-conductor, 300,000-cir. mils, sector, conductor 25,000-volt cable

The joint, after the high-voltage test, was cut open and examined, and there was no evidence of burning or charring of insulation.

The second joint tested was of practically the same dimensions as the first, with impregnated paper for insulation. The dimensions and construction were as shown in Fig. 5.

The impregnated paper used was a four mil tape,

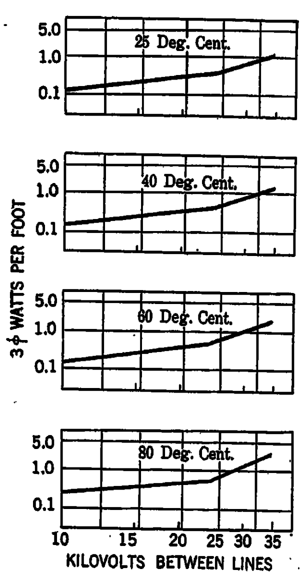

FIG. 6—DIELECTRIC LOSS—THREE-PHASE WATTS PER FOOT VS. KILOVOLTS
Impregnated-paper joint three-conductor, 300,000-cir. mil, sector, conductor 25,000-volt cable

kept immersed in cable compound in a sealed can until applied to the joint. The joint was filled with a paper cable compound. The results of dielectric loss tests on this joint are shown in Fig. 6.

TABLE II

Ratio of Three-Phase Dielectric Loss
Impregnated Paper Joint to that of the Original Cable
Three-Conductor, 300,000-Cir. Mil Sector Conductor-25,000-Volt Cable

Temperature Deg. Cent.	Ratio—Three-Phase Dielectric Loss Joint to Cable
25	2.4/1
40	2.3/1
60	2.1/1
80	2.1/1

After the dielectric loss, the following dielectric strength test was made at room temperature—Single-phase voltage.

No. 1 Conductor vs. Nos. 2-3 and Lead Sheath
75,000 volts—five minutes
100,000 volts by 5000-volt steps held 30 seconds at each step.
Return to 75,000 volts—30 minutes
No. 2 Conductor vs. Nos. 1-3 Conductor and Lead Sheath
75,000 volts—173 minutes when breakdown occurred.

Internal discharges were heard at the end of 160 minutes. These discharges grew gradually more frequent and severe until breakdown occurred.

Examination of the joint after breakdown showed the failure occurred $9\frac{3}{4}$ inches from the center of the joint. Severe burning was evident from the end of the copper sleeve along the conductor and up the insulation penciling. The paper on the joint showed burned spots at many places.

While this joint showed much less dielectric loss than the varnished cambric joint, its dielectric strength was considerably lower.

The third joint to be constructed and tested was a paper-insulated "step" joint with dimensions and construction as shown in Fig. 7.

In the "step" joint, the conductor insulation instead of being "penciled" or "scarfed" smoothly down to the conductor, was cut away in steps or terraces. In every other way the construction was similar to the previous paper joint.

The results of dielectric loss tests for this joint are shown in Fig. 8.

The dielectric losses in this joint are somewhat lower than those of the pencilled paper joint (see Fig. 6), but are still higher than those of the cable. Table III shows the ratio of the dielectric losses of the paper step joint to those of the cable.

An examination of the joint after failure showed extreme burning starting at the end of the first step and extending to the edge of the joint insulation.

The fourth and last joint for the 25,000-volt cable to be described was the so-called "Conducel" joint, a cross-section of which is shown in Fig. 9.

The conductor insulation was pencilled as in the second joint made, and the insulation over the copper sleeve built up even with the original conductor insulation. After the porcelain and conducel insulators were in place, the lead sleeve was wiped on and the joint filled with paper cable compound.

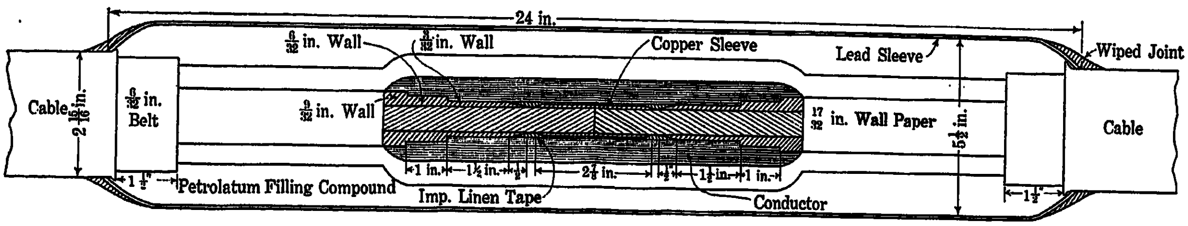

Fig. 7—Construction and Dimensions of Impregnated-Paper Step Joint
Three-conductor 300,000 cir. mil., sector conductor 25,000-volt cable

TABLE III

Ratio—Three-Phase Dielectric Loss
Impregnated-Paper Step Joint to that of the Original Cable
Three-Conductor, 300,000-Cir. Mil Sector Conductor 25,000-Volt Cable

Temperature Deg. Cent.	Ratio—Three-Phase Dielectric Loss Joint to Cable
40	1.7/1
60	1.7/1
80	1.7/1

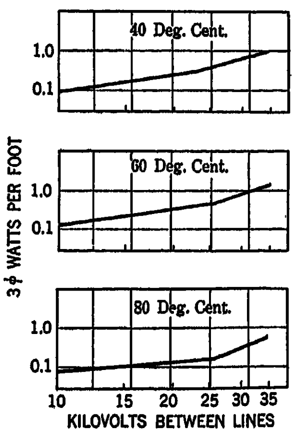

Fig. 8—Dielectric Loss—Three-Phase Watts per Foot vs. Kilovolts
Impregnated-paper "step" joint three-conductor—300,000-cir. mil, sector conductor 25,000-volt cable

After the dielectric loss test, the following dielectric strength test was made with single-phase voltage.

No. 1 Conductor vs. Nos. 2-3 and Lead Sheath
75,000 volts—five minutes
80,000 volts—30 seconds
85,000 volts—joint failure.

The results of dielectric loss tests on the Conducel joint are shown in Fig. 10.

Table IV gives the ratio of the dielectric loss in the Conducel joint to that of the original cable.

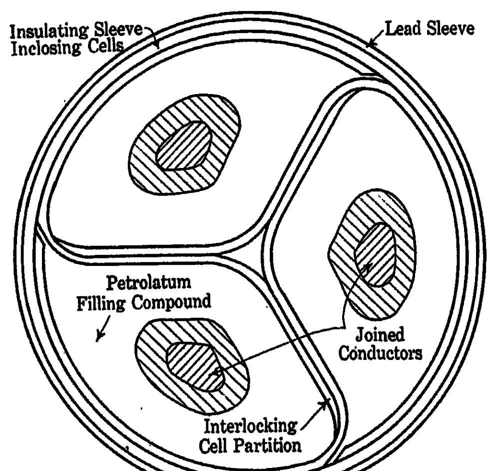

Fig. 9—Construction and Dimensions—Conducel Joint
Three-conductor 300,000-cir. mils, sector conductor 25,000-volt cable

TABLE IV

Ratio—Three-Phase Dielectric Loss
Conducel Joint to that of the Original Cable
Three-Conductor, 300,000-Cir. Mil Sector Conductor 25,000-Volt Cable

Temperature Deg. Cent.	Ratio—Three-Phase Dielectric Loss Joint to Cable
40	1.7/1
60	2.0/1
80	2.9/1

It should be noted that while the dielectric loss of this joint at low temperatures is practically the same as found for the other paper joints, it is very much greater at the high temperatures.

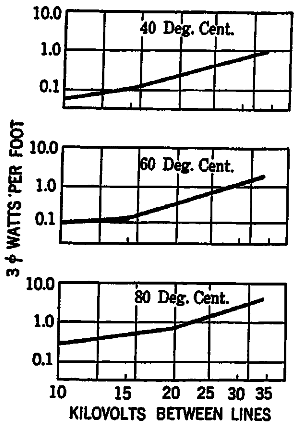

FIG. 10—DIELECTRIC LOSS—THREE-PHASE WATTS PER FOOT VS. KILOVOLTS

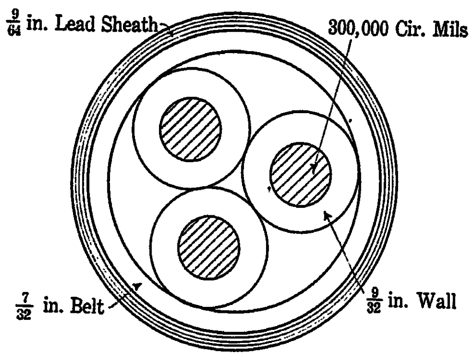

FIG. 11

Three-conductor 300,000-cir. mils, round conductor
10/32-in. wall paper on conductors
7/32-in. belt paper over three conductors
9/64-in. lead sheath, 33,000 volts

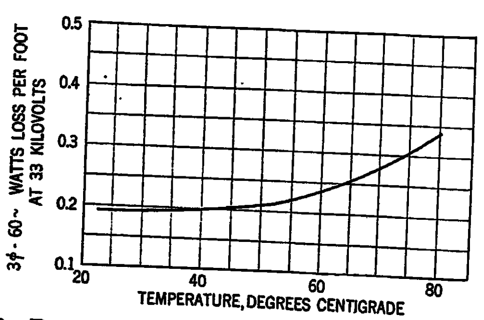

FIG. 12—DIELECTRIC LOSS—THREE-PHASE WATTS PER FOOT VS. TEMPERATURE

Three-conductor 330,000-cir. mils, round conductor 33,000-volt cable

The high potential tests on the Conducel joint showed very low dielectric strength.

No. 1 Conductor vs. Nos. 2-3 and Lead Sheath
75,000 volts—three minutes—failure between conductor.

At the end of two minutes, loud internal discharges were heard, which gradually increased in frequency and magnitude until failure occurred.

Examination after failure showed the conductor insulation badly burned and the conducel insulator punctured.

The remainder of the joints to be described in this paper were constructed for 33,000 volts.

The cable used was three conductors 300,000 round type, 10/32-in. wall paper by 7/32-in. belt paper, 9/64-in. lead sheath, designed and manufactured for 33,000 volts. A cross section of this cable is shown in Fig. 11.

Fig. 12 shows the results of three-phase dielectric loss tests on this cable.

The construction and dimensions of the first joint made in this cable was as shown in Fig. 13.

Results of dielectric loss tests at 33,000 volts at various temperatures are shown in Fig. 14.

Table V gives the ratio of dielectric loss in the joint to that of the original cable.

TABLE V

Ratio—Three-Phase Dielectric Loss
Impregnated paper joint to that of the original cable
Three-conductor, 300,000-cir. mil round conductor 33,000-volt cable

Temperature Deg. Cent.	Ratio—Three-Phase Dielectric Loss Joint to Cable
25	1.32/1
40	1.11/1
60	1.22/1
80	1.27/1

The dielectric loss of this joint is very nearly the same as that of the original cable.

The following dielectric strength test was made on the cable with joint after the above dielectric loss test had been completed. Three-phase, 60-cycle voltage used.

103,000 volts	................60 minutes	
110,000 "	................30 "	
120,000 "	................30 "	
130,000 "	................30 "	
140,000 "	................30 "	
150,000 "	................26 "	Failure.

The breakdown occurred inside the metal sleeve of the joint about one and one half inches from the end of the jacket. Excessive burning of the filling compound and the outside layers of tape on the conductors indicated that there was considerable stress between the edge of the jacket and the edge of the joint insulation. There were no signs of burning in the insulation over the copper sleeve nor along the penciling of the conductor insulation.

Throughout the high potential test after the first five minutes, internal discharges were clearly heard,

although they were rather intermittent and did not increase in frequency or magnitude during the test.

After careful examination of this first joint in the 33,000-volt cable, a second joint was designed which was substantially the same as the one just described except that the conductor insulation was reinforced from the cable crotch to the insulation over the copper sleeve. Construction and dimensions were as shown in Fig. 15.

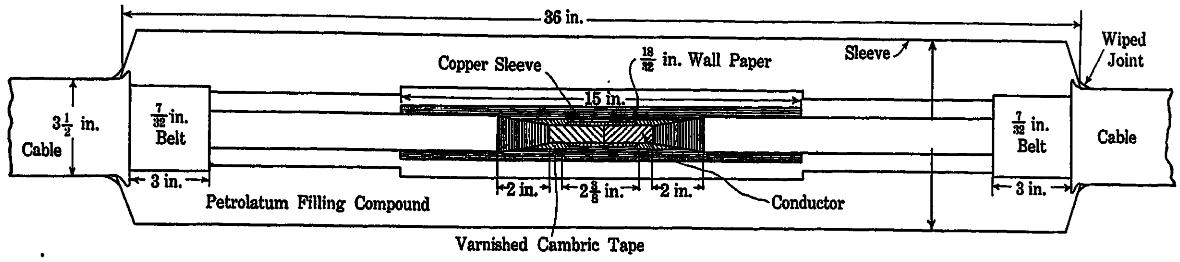

Fig. 13—Construction and Dimensions of Impregnated-Paper Joint

Three-conductor 300,000-cir. mil, round type, 33,000 volts

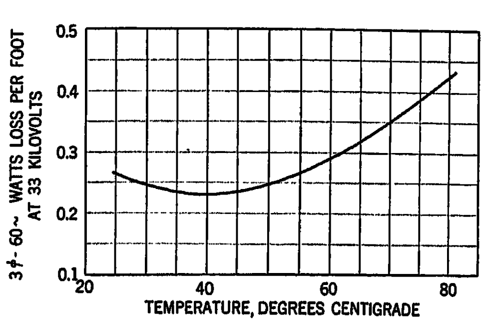

Fig. 14—Dielectric Loss—Three-Phase Watts per Foot vs. Temperature at 33,000 Volts

First impregnated-paper joint in three-conductor 300,000-round conductor 33,000-volt cable

The dielectric loss of this joint was very close to the same as that of the first joint in the 33,000-volt cable. (See Fig. 14.)

The following dielectric strength test was made on the second joint, three-phase, 60-cycle voltage.

103,000 volts	60 minutes
110,000 "	30 "
120,000 "	30 "
130,000 "	30 "
140,000 "	30 "
150,000 "	30 "
160,000 "	26 "

At the end of twenty-six minutes with 160,000 volts, flashover occurred and the test was discontinued.

Examination of the joint showed no signs of burning either in the joint insulation or the filling compound. No internal discharges were heard during the test nor was there any evidence of the joint temperature being higher than that of the cable.

The last 33,000-volt joint to be described in this paper was an "undercut curtain" joint, the construction and dimensions of which are shown in Fig. 16.

This type of joint was somewhat different from any o

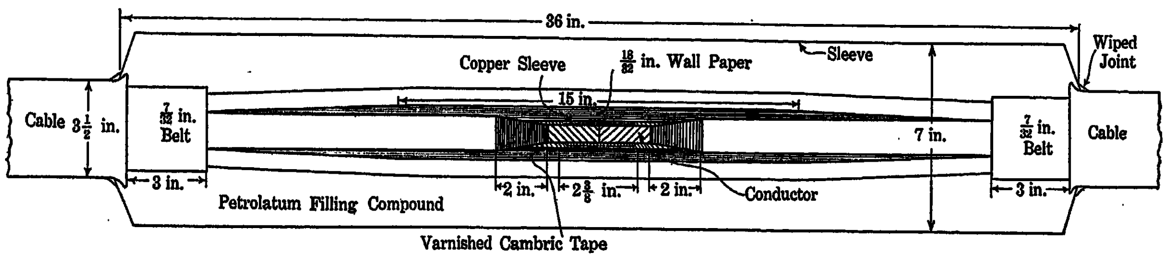

Fig. 15—Construction and Dimensions—Reinforced Paper Joint

Three-conductor 300,000, round conductor 33,000-volt cable

Three-conductor 300,000 cir. mils, round conductor 33,000-volt cable

preceeding joints in both design and assembly. The conductor insulation was undercut by means of a special tool and copper sleeves of the same outside diameter as that of the insulated conductor, sweated on. The paper insulation, which was in the form of a roll of single sheet, was spiralled around the conductor and then "wound up" or tightened until it was as solid and firm as the conductor insulation itself.

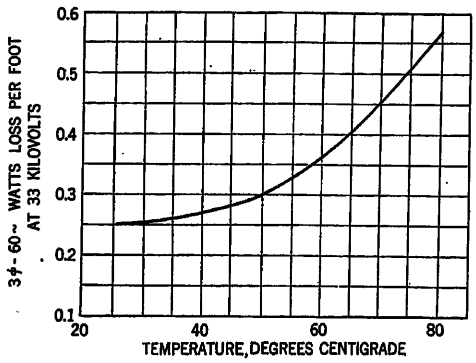

FIG. 17—DIELECTRIC LOSS—THREE-PHASE WATTS PER FOOT VS. TEMPERATURE AT 33,000 VOLTS

Undercut curtain joint on three-conductor 300,000 cir. mils, round conductor 33,000-volt cable

The dielectric loss at 33,000 volts at various temperatures are shown in Fig. 17.

Table VI gives the ratio of dielectric loss in this joint to that of the original cable.

TABLE VI

Ratio—Three-Phase Dielectric Loss
Undercut Curtain Joint to that of the Original Cable
Three-Conductor, 300,000-Cir. Mil, 33,000 Volt Cable

Temperature Deg. Cent.	Ratio—Three-Phase Dielectric Loss Joint to Cable
40	1.30/1
40	1.33/1
60	1.34/1
80	1.68/1

The following dielectric strength test was made on this joint with three-phase, 60-cycle voltage.

103,000 volts	60 minutes
110,000 "	30 "
120,000 "	30 "
130,000 "	30 "
140,000 "	30 "
150,000 "	10 "

At the end of ten minutes with 150,000 volts, failure occurred apparently in the joint. Examination of this joint showed burning at the edge of one of the paper tubes and much burned grease at one end of the joint.

We have not offered any theories as to the behavior of certain of the described joints nor have we drawn any definite conclusions as to the proper joint construction. This paper is merely a preliminary report of the work what has been completed to date. Conclusions will be drawn only after the work is completed.

The authors are greatly indebted to Mr. L. R. Hicks and Mr. C. A. Mayo of the C. H. Tenney Co., Boston—and Mr. Harry Tounge of McGonigle & Tounge, Boston—for materials and suggestions made during the experimental work.

Discussion

A. P. Thoms: I do not see why so much stress should be placed on the dielectric loss in a joint. E. S. Lee, in a paper before the A. I. E. E. Midwinter Convention[1], stated that the dielectric-strength test is the most important and the best test available at the present time; that indications are that the present standardized voltages should be increased and that increasing the application of the test two or three minutes is of doubtful value. The authors of this paper have used the standardized dielectric-strength test with the application increased a few minutes, and this test, according to Lee, is of doubtful value.

All the dielectric-strength tests were made at room temperature. They should be made at maximum and minimum temperatures experienced in normal operation of the cable, and should range down to at least 5 deg. cent.

Accelerated life tests should, in my opinion, be at from 2.5 to 5 times the rated voltage. A single dielectric-strength test will not determine whether a joint will be satisfactory in operation. We should have a test on a joint similar to that required on a cable. If the joint is not subjected to tests to which we subject a cable, such as those required by the N. E. L. A. specifications, we should at least standardize our tests so that we can compare them. I do not see why all the tests were not made with three-phase voltage.

After a joint fails on a test, it is very important that the joint be opened and examined in very minute detail. In looking over the paper, I could not determine the complete path of carbonization. This seems very essential, as it affords information whereby we may improve the weak points in the joints, either by changing the material or by changing dimensions.

The voltage at which sounds of distress in the joint are heard is also very important as this voltage denotes deterioration in the joint. This can be taken with a stethoscope or with a long paper tube held to the ear. Most of the large operating companies are testing their long transmission lines with a kenotron or d-c. test. If the proper ratio between the a-c. and d-c. for the cable is 2.4, it may be 1.7 for the joint, and it is very essential that we know beforehand that these joints are not going to break down when the line is subjected to the initial acceptance test.

Mario Puritz: In giving the results of the last 33,000-volt joint described, Mr. Davis speaks of an "undercut curtain" joint. The patented Pirelli, three-phase joint, with undercutting and tightened paper rolls, is exactly of that type and has been used in Europe for many years. A full description of this joint may be found in the *Electrical Review*, London, August 10, 1923, and a further description with the latest improvements will be published in the Report of the Underground Systems Committee, N. E. L. A., to be printed this year.

About 200 of these joints for 35,000 volts have lately been installed in Chicago and Boston and it may be interesting for you to know some of the results obtained in the tests made in the laboratories of companies of this country. The test joints were all of about the same dimensions as those described by Mr. Davis which were filled with soft compound and differed only in that the lead sleeve was of smaller diameter and the

1. Testing High-Tension Impregnated Paper-Insulated, Lead-Covered Cable, by E. S. Lee, A. I. E. E. JOURNAL, February, 1925, page 156.

reservoir on top. One joint was tested on three-phase, starting at 100 kv. and increasing 15 kv. every 30 sec. At 200 kv., after 5 sec., flashover occurred at the pothead. The voltage was lowered to 183 kv. and after 5 min., failure again occurred in the pothead. No sign of failure or carbonization was evident in the joint.

Four other joints of the same type were tested on single-phase, one conductor against the other two, with the lead at the middle point. The voltage was applied, starting at 120 kv. and increasing 10 kv. every 30 sec. One joint failed at 190 kv. after 21 sec. because of moisture in the compound. The three other joints withstood the test potential of 200 kv. (the maximum pressure available) without evident trouble, and all failures occurred *in the potheads* as follows: after 20 min. at 200 kv. for the first; after 20 min. 15 sec. for the second; and after 20 min. 5 sec. for the third. No signs of carbonization were found in the joints.

Tests of the three conductors in parallel against ground were also made on three other joints with failures of the joints at voltages corresponding to 225,000, 242,000 and 225,000 volts, delta pressure.

In a long-time test run in single-phase, 100-kv., one phase against the other two and the lead at the middle point, another joint was perfect after 18 hr. and 18 min. when the cable failed at a bend, due to excessive increase of temperature of the dielectric. Of course, after this test some leaf-shaped carbonizations were found on the conductors all along the cable and in the joint, and these carbonizations showed on about 15 of the outside layers of the conductors, especially due to the single-phase test, but the carbonizations in the joint were not so deep as carbonizations on the cable.

The cables on which the test joints were made were either three 350,000-cir. mil. or a three 300,000-cir. mil., 35,000-volt, round conductor, 8 × 4.5/32-in. insulation, 1/8 in. lead and 3-in. over-all diameter.

F. A. Brownell: The authors touch upon a vital point when they state that extreme care should be used in assembling the joint. We believe that is at least 50 per cent of the battle, and that the balance is in the right combination of materials entering into the joint.

From our experience with the right combination of low-dielectric-loss materials, we have found that the joint under stress is cooler than the cable. No actual temperature data are at hand, but in one case, after 13 hr. at 105 kv., the cable and joint were examined and while the cable was actually hot, the joint was at only slightly higher than room temperature.

If the theory of graded insulation is sound, then we are not following the correct principle by wrapping varnished cambric upon paper of a lower specific inductive capacity, as this will place a higher stress upon the penciled surface. By plotting voltage-gradient curves using a specific inductive capacity of 3.5 for paper and 4.5 for varnished cambric and taking a point 1/8 in. back on the penciled surface of the paper, we get a voltage gradient of 12 kv. per cm. more than if paper had been used for insulation.

We made up two single-conductor joints with stepped insulation and with the same thickness of insulation in each case; we wrapped one joint with varnished cambric and in the second paper was used.

Failure in each case was at 190 kv. and the surface of the stepped insulation was badly burned. Then we were at loss to know whether this was due to reverse grading or to voids, due to the fact that it is practically impossible to obtain a tightly wrapped joint with paper. The one advantage in the use of varnished cambric is that it makes a tighter wrapping.

It might be of interest to compare two joints we made, similar in design to joint No. 3 except that we used a special material for wrapping over the connector to a level of the factory insulation and then wrapped paper over this, giving the same thickness of insulation as in joint No. 3.

Tests made on these joints with single-phase voltage are as follows: 100 kv., 4 hr.; 120 kv., 2 hr.-45 min.; failure in crotch of joint.

On the second joint, we held 80 kv. for 4 hr. and raised the voltage 10 kv. each hour. After 13 min. at 130 kv., failure occurred in the end-bell. This was repaired and when voltage was rapidly applied, failure occurred at the same place at 160 kv. The ends were again cut back and failure occurred again in the end-bell at 166 kv.

While the second joint did not fail, it showed signs of high stressing. The surface of one conductor at the edge of the belt was charred and the petrolatum had changed in color with particles of carbon throughout. In neither joint were there signs of charring along the surface of the stepped insulation.

Our experience has been that we could get higher breakdowns with a stepped joint and we have found that the average cable splicer will make a better and more uniform stepped joint than penciled joint.

We have examined joints that have been in service for a number of years and found that where they had been penciled very uneven surfaces were left to tape over.

In the first 33-kv. joint, the failure and signs of distress near the edge of the belt showed plainly that this was due to the tangential stresses at this point. In the second joint the insulation was extended back to the crotch and as this joint did not fail, we are led to believe that this is due to the added insulation.

I cannot conceive of overcoming tangential stresses by adding more insulation, but would rather borrow Mr. Ely's idea (and this was done) of using an electrostatic shield to overcome the tangential stresses and smooth out the voltage gradient at the edge of the lead sheath. In fact, by using this and some slight refinements, we have developed a joint that is apparently stronger than the cable.

In the final joint, the use of the Cleveland idea of undercutting the insulation and extending the connector to the level of the factory insulation is no doubt good, but it is limited to round conductors.

From our observation of splicing cable in the field we could not conceive of using a paper roll on three-conductor cables, for it is seldom that the three conductors can be brought out on a plane and a tight wrapping cannot be obtained.

As the authors have drawn no conclusions from their experiments, we are tempted to advance the following for them:

That with varnished-cambric wrapping and the joint filled with a hard asphaltum compound, the dielectric strength on short-time breakdown is high, but on life tests at high potential, a well wrapped paper joint filled with petrolatum will give a higher breakdown. This is perhaps accounted for by lower dielectric loss.

That the difference of tests between the joints shown as Figs. 13 and 15 could be accounted for in workmanship.

To sum up, we have concluded from our experimental work that for a 33-kv. joint (*a*) the material entering into the construction of the joint should in characteristics approximate the material in the cable; (*b*) we cannot get a tightly wrapped joint with impregnated paper and we have substituted a material with the same characteristics but more pliable; (*c*) tangential stresses at the termination of the lead sheath should be taken into consideration and it is believed that they could be overcome by the use of static shields or by the proper slope of the lead sleeve; (*d*) to get a well-filled joint, it must be filled under pressure and (*e*) the education of the splicer is very essential.

The only apparent objection to the use of petrolatum in filling joints is due to migration of the oil from the joint and this we believe could be overcome to some extent by using a petrolatum with a higher viscosity than possessed by that used at present and still having approximately the same dielectric strength.

Regarding Joint 13, Mr. Crowder asked us if we didn't believe that, due to the fact that he has added more insulation, he has given a higher dielectric strength to that joint? I don't believe so. We made up joints of different thicknesses of insulation. In two cases I recall we made up joints with 40 per cent more insulation than used on the cable; in another case, 65 per cent more, and by some peculiar coincidence, the joints with the most insulation failed at a lower voltage. If we plot a curve between voltage gradient and distance from the conductor we would find that we would get what could be likened to a saturation curve, or a point out from the conductor at which there is a very small voltage gradient—in fact practically no stressing,—and from the little work I did I should imagine that they had just about reached that saturation point, or perhaps extended beyond it. In other words, they had more paper than they actually needed.

C. F. Hanson: In witnessing a dielectric-strength test on cable splices recently, I observed a phenomenon which, in my opinion, requires consideration.

The cable with the splice was bent into the form of a horse shoe and rested on wooden blocks supported by two I-beams laid across the top of a tank with the cable ends dipping into transformer oil in the tank. Between the sheath of the cable and the I-beam was an air-gap about 1 in. long.

The voltage was applied in steps and at each step the voltage was maintained constant for a given period of time. When the voltage reached a certain value a train of electrical discharges would occur intermittently across the air-gap. Coincident with these discharges, bubbles in the transformer oil would rise from the end of the cable. As the voltage was further increased, these intermittent discharges would generally cease for a while. Then later on, when the voltage had been increased still further, these discharges would again occur but with greater intensity. They would grow more violent until complete electrical breakdown occurred either in the cable or in the splice.

The phenomenon to which I alluded is the first train of discharges across the air-gap in conjunction with the bubbles rising in the transformer oil. The only logical explanation for this phenomenon which I can give, is as follows:

The discharges must have a high frequency in order that the impedance across the air-gap may be less than that of the return wire to the transformer. The thing which caused these high-frequency surges must have been a disturbance in the electric circuit. One source of disturbance is a surface discharge in the splice along the penciling of the original cable insulation. After a number of these surface discharges have occurred, the compound, which in this case was petrolatum, would have been heated locally and sufficiently to permit the compound to flow into the discharge path and temporarily oppose further discharges. The local heating would, of course, expand any air which might be present. The increased pressure could be relieved at the end of the cable, causing bubbles to rise. With further increase in voltage, the dielectric stress may become sufficient to expel the compound which had flowed in, when discharge would again occur. If the stress is sufficiently great to prevent the compound from flowing back into the path of discharge the splice will finally break down completely with a mass of carbonized compound. On the other hand the surges may break down the cable insulation before enough compound has become carbonized to form a complete short circuit in the splice.

A subsequent examination of one of the splices seems to substantiate the foregoing explanation. Apparently, this splice had not failed but the cable had. However, upon dissecting the splice, six layers of the original insulation and eight layers of the applied insulation were badly charred. Also a considerable amount of petrolatum was charred.

If the foregoing reasoning is correct then the breakdown voltage of a splice is that obtained when the first electrical disturbance occurs and not that obtained when a complete short circuit occurs. When the first disturbance occurs, the splice has become a menace in the electric circuit because it produces disturbances which are hazards to other electrical equipment in the circuit.

When reporting tests of splices it is frequently stated that the cable fails before the breakdown voltage of the splice is reached. If, however, the tests are interpreted as above suggested, it will probably be found that the splice has failed first.

C. F. Hood: The purchasers of high-tension cable have kept the manufacturers so busy in trying to meet their demand that the efforts which we have put forth in developing joints have followed somewhat behind the effort put into the development of cables.

In attempting to develop a joint which we feel can be recommended to the users of high-tension cables, we are now conducting a series of experiments similar to those outlined by Mr. Davis.

So far it appears that we can produce a wrapped joint which will be as good as the cable for which it is intended. We have made some experiments on wrapped joints in comparison with the so-called patented joints, and so far the wrapped joints have shown themselves to be considerably better than the type of joint built up with a barrier insulation.

Along these lines, I don't think that we can stress too strongly the necessity of having the jointers appreciate just what work they are trying to do. If they are not men who realize the importance of detail and following that very closely, as already pointed out, a good joint can be spoiled by a poor workman.

I think that a great deal can be gained by much closer cooperation between the manufacturers of the cable and the users.

A. H. Kehoe: The paper infers that due to the existing situation in joint design satisfactory operation of high-tension cable systems cannot be assured. I believe that satisfactory joints are now in operation on cable systems of all voltages for which we have been able to obtain cables. For ordinary joints we know that adequate factors of safety exist. For the high-voltage joints the factors of safety can only be estimated as we do not have good enough cable to test these properly.

The authors divide the essential properties of a good joint into three classes. We believe that simplicity of design is by far the most important element in comparing successful types of joints in service.

To further decrease the dielectric loss obtained with any practical joint today is not highly important, as cables in ducts run at a higher temperature than cables in manholes, so that the limiting condition is the heat of the cable in the duct.

Short-time applications of extremely high voltages may set up conditions not duplicated in actual service as certain types of dielectric have a high voltage-breakdown value for short-time applications, while other types do not. Results in practise at normal stress may thus give opposite results from such tests. In selecting test values it is important to ascertain whether the particular materials tested are stressed beyond their known breakdown values, rather than to make a large number of different joints some of which only demonstrate this breakdown limit which could have been positively predicted before the expense of testing was undertaken. The high-voltage accelerated-life test provides an important element of time saving in making tests but results are not directly comparative between varying types, as to normal voltage operation, particularly if high-voltage short-time values are used as is the case in these tests.

I believe that the essential element in cable joints and in cable installations is simplicity of design. From it, uniform results are most likely to be obtained. The greatest difficulty I have experienced in making joints is to be certain that all of them are tight, that is, that they are all waterproof. It is important in order to accommodate existing structures that a

short joint be used. This same condition causes many companies to use sector cable and it is more difficult to obtain a joint with proper factors of safety on sector cable than on round-conductor cable. Simplicity of design also makes it easy to eliminate voids. I believe that many of the joints tested failed because of voids in the filling compounds. Testing a few joints all of different types or even a few joints of one type does not give a definite indication of the factors of safety unless they all target very closely to the same value on the test curve.

I should like information from the authors as to how they handled the end-bells in testing. The paper infers that dielectric loss was obtained first on long cable lengths averaging so much per foot, and any increase was attributed to the joint. It is not clear how the dielectric loss of the end-bells was accounted for.

We have had several thousand joints of the fourth type tested by the authors, operating successfully at 28 kv. for over two years, and several other operating companies have had similar experience with this joint at similar voltage. The uniformly successful operation obtained with this type of joint for installation up to 33 kv. would not be predicted from the one joint tested.

In testing the first four types of joints, the dielectric strength to ground was tested, as three-phase potential should have been used to obtain the comparable results with the last three joints made from round-conductor cable. The initial voltage applied to the first four was equivalent to 130 kv. in so far as failure to ground was concerned. Certain of the joints tested have factors of safety to ground which are slightly lower than failure between phases, as this makes the best operating type of joint. The failure of No. 4 joint by puncture of the factory-formed insulator is the second case which has come to my attention; in the first one the workman did not understand the assembly of the material and the joint was poorly made with large voids existing in it. From the internal discharges reported on this test I judge that some similar phenomena occurred.

In discussing the last three types of joints tested it is well to emphasize the practical advantages in using a short-length joint where proper factors of safety can be obtained. It is evident, however, that the longer the joint the more reliable it will be in operation regardless of its type.

The method of accelerated-life testing is important in comparing results published by other authors. For instance, this is the first case which has come to my notice where thirty minutes per 10 kv. change has been used instead of increments of one hour for 10 kv. As there has been considerable doubt expressed in the past that even the one-hour increment gives proper comparative results for various types of joints, we believe that testing of this character should be longer and reduced voltage values used. Such a test method is more expensive but gives a better indication of the service results that are likely to be obtained.

The seventh joint of the so-called "curtain-roll" type is one with which we have had successful experience on a single-conductor 44-kv. installation. The joints are but 20 in. long, although the stresses are approximately the same as those tested by the authors on a 36-in. structure. This construction produces simple joints of uniform workmanship for round conductors, as long as they are straight, but it cannot be applied to sector conductors.

C. A. Adams: As yet we know practically nothing about the fundamental nature of dielectric phenomena. There are several hypotheses and much superficial misconception. As yet, we don't know even what are the significant variables with which we are concerned in this field. Moreover, much of the so-called "practical research work," which has been done bit by bit here and there without coordination is likely to be not only useless but in some cases actually misleading.

If manufacturers and users of insulated wires and cables and of other insulated apparatus would cooperate in a comprehensive research into the fundamental nature of dielectric phenomena at an expense to each which would be extremely modest as compared with the probable value of the results, there would be some hope of solving this most important problem. In such an undertaking, it would be necessary to enlist the assistance of the ablest physicists and chemists in the civilized world, but for work of this kind such assistance can be obtained at relatively small expense.

I have been endeavoring to start such a movement for the past seven years and a small start has been made by the organization of the Insulation Committee of the Engineering Division of the National Research Council, this Committee being also attached to the Research Committee of the A. I. E. E. But it is only recently that some of the users of cables are being forced to realize the need of such fundamental research.

L. A. Zima (by letter): The authors start out with an assumption of "Suitable Cable." This is a broad assumption to make for high-voltage cable, considering our limited operating experience to date. They further state that high-voltage cable jointing must receive considerable attention in the near future. Perhaps, from the manufacturer's standpoint, this is correct; but the cable user has given a great deal of attention to this problem ever since high-voltage cable has been manufactured, and has had reasonable success. This success is based on long practical experience following long tedious research work on experimental joints. Work along this line has been somewhat retarded waiting for the cable manufacturers to make suitable cable.

I rather question the three essential properties mentioned. Simplicity of design is certainly to be desired but it is not an essential property.

High dielectric strength is desirable but this does not necessarily mean very high instantaneous breakdown voltages or on short-life test. It is possible to make up a joint to give very high dielectric strength on instantaneous voltage application, but which will fail utterly to give satisfactory results in normal operation.

Dielectric loss, as low as that of the cable, is not an essential property of a cable joint. Due to the large radiating surface of the joint and the large volume of surrounding air in the manhole, the cable joint is at a much lower temperature than the cable inside the duct line.

The essential properties and requirements of a satisfactory cable joint are as follows:

a. Proper design, keeping the voltage gradient of all points in the joint within proper limits.

b. Materials of good quality, having high dielectric strength, with an specific induction capacity of relatively the same value as that of the cable. These should not vary in normal operation.

c. Workmanship of the highest order.

The voltage tests made on the various joints were of comparatively short duration, lower values and longer time would be more desirable and would more nearly approximate service conditions.

My attention is particularly directed to the electrical characteristics of Joint No. 4. Of the seven types of joints, the author finds this one to be the poorest of the lot as it has the lowest dielectric breakdown value. The reason for this, it seems to me, is not that of design but rather the general method of construction, especially of workmanship. The materials were not properly assembled and the filling probably faulty.

There are many of these joints in operation and they are giving satisfactory service. If properly assembled, using good material and with high-grade workmanship this joint will give a dielectric-breakdown test value, instantaneous and accelerative life, equal to that of the cable.

The Brooklyn Edison Company has had a large number of these joints in service over a year,—probably from 2500 to 3000,

—and the operating results have been satisfactory. Refinements on these joints have continued, slight changes made in the construction, strengthening the weakest points, properly training the splicer for this type joint, and maintaining close supervision to insure high-grade workmanship.

A number of joints constructed with these refinements are now under test. The result of the first eight joints is as follows:

Tests on Joints in Sector Cable. These were three-conductor 350,000-cir. mil, sector cables with $20 \times 10/64$-in. paper insulation, 9/64-in. lead. Tests were made with three-phase, 60-cycle voltage.

On all the joints except No. 1 the voltage was started at 70 kv. between phases and increased in 10-kv. steps remaining constant for one hour at each step. At 120 kv., voltage was held constant until breakdown occurred.

Joint No. 1 was subjected to 50 kv. for 405 hours before it was raised to 70 kv., after which the test was identical with those on the other joints.

Joint No.	Hours at 120 Kv.	Total Hours on Test
1	3.1	413.1
2	6.4	11.4
3	6.4	11.4
4	7.2	12.2
5	7.8	12.8
6	5.3	10.3
7	4.3	9.3
8	5.0	10.0

The failures occurred at 120,000 volts after a number of hours as shown. Examination showed the following:

Breakdown between conductors at sharp bend in conductor insulation near cable crotch.

Failure between conductors at porcelain spacer due to jamming and breaking conductor insulation.

Breakdown at edge of belt insulation due to sharp bend in conductor insulation.

A number of failures in cable crotch of the prepared cable ends.

These tests are a fair measure of the dielectric breakdown voltage values of the cable joint on a long-life test at comparatively high values.

As experience has demonstrated the value of long accelerated life tests to determine satisfactory cable, the same holds true for cable joints.

I would recommend that a standard method of long accelerative life tests be set up so that a direct comparison can be made on joints and cable of different types of construction as made by various manufacturers or operating companies These tests should then be supplemented by simi ar tests, using d-c. voltage instead of a-c

G. J. Crowdes: The work on joints, when completed, will comprise the construction and testing of about twenty joints. The following are results of tests on five more joints which may be of interest.

A duplicate of the varnished-cambric joint (see Fig. 3) was constructed with No. 00, $9 \times 6/32$ in. paper-insulated cable having round conductors. This joint had the same high loss characteristics as the previous varnished-cambric joint. The dielectric strength of this joint was quite high as shown by the following table:

3-Phase, 60-Cycle Kv.	Time (Min.)
92.5	60
110	30
120	30
130	30
140	28 to failure

The failure occurred between conductors about 4 in. from the edge of the belt. There was no evidence or charring or burning along the penciling.

Two joints were next built on 250,000-cir. mil. round-type cable with $9 \times 6/32$-in. of impregnated-paper insulation designed for 25 kv. working pressure. The construction of the joints was identical with the previous 25-kv. penciled paper joint (see Fig. 5) with two exceptions, (1) the length of penciling was increased to 2 in. and (2) each conductor was reinforced back to the crotch of the cable. One joint was filled with a standard hard filling compound and the other with petrolatum.

The loss in the joint with hard filling was considerably higher than the loss in the petrolatum-filled joint, at working voltage and a temperature of 80 deg. cent., the ratio being about 2 to 1. In dielectric strength there was practically no difference:

3-Phase, 60-Cycle Kv.	Hard filling Time (Min.)	Petrolatum filling Time (Min.)
92.5	60	60
110.0	30	30
120.0	30	30
130.0	30	30
140.0	30 failure	24 failure

The failure in both joints occurred at the edge of the belt insulation between conductors. There was no evidence of burning along the penciling.

The next two joints were constructed using 300,000-cir. mil. sector-type cable, with $9 \times 6/32$-in., impregnated-paper insulation. These joints were identical with the previous penciled paper joints described in the paper (see Fig. 3), with two exceptions, (1) the penciling was increased to 2 in. in length, and the built-up insulation was carried farther along the conductor for a distance of about 2 in. The conductors were not reinforced to the crotch. One joint contained hard filling compound and the other petrolatum.

Here again the joint with hard compound showed much higher loss characteristics. The slope of the loss curves with both voltage and temperature was considerably steeper in the hard-compound joint than in the petrolatum-filled one.

The dielectric strength of the hard-compound joint in this case was somewhat greater than the petrolatum joint as shown in the following table:

3-Phase, 60-Cycle Kv.	Hard Filling Time (Min.)	Petrolatum Filling Time (Min.)
92.5	60	60
100.0	30	12 failure
120.0	30 failure	

The failures on both of these joints were between conductors at the end of the tape-on insulation. Severe burning was evident along the penciling in each case.

There is one striking fact evident from the tests on the last four joints and that is the difference in dielectric strength between the sector-type cable joints and the joints on round cable. The joint construction is identical except that there is no reinforcing on the sector-cable joints. Yet, on the round-type cable joints it was possible to reach a voltage of 140 kv. and hold this stress for considerable time. On the sector-cable joints, 120 kv. was reached on one joint and 110 kv. on the other. The failure on the sector-type joints followed the penciling.

It does not seem possible that the reinforcing of the conductor to the crotch (which was the only difference between the two types of joints) could account for the great difference in dielectric strength.

E. W. Davis: We quite agree with those who have discussed our paper, that dielectric-strength tests should be standardized, but we are not ready to accept such tests as the sole criterion for

the value of an insulating material. Of all the electrical tests that we made on the various types of joint, we found that the dielectric-loss test was the most sensitive, and that it gave the most consistent and conclusive results. Experience has shown that a joint designed for normal dielectric strength and low dielectric loss will stand up better under severe operating conditions than one with high dielectric strength and high dielectric loss.

All the joints tested were opened and carefully examined and photographic records made of the paths of carbonization. A few of the joints were tested with radio apparatus installed in the ground circuit, and the tests stopped at the first signs of internal discharge. It was from a careful study of the paths of carbonization that the weak spots in the cable joints were found and the design changed so as to eliminate them as far as possible.

We have not discussed the question of workmanship in this paper. A poorly designed joint will not give satisfactory results, even though the workmanship is perfect. All of the joints tested were made by the same man so that the quality of workmanship was undoubtedly the same in all cases. In none of the joints that we opened and examined was it possible to say that the cause of the failure was due to poor workmanship.

Unfortunately, when the earlier work was done on the joints, we had only single-phase voltage available. Some of this work has been repeated with three-phase voltage with substantially the same results. Dielectric strength tests at high and low temperatures, show very little variation, especially if the results are comparative. The joints that show the higher dielectric strength at low temperatures, invariably have the higher dielectric strength at high temperatures.

We feel that the proper design of a joint to be put into a cable installation is well within the province of a cable manufacturer, but that the question of workmanship is a matter with which the operators should deal.

Predetermination of Self-Cooled Oil-Immersed Transformer Temperatures Before Conditions are Constant

BY W. H. COONEY[1]

Associate, A. I. E. E.

Synopsis.—*The temperature rises of dynamo-electric machines, in changing from one steady thermal state to another, follow an exponential law of the form $1 - \epsilon^{-\beta t}$, where $1/\beta$ is the thermal time constant, or the time required to attain 63. 2 per cent of the final change in temperature rise. It is shown here that while the winding temperature rise over room of self-cooled oil-immersed transformers follows this law only after a certain time has elapsed, quite accurate results may be obtained by calculating the time-temperature curves of the top oil temperature rise above room, and the winding temperature rise above top oil separately, since each follows the above exponential law quite closely, then adding them together to get the winding temperature rise above room at any time before conditions are constant. A procedure is explained in detail for calculating β, for either the top oil rise or the winding rise above top oil from the weights of materials the iron and copper losses and the winding and top oil constant temperature rises at any given load. Comparisons of temperatures by test and calculation are presented.*

* * * * *

Introduction

WHILE it is of interest to know the length of time necessary for a transformer to attain its final winding temperature rise at rated load, it may sometimes be desirable to know how long an overload may be carried, without exceeding a safe winding temperature, starting at room temperature or at any constant temperature rise less than that due to normal load.

For instance, it is required that railway transformers be tested at a load of 125 per cent or 150 per cent for two hours, starting at the temperature rise due to normal load, without exceeding a winding temperature rise over room of 60 deg. cent. This sort of test does not indicate how long the overload could be carried starting at some other initial steady state, such as room temperature.

To intelligently load the transformer, the operating engineer should have either the results of tests made under the various load conditions or the thermal time constants[2] for the different load and initial conditions for a given transformer. Of course, the most accurate results can be obtained from tests, but it is obvious that this method has its disadvantage in that it is not practical to make tests under all the various conditions under which the transformer might be required to perform. It is, therefore, highly desirable to be able to calculate the time constant, or constants, as the case may be.

In a recent paper[3] a method of calculating the time constant for machines where the parts generating heat (windings and iron of a generator, for example) are not thermally independent and the temperature rise is proportional to the loss, was outlined. It was shown in this paper that the winding temperature rise above room followed an exponential rise with time such that the ratio of temperature rise, at time, t, to final temperature rise $\left(\frac{\theta}{\theta_f}\right)$ could be expressed by $1 - \epsilon^{-\frac{t}{\tau}}$, where τ is a time constant which can be determined graphically from the tested time-temperature rise curve. It was also shown that the value $\left(1 - \frac{\theta}{\theta_f}\right)$

1. General Electric Co., Pittsfield, Mass.

2. The reason the value of the constant changes for different loads is because, as shown later, the temperature rise of self-cooled transformers for constant conditions is never proportional to the loss but to the loss raised to some definit power.

Presented at the Regional Meeting of Dist. No. 1, Swampscott, Mass., May 7-9, 1925.

3. Kennelly: Thermal Time Constants of Dynamo-Electric Machines, Presented at Midwinter Convention, New York, Feb. 9-13, 1925.

which is equal to $\epsilon^{-\frac{t}{\tau}}$, could be plotted as a straight line against time on semi-log paper.

During the discussion[4] of the previously mentioned paper, it was pointed out that in an oil-immersed self-cooled transformer, the windings are separated from the core by an appreciable amount of insulation and oil, so that the windings may for all practical purposes be considered thermally independent of the rest of the transformer. Although the top oil temperature rise and the winding temperature rise above top oil may each be plotted in terms of $\left(1 - \frac{\theta}{\theta_f}\right)$ as a straight line on semi-log paper, the sum of the two, or winding temperature rise above room becomes a straight line only after the winding temperature rise above top oil has become constant. Moreover, the latter, when continued back as a straight line, does not pass through the origin.

The object of this discussion is to present a method, based on treating the winding temperature rise above top oil and the top oil temperature rise separately, whereby the winding temperature of a transformer can be calculated at any time after a change in load has occurred following a steady state. This method requires a knowledge of the weights of the materials in the transformer, the copper and iron losses, and the constant top oil and winding temperature rises above room for some given load such as that required in the acceptance tests.

It is not claimed that this formula is absolutely correct, since the first expression, Eq. No. 3, in its derivation, as pointed out later, is intended to cover not only winding temperature rise over top oil, but also the top oil temperature rise above room. However, it should be accurate enough for most practical purposes, as an inspection of Figs. 5 to 10 will show.

Final Temperature Rises

In order to calculate temperature rises before conditions are constant, it is, of course, necessary to know the final rise which would be obtained if the load were maintained until conditions become constant. Fortunately, the final rise for any assumed loss of most transformers can be estimated fairly accurately, especially if the rise for some given loss is known.

In the following exposition, the winding temperature rise above room temperature is separated into two parts: top oil temperature rise above room and winding rise above top oil. There are two reasons for this distinction:

In the first place, due to greater thermal capacity, top oil temperature rise, following a change in load, requires approximately as many hours to become constant as the winding rise over oil requires minutes. Secondly, the final values of the two rises do not vary at the same rate with change in load.

4. By V. M. Montsinger.

It has been found[5] that both the top oil rise of the usual self-cooled transformer and horizontal disk coil rise over top oil vary with loss approximately in accordance with the formula:

$$\theta = k\,P^{0.8} \qquad (1)$$

where θ is the temperature rise, k is a constant in which area of dissipation is one factor, and P is the loss. Temperature rises of vertical coils over top oil vary between the 0.9 and the first power of the loss, and can be expressed close enough for practical purposes by:

$$\theta = k\,P \qquad (2)$$

Formula (1) is shown for convenience on log-log paper in Fig. 1. A reference to this figure makes the distinction between top oil rise and coil rise over top oil more readily apparent. Assume that with a ratio of copper loss to core loss of 1:1 the final coil rise over top oil is 10 deg. cent. and the final top oil rise is 30 deg. cent. at some given load. If, due to an increase in load, the copper loss is doubled, the coil rise over top oil according to equation (1) for a relative loss of 2 becomes 1.75×10 deg. cent. = 17.5 deg. cent (and according to equation (2) becomes 20 deg. cent.) but the relative watts loss for top oil rise, since core loss remains constant, is $(2 + 1)/(1 + 1) = 1.5$ and the rise (Fig. 1) is 1.38×30 deg. cent. = 41.4 deg. cent.

By means of equations (1) and (2) the final temperature rise for any load can be found provided the rises are known for some definite load and the corrections for change in resistance from one temperature to another are made.

Increase of Temperature Rise with Time

It is a well-known fact that temperature rise varies with time according to the exponential curve as shown in Fig. 2. Immediately after the generation of loss in the body under consideration has begun, the temperature rise increases rapidly, since at first it is not sufficient to dissipate any loss, and, consequently, practically all the loss is stored. As the rise increases, the dissipation to the surrounding medium (oil or air, as the case may be) increases, until finally heat storage has been completed and all the generated loss is dissipated.

If the initial generated loss is W before the temperature rise has begun, the generated loss at time t and temperature rise θ for a constant current can be expressed as $W(1 + \alpha\,\theta)$ where α is the resistance coefficient of copper. The loss stored at time t is $C\frac{d\,\theta}{d\,t}$, where C is the thermal capacity of the body being heated. The loss dissipated can be expressed

5. Montsinger. Effect of Barometric Pressure on Temperature Rise of Self-Cooled Stationary Induction Apparatus. Proceedings A. I. E. E., Vol. 35, pp. 451-478, April, 1916.

oximately by $K\theta$. Multiplying the initial loss by stance correction is not strictly correct when using ormula for oil temperature rise, since core loss may decrease slightly with temperature. But $\alpha\theta$ is ly of the order of 15 or 20 per cent and copper loss, ially for overloads, is several times as large as the oss, so that no great error is caused. If α were plied by the ratio of copper loss to total loss, uld result not only in a complicated equation, but he necessity of a separate one, for oil top tempera-ise.

uating the loss generated to the loss stored and ated at time t and temperature rise θ the equation ned is

$$W(1+\alpha\theta) = C\frac{d\theta}{dt} + K\theta \tag{3}$$

integration of this equation, shown in the ndix, gives the formula:

$$\theta = \theta_f(1 - \epsilon^{-\beta t}) \tag{4}$$

θ_f is the final temperature rise caused by the loss initial value is W, ϵ is the base of Naperian thms and

$$\beta = \frac{W}{C\,\theta_f} \tag{5}$$

s constant may be more familiar in its reciprocal where it is known as the exponential thermal time nt, or the time necessary to attain 63.2 per cent l rise:

$$\tau_e = \frac{1}{\beta} = \frac{C\,\theta_f}{W},$$

the binary time constant[3]:

$$\tau_2 = 0.69315\,\frac{C\,\theta_f}{W}$$

is expressed in minutes and W in watts, for ng rise over top oil

$$C = 2.96\,\frac{A+a}{2a} \times \text{lb. of bare copper} \tag{6}$$

A and a are the insulated and bare cross-ns of conductor in the windings, respectively.

top oil temperature rise over room, when t is ssed in hours and W in watts,

$$C = \frac{3.5\,(\text{lb. Copper} + \text{lb. Core} + \tfrac{2}{3}\,\text{lb. Tank}) + 90\,(\text{Gallons of Oil})}{60} \tag{7}$$

e the calculation of C is of great importance in nethod, it may be of interest to show the reasons e above values of the constants.

c. g. s. units, the following values of specific heat ssumed constant for all temperatures, although actually is a small variation, which may be ted for the ranges of temperature considered.

Specific Heat Copper = 0.0935
Specific Heat Iron = 0.115
Specific Heat Oil = 0.47

The thermal capacity may be expressed in more practical units:

Copper = 2.96 watt minutes per pound per deg. cent.
Iron = 3.6 watt minutes per pound per deg. cent.
Oil = 105 watt minutes per U. S. gallon per deg. cent.

It is apparent that all the oil in a transformer is not heated to the same temperature as the top oil for the reason that the temperature at the bottom of the tank is cooler than at the top. The ratio of mean to maximum temperature in the gradients of self-cooled tanks ranges from about 75 per cent to 95 per cent, depending on the design. Assuming an average of these figures, or about 86 per cent as a representative figure, the constant for oil then becomes 0.86 × 105, or 90, as shown in formula (7).

A similar line of reasoning applies to the tank. The base of the tank, the bottom end of the wall, and, unless there is an oil conservator, the cover dissipate very little or no heat. For this reason, ⅔ of the tank weight is taken. Since the ratio of iron to copper in a transformer is about 5 or 6 to 1, the metal may be lumped together and multiplied by the factor of 3.5 instead of 2.96 and 3.6 for copper and iron respectively.

In considering the windings of a transformer, if the insulated cross-section of the wire is appreciably larger than the bare cross-section it should be taken into account. Fibrous insulation is usually so impregnated with insulating compounds or oil that its thermal capacity is practically that of the latter. Although oil has five times the thermal capacity of copper by weight, copper has about ten times the density of oil, so that the insulation may be considered to have ½ the thermal capacity of copper by volume as indicated in eq. (6).

When the weights of materials are not known, the values of C may be found by observing the time-temperature rise curves for both the top oil and the winding rise over oil when the transformer heats up, preferably starting at room temperature and 100 per cent load and excitation. The values of W and θ_f should be determined. β may be found by a graphical method[3], and C solved for in equation (5). This value of C will be constant regardless of the loads applied or the initial conditions.

Application of the Formula

In changing from one steady state to another, the problems encountered may be grouped into three classes:

a. The application of excitation and load to a transformer which is at room temperature.

b. Application of load after a constant oil rise over room temperature has been attained due to core loss.

c. Application of an increase in load after a constant

rise of windings and oil has been attained due to a smaller load and core loss.

Since the application of a formula becomes simpler, both in explanation and in use, when examples of it are shown, the following problems are worked out under each of the classifications just specified. The relative values of the characteristics given below are typical of a moderate sized power transformer.

Assume a transformer with the following characteristics:

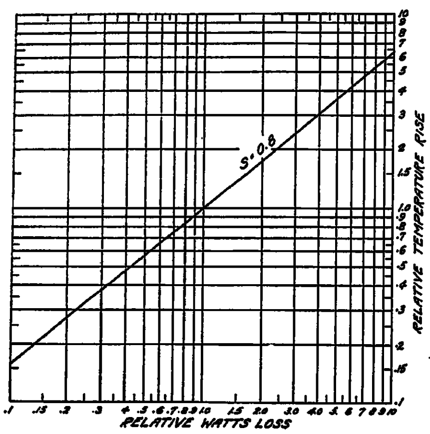

FIG. 1—REPRESENTATION OF $\theta = k\,P^{.8}$ (FORMULA 1) IN TERMS OF RELATIVE TEMPERATURE RISE AND RELATIVE WATTS

At 100 per cent load and excitation:
- 40 deg. cent. top oil temperature rise
- 15 deg. cent. winding temperature rise over top oil
- Copper loss, 9000 watts
- Core loss, 6000 watts

Weights:
- 900 gallons of oil
- 1000 lb. copper
- 4200 lb. core iron
- 4500 lb. tank

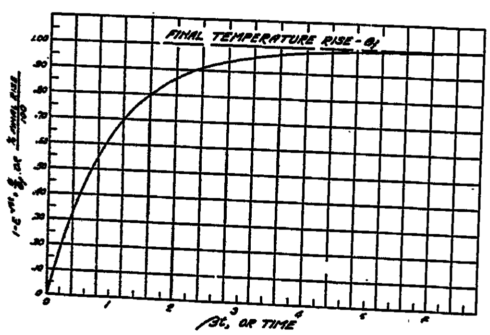

FIG. 2—VARIATION OF $1 - \epsilon^{-\beta t}$, WITH βt, OR INCREASE OF TEMPERATURE IN PER CENT OF FINAL RISE WITH TIME

(Neglect resistance corrections for simplicity.)

(a) 125 per cent load and excitation starting cold.

θ_f: For top oil rise, relative watts $= \dfrac{20080}{15000}$ $= 1.338$; from Fig. 1, oil rise $= 1.26 \times 40$ deg. $= 50.4$ deg. cent.

For coil rise over top oil, assume that the construction is such that formula (2) applies. Coil rise over oil $= 1.563 \times 15$ deg. $= 23.5$ deg. cent.

C: For oil rise

$$= \frac{3.5(1000 + 4200 + 3000) + 90 \times 900}{60}$$

$= 1830$

For coil rise over oil $= 2.96 \times 1000 = 2960$, (Neglecting insulation.)

W: For top oil rise $= 20{,}080$ watts.
For coil rise over top oil $= 14{,}080$ watts.

$$\beta: \text{ For oil rise} = \frac{20{,}080}{1830 \times 50.4} = 0.217$$

$$\text{For coil rise over oil} = \frac{14{,}080}{2960 \times 23.5}$$

$= 0.202$

When these values of β are multiplied by t in hours and minutes respectively, the corresponding values of $1 - \epsilon^{-\beta t}$ may be found from Fig. 2. The latter when substituted in formula (4) determines the value of θ at time t. The results are plotted in Figs. 3 and 4.

(b) Constant oil rise due to excitation, followed by 100 per cent load.

θ_f: For oil rise
Due to excitation, relative watts $= 0.4$, rise $= 19.2$ deg. cent.
Due to excitation and 100 per cent load, oil rise $= 40.0$ deg. cent.
Rise due to copper loss $= 20.8$ deg. cent.
For coil rise over oil at 100 per cent load $= 15$ deg. cent.

C: Same as in (a).

W: For oil rise $= 9000$ watts.
For coil rise over oil $= 9000$ watts.

$$\beta: \text{ For oil rise} = \frac{9000}{1830 \times 20.8} = 0.236$$

$$\text{For coil rise over oil} = \frac{9000}{2960 \times 15} = 0.202$$

The variation of θ, with time, following the same procedure as in (a), is plotted in Figs. 3 and 4.

(c) 125 per cent load following (b).

θ_f: For oil rise $= 50.4$ deg. $- 40$ deg. $= 10.4$ deg. cent.
For coil rise over oil $= 23.5$ deg. $- 15$ deg. $= 8.5$ deg. cent.

C: Same as in (a).

W: For oil rise $= 20{,}080 - 15{,}000 = 5080$ watts
For coil rise over oil $= 14{,}080 - 9000 = 5080$ watts

$$\beta: \text{ For oil rise} = \frac{5080}{1830 \times 10.4} = 0.267$$

$$\text{For coil rise over oil} = \frac{5080}{2960 \times 8.5} = 0.202$$

The results obtained from these values of β and θ_f are also plotted in Figs. 3 and 4.

Although corrections for resistance have been purposely omitted in the foregoing, the distinction should be made that θ_f is calculated for the loss at the final temperature whereas the W used in β is the loss at the initial temperature before the change.

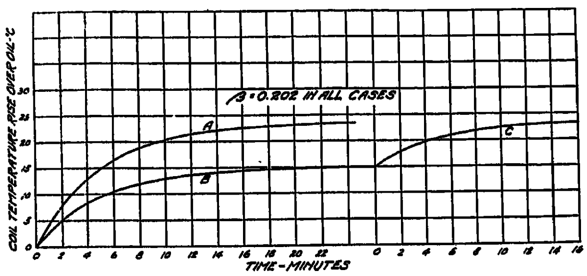

FIG. 3—WINDING TEMPERATURE RISE OVER TOP OIL, CALCULATED FOR THE TRANSFORMER OF ASSUMED CONSTANTS UNDER THE FOLLOWING CONDITIONS:

(A) 125 per cent load and excitation, starting at room temperature.
(B) 100 per cent load and excitation, starting at oil temperature rise due to core loss alone.
(C) 125 per cent load applied after conditions are constant for (B).
Calculations of β are shown in the text.
Note: 0 time for (C) corresponds to 18 hours in Fig. 4.

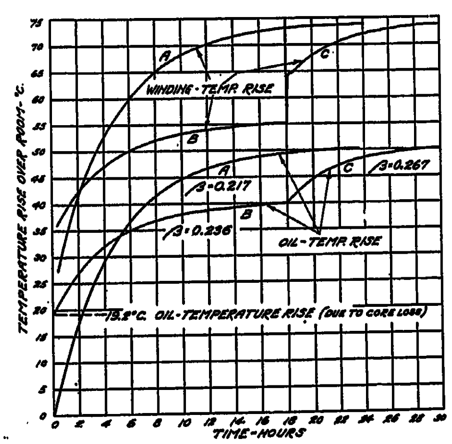

FIG. 4—OIL AND WINDING TEMPERATURE RISES ABOVE ROOM CALCULATED FOR THE TRANSFORMER OF ASSUMED CONSTANTS UNDER THE FOLLOWING CONDITIONS:

(A) 125 per cent load and excitation, starting at room temperature.
(B) 100 per cent load and excitation, starting at oil temperature rise due to core loss alone.
(C) 125 per cent load applied after conditions are constant for (B).
Winding temperature rises above room are obtained by adding the winding rises over oil (Fig. 3) to the oil rises. Calculations of β for the oil rises are shown in the text.

It will be noted that in all three cases the value of β for coil rise over top oil remains the same. This is due to the fact that θ_f is taken as proportional to W, which would not be the case if resistance corrections were considered or if a winding were assumed whose construction caused it to follow formula (1).

COMPARISON OF TESTED AND CALCULATED RISES

A comparison of tested coil temperature rise over top oil and that calculated by formula (4) is shown in Fig. 5. Insulated thermocouples were inserted in a horizontal disk coil stack, and various currents, in excess of normal to get higher readings to minimize any absolute errors, were put through the windings. A thermocouple was selected which was representative of the coil rise over oil by resistance. Readings were taken at intervals during the time required to attain final rise over oil. The calculated values are somewhat higher at first than test, but this may be due to the insulation, between the copper and the thermocouple, causing a temperature lag in the readings. The calculated values of β are shown in the figure.

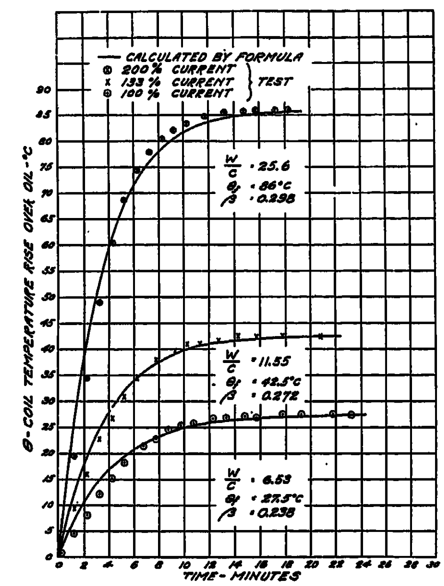

FIG. 5—VARIATION OF COIL TEMPERATURE RISE OVER OIL, WITH TIME, FOR VARIOUS CURRENTS, AS OBSERVED BY THERMOCOUPLE ON DISC COILS IN HORIZONTAL POSITION

An important point to be noted in connection with Fig. 5 is that, since θ_f does not increase as fast as W for this type of winding, β increases for the higher values of current. An inspection of the test values shows a confirmation of this method of calculating β, for the greater the current, the quicker is a given percentage of final rise attained.

To determine how closely tests would agree with the type of calculation shown in (c) of Fig. 4 for oil temperature rise, a 75-kv-a. transformer was given 100 per cent load and excitation starting at room temperature. Hourly readings were taken to determine the variation of top oil temperature rise over room with time until the readings were practically constant. Then 125 per cent load was applied, and the readings continued until conditions were again practically constant. The readings and calculation of β, and the factors on which it is based are shown in Fig. 6. The observations made in connection with Fig. 5 apply here

also. θ_f has not increased as rapidly as W (see formula 1) and consequently β has increased about 50 per cent in the overload. The general conclusion is that when the ratio of W to θ_f is not constant in all cases, β should be calculated for the particular load and initial condition under consideration.

For the purpose of checking up the form of calculation

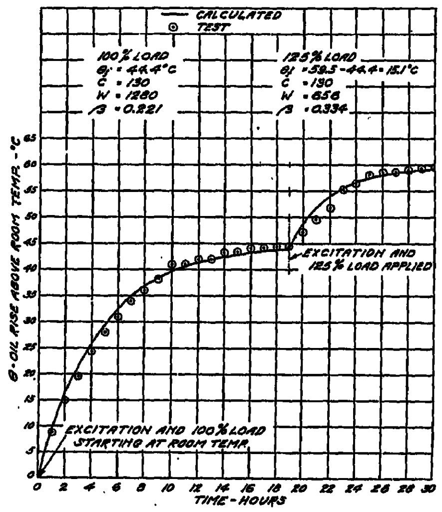

FIG. 6—VARIATION OF TOP OIL TEMPERATURE RISE, WITH TIME, IN A 75-KV-A. TRANSFORMER. 100 PER CENT LOAD AND EXCITATION APPLIED AT ROOM TEMPERATURE UNTIL RISE IS CONSTANT, FOLLOWED BY 125 PER CENT LOAD UNTIL CONDITIONS ARE AGAIN CONSTANT. (SIMILAR TO (C) IN FIG. 4)

shown in (b) of Fig. 4 for oil temperature rise, a 100-kv-a. transformer was put under excitation until the top oil temperature rise caused by the core loss was constant. Then normal load was applied and the top oil temperature rise observed hourly until practically final

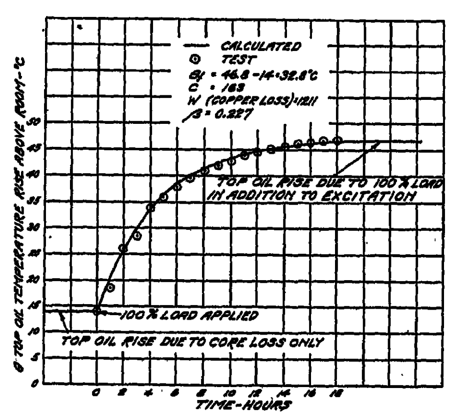

FIG. 7—VARIATION OF TOP OIL TEMPERATURE RISE, WITH TIME, IN A 100 KV-A. TRANSFORMER. NORMAL LOAD APPLIED AFTER CONSTANT TOP OIL TEMPERATURE RISE, DUE TO CORE LOSS ONLY, HAS BEEN ATTAINED. (SIMILAR TO (B) IN FIG. 4)

rise was attained. The observations obtained, and the calculation of β, are presented in Fig. 7. Hourly readings were also taken as the top oil was heating up due to core loss. They check up very closely with the calculated values, but since they are of minor importance they are omitted.

The 100-kv-a. transformer, whose performance is shown in Fig. 7, was also tested starting at room tem-

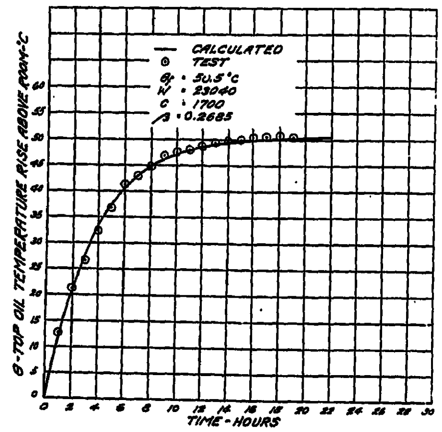

FIG. 8—VARIATION OF TOP OIL TEMPERATURE RISE, WTIH TIME, IN A 2000-KV-A. TRANSFORMER. NORMAL LOAD AND EXCITATION APPLIED STARTING AT ROOM TEMPERATURE. (SIMILAR TO (A) IN FIG. 4)

perature, with a good agreement of tested and calculated values, but due to the similarity of the test to the one starting with core loss temperature, it is not reproduced. Figs. 6, 8, 9, 10 show how well the formula checks tests starting at room temperature, regardless of the size of transformer, for 75, 2000, 5000 and 12,500 kv-a., respectively. These observations of top oil temperature were all taken hourly as the transformers

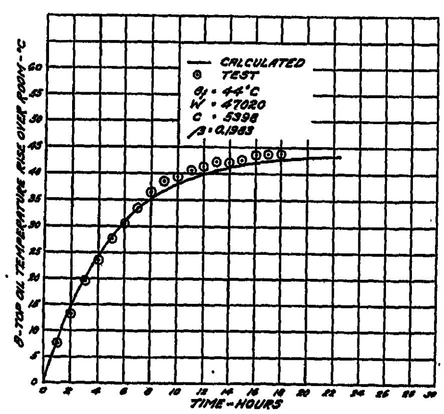

FIG. 9—VARIATION OF TOP OIL TEMPERATURE RISE, WITH TIME, IN A 5000-KV-A. TRANSFORMER. NORMAL LOAD AND EXCITATION APPLIED STARTING AT ROOM TEMPERATURE. (SIMILAR TO (A) IN FIG. 4)

were heating up, starting at room temperature, after 100 per cent load and excitation had been applied, conditions similar to those of (a) in Fig. 4. The calculated values of β are given in the respective figures in addition to the test data.

A general inspection of Figs. 5 to 10 shows that the calculated curve does not reach a maximum and flatten out quite as quickly as the test results. This is due to the fact that theoretically the exponential curve does

not become constant until infinity. After a certain per cent rise has been attained, extending the calculation several hours, in considering oil rise, may result in the addition of only one or two tenths of a degree. This is obviously absurd. Since commercial thermometers and thermocouples are seldom more accurate than ± 0.5 deg. cent., calculations may be shortened by carrying them only up to within 0.5 deg. cent. of final rise.

Restrictions in the Use of the Formula

While the proposed method should apply to the majority of self-cooled transformers, it would be misleading not to indicate some of the factors which may affect its applicability.

Considering first the question of coil rise over oil, it is apparent that the windings should be practically thermally independent of any surrounding medium except the oil, which carries away heat from the windings chiefly by convection. If, for instance, the coils

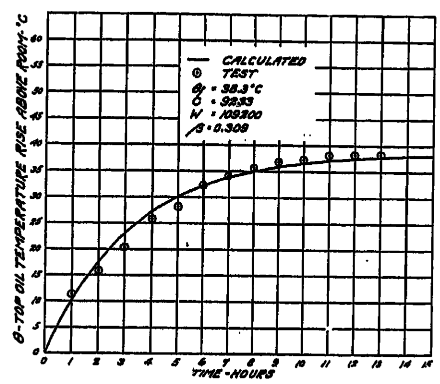

Fig. 10—Variation of Top Oil Temperature Rise, with Time, in a 12,500-Kv-a. Transformer. Normal Load and Excitation Applied Starting at Room Temperature. (Similar to (A) in Fig. 4)

are wound directly on the core, as in the case of many small transformers, there is a flow of heat into the core by conduction in addition to that given to the oil. The result is a very complicated thermal condition as far as calculation is concerned. Naturally, such a winding will not rise in temperature as fast as the proposed formula would indicate for a similar winding separated from the core by an insulating cylinder, for example, since, in such a case, the formula would indicate too high a rise. Tests would be necessary to show the true heating curve in order to get the safe maximum performance for any given design. It might be possible, by adding a portion of the core's thermal capacity to that of the copper, to get a good approximation but the amount added would be empirical, consequently it is impossible to give any general rule that would apply to all cases.

Before applying the formula to top oil temperature rise, it might be well to consider whether the transformer under consideration corresponds to the assumptions on which C in formula (7) is based. For instance, in small transformers of low voltage where it is not necessary to have large voltage striking distances the metal factor (weights of metal multiplied by 3.5) may be as large or larger than the oil factor (90 × gallons of oil). In that case, it may be advisable to give more attention to the former. The copper and iron may be multiplied by their respective factors of 2.96 and 3.6, more than ⅔ of the tank may be used, and the other metal in the transformer such as the core clamps, if appreciable, should be added in. Moreover, a core which runs at high density and consequently high mean temperature rise may have its weight multiplied by the ratio of mean core temperature rise above room to top oil temperature rise. If these factors are not taken into account the test points may be somewhat lower at first than the calculated. These additions should not be made unless it is desired to get maximum performance from the transformer. In any event, they should be made cautiously, for the formula as it stands will be only a little conservative for the cases mentioned above.

About the only factor which could possibly cause the tested top oil temperature rise to exceed the calculated would be a ratio of mean to top oil temperature rise of less than the 86 per cent used for the determination of C in Formula (7). This could conceivably happen through the use of a type of winding cooled in such a way, or so located, that all its heat is delivered to the oil near the top of the tank. Any doubts as to this point can be easily and quickly settled by placing thermometers in a vertical line from top to bottom of the outside of the tank in question and determining the ratio of the mean to the maximum temperatures read when the top oil temperature rise is near its normal value. If this ratio is less than 86 per cent, the factor of 90 should be decreased in like proportion.

Temperature Limits

Although the purpose of this paper is only to indicate a method of calculating temperature rises, it may not be amiss to indicate the temperature limits which should not be exceeded. According to the A. I. E. E. Rules, a maximum rated transformer should not exceed a 55 deg. cent. winding temperature rise by resistance over a 40 deg. cent. room at normal load. For railway transformers, a 2-hour overload resulting in a 60 deg. cent. rise is permitted. Therefore, this method of calculation should be used to show the length of time for which load may be maintained before the calculated winding temperature rise above room plus the room temperature, assumed for the transformer under consideration, exceeds a temperature of 95 deg. cent., by resistance, for maximum rated transformers, or 100 deg. cent. for railway transformers.

Acknowledgment

The author wishes to acknowledge the criticisms and suggestions of Mr. V. M. Montsinger, which have been of great assistance in the preparation of this paper.

In fact, the development of this particular method of applying the exponential law to the heating of transformers during a transient state was made by Mr. Montsinger several years ago, but it was never published. Experience has shown this method to be accurate enough for all practical purposes.

Appendix

Derivation of Formula (4)

$$W(1 + \alpha\, \theta) = C\frac{d\,\theta}{d\,t} + K\,\theta$$

$$C\frac{d\,\theta}{d\,t} + \theta\,(K - \alpha\, W) = W$$

$$C\frac{d\,\theta}{d\,t} + C'\,\theta = W, \text{ where } C' = K - \alpha\, W$$

$$\frac{d\,\theta}{d\,t} = \frac{C'}{C}\left(\frac{W}{C'} - \theta\right)$$

$$\int\frac{d\,\theta}{\theta - \dfrac{W}{C'}} = -\frac{C'}{C}\int d\,t$$

$$\log\left(\theta - \frac{W}{C'}\right) = -\frac{C'}{C}\,t + \log C''$$

$$\theta - \frac{W}{C'} = C''\,\epsilon^{-\frac{C'}{C}t}$$

$$\theta = \frac{W}{C'} + C''\,\epsilon^{-\frac{C'}{C}t}$$

When $t = 0$, $\theta = 0$, and

$$-\frac{W}{C'} = C''$$

Then $\theta = \dfrac{W}{C'}\left(1 - \epsilon^{-\frac{C'}{C}t}\right)$

Substituting for C',

$$\theta = \frac{W}{K - \alpha\, W}\left(1 - \epsilon^{-\frac{K - \alpha W}{C}t}\right)$$

When $t = \infty$, $\theta = \dfrac{W}{K - \alpha\, W} = \theta_f$

Letting $\beta = \dfrac{K - \alpha\, W}{C} = \dfrac{W}{C\,\theta_f}$,

$$\theta = \theta_f\,(1 - \epsilon^{-\beta t})$$

Accuracy of Alternating-Current Test Instruments

BY S. C. HOARE[1]

Associate, A. I. E. E.

Synopsis:—The paper deals mainly with the accuracy of instruments used under maintained conditions of load. Well designed voltmeters, ammeters, and wattmeters show very small errors due to self-heating and changes in ambient temperatures. Iron-vane ammeters are described which have small errors due to direct-current hysteresis and changes in wave-forms.

PRECISION a-c. instruments are today expected to meet demands for accuracy almost unthought of a few years ago. This applies particularly to acceptance and water-rate tests, which require maintained accuracy of instrument indication over long periods of time,—several hours. Compared with the d'Arsonval types, the a-c. instruments have relatively higher internal losses, and are more apt to be susceptible to error due to maintained conditions of load. It is the purpose of this paper to set forth some of the errors to be expected and show how well some modern instruments meet the exacting requirements.

Instruments for field service must incorporate sturdiness of construction with a torque sufficiently high to insure dependable behavior, provided the two features are not incompatible with good sensitivity and low losses. By torque, we refer to the absolute value and not necessarily the torque to weight ratio, though the latter must receive some consideration. It is not so much the torque to weight ratio, but torque itself which determines the life of accuracy in an instrument, other things being equal.

An instrument can be no more constant in indication than are its control springs, and we accordingly begin with springs and treat of the various factors tending to cause errors.

SPRINGS

A great deal of development work has insured that, with careful selection and treatment of the bronze, a control spring which is almost ideal can be made. This is fortunate inasmuch as other instrument refine-

1. Standardizing Laboratory, General Electric Company, West Lynn, Massachusetts.

Presented at the Regional Meeting of Dist. No. 1, at Swampscott, Mass., May 7-9, 1926.

ments would be of little value with springs possessing appreciable "set" and "fatigue" characteristics.

Well made and properly mounted springs do not show "set" in instruments having the usual 90-deg. scale angle, and "fatigue" amounts to less than one minute of arc. This applies to the most severe conditions of stress, and means that the pointer should return to zero within one thickness of its thin knife-edge immediately after release from a four-hour 90-deg. deflection. With the ordinary four-inch pointer, the deviation from zero would not be greater than about 0.004 in., barely perceptible.

The temperature coefficients of both elasticity and resistivity, while not small in value, are, however, quite definite and can be compensated for in the layout of the various circuits o the instrument.

Temperature Errors

Present day demands are such that the precaution of removing instruments from the circuit after reading cannot always be observed. Instruments must, therefore, indicate, with good accuracy, continuously, over a period of hours instead of minutes. This requires among other things a consideration of the effects of temperatures due both to self-heating and to ambient changes.

We do not generally expect errors due to changes in mechanical dimensions, but some instruments do have a tendency for stickiness with an increase in temperature. This is due to the high expansivity of the shaft which makes it "freeze" in its jewel bearings. This especially applies to shafts of aluminum or its alloys. The defect could, of course, be corrected by setting the shaft loose in its jewels, but with a risk of "wobbly" and uncertain indication under normal temperature conditions. A better way is to use material of low expansivity.

The factors most apt to cause errors during sustained conditions of load has been that of inconstancy of the control springs. Though not always the case, many instruments today have springs of a quality which precludes further consideration of spring inconstancy in this paper.

Temperature effects, however, are inherent to all but the electrostatic types and offer a more serious problem. The elasticity of the control spring decreases about 0.04 per cent per deg. cent. rise in temperature at ordinary room temperatures, and by this amount, tends to make the instrument indicate high. The potential circuit, consisting of windings of copper or aluminum, in series with a "swamping" resistor, is increased in resistance with a rise in temperature. This makes for a lower instrument indication. The two effects tend to compensate each other to a degree, depending upon the proportion of windings and series resistor in the potential circuit.

At ordinary room temperatures the windings increase in resistance by about 0.4 per cent per deg. cent. rise, and the series resistor remains practically constant in value. If the circuit is adjusted so that the resistance of the windings is one-tenth that of the whole circuit, then its resistance will increase 0.04 per cent per deg. cent. rise. It might seem that this proportion would effect perfect compensation for effects of the control spring. However, due, to different rates of heat dissipation, it is generally necessary to use other circuit proportions than that of 1 to 10, depending upon the make and type of instrument.

In wattmeters, the resistance of the moving coil may be too low to effect any great degree of compensation. Thus, they may indicate high with increase of temperature. The comparatively high proportion of windings

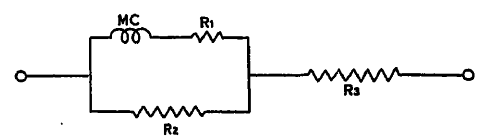

Fig. 1

resistance to total resistance,—unavoidable in voltmeters,—tends for overcompensation, and it is therefore found that voltmeters may indicate low with temperature rise.

Ammeters of the iron-vane type are inherently of a high-torque, which permits us to use windings of few turns and consequential low resistance. The self-heating errors are, therefore, small and we may expect errors due only to changes in ambient temperature.

The sign and magnitude of temperature errors in a-c. instruments may, therefore, vary with different conditions of load, instrument connections and room temperatures. The errors are largely eliminated by careful design and construction. Features receiving

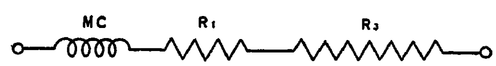

Fig. 2

special consideration are, (a) internal losses and overload capacities, (b) proportion of component parts of the various circuits, and (c) compensating circuits.

Accuracy of indication under sustained loads is not attained at the expense of other desirable features as, for example, high torque, low internal-phase angles, and low frequency and wave-form errors. Such compensating schemes as we find necessary to apply must vitiate none of these important features.

A common form of compensating scheme used for both wattmeters and voltmeters is that given in Fig. 1. Here $M\ C$ denotes the moving coil and R_1, R_2 and R_3 non-inductive, non-capacitive resistors. Effective compensation is secured with the proper values of both resistance and temperature coefficient of resistance of R_1 and R_2. The arrangement is not, however, critical of adjustment. If the initial error in the instrument is

positive, (as is often the case in wattmeters), then we may make R_1 of copper wire, and R_2 of wire possessing a negligible temperature coefficient of resistance. The effect of an increase in temperature then, is to reduce the current in the moving coil by the amount necessary for compensation. In voltmeters the circuit constants would be interchanged.

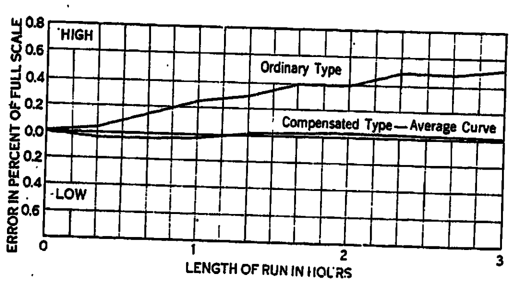

Fig. 3—Electrodynamic Wattmeters

Variation of instrument indication with time under maintained load conditions

Though effective in compensating for temperature, the circuit of Fig. 1 is almost certain to cause in wattmeters large and indefinite inductive errors. The shunting of the moving coil branch with the relatively low resistor R_2 may cause serious errors due to mutual inductance. It is not generally possible to secure good temperature characteristics with R_1 and R_2 of resistance values high enough to avoid complications due to phase angles.

This form of circuit should be reserved for voltmeters. Voltmeters are not sensitive to small differences of phase-angle between moving coil and field coil currents.

For wattmeters, the series method of compensation given in Fig. 2 is preferred. It is equally as effective as the shunted arrangement and does not disturb the internal phase-relations of the instrument. R_1 in this case is a small copper wire resistor placed near the spring.

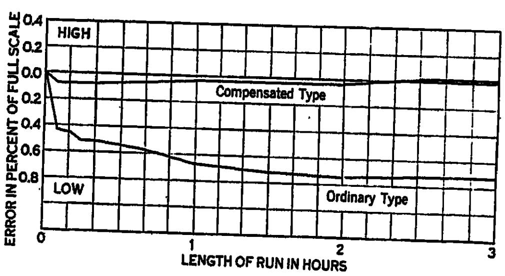

Fig. 4—Electrodynamic Voltmeters

Variation of instrument indication with time under different maintained load conditions

The curves of Figs. 3, 4 and 5 contrast the performance of some compensated instruments with those of the ordinary types. The curves for wattmeters show first, the initial dip due to increase in resistance of the moving coil, and second, as heating continues, the upward trend due to decrease in elasticity of the spring. Finally, as the compensation becomes more and more effective the curves gradually flatten out. The curves for voltmeters show much the same characteristics, though the effect of the spring is inconsiderable.

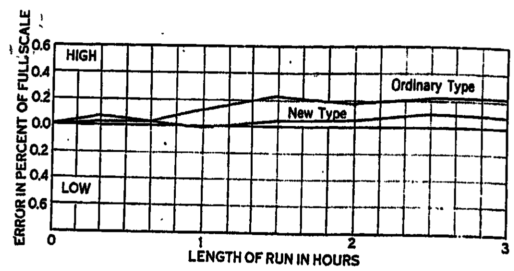

Fig. 5—Iron-Vane Ammeters

Variation of instrument indication with time under maintained load conditions

Figs. 6 and 7 are indicative of what may be expected in good instruments when used under widely

different conditions of loading. Errors observed with one deg. cent. rise in ambient temperature are given in Table I.

TABLE I

	Ordinary Type	Compensated Type
Wattmeters	+ 0.03%	+ 0.006%
Voltmeters	− 0.005%	+ 0.007%
Ammeters	+ 0.02%	+ 0.016%

Internal Phase Angles

These are due both to self inductance in the potential circuit and to mutual inductance in the windings. We are concerned ordinarily with the effects of phase-angles in wattmeters when used on circuits of low power factor, though it is also possible for voltmeters and ammeters to show errors due to phase-angles. Voltmeters and ammeters in which are incorporated certain compensating circuits can be quite sensitive to variations in both frequency and wave form due among other things to incorrect "time constants" of the circuits.

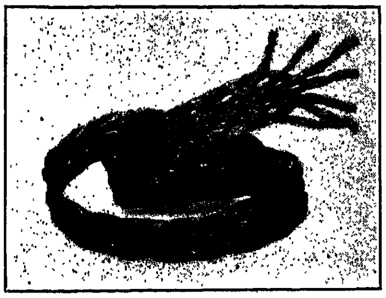

Fig. 8

Mutual inductance effects are negligible in well constructed instruments, and in fact the only possibility of errors from this cause lies either in short-circuit turns in the windings or in the use of low voltage connections in instruments designed for higher voltages, *i. e.*, the results of a 30-volt connection in the ordinary 150-volt instrument should be regarded with suspicion. Wattmeters compensated for temperature with the shunted arrangement of Fig. 1 are very apt to show errors due to mutual inductance.

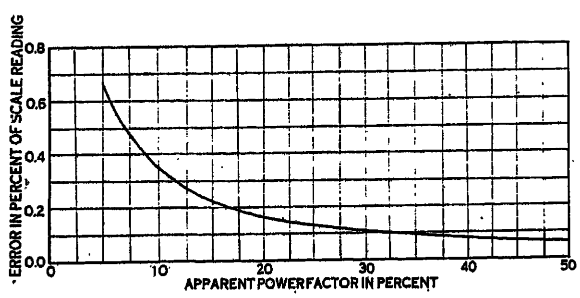

Fig. 9—Electrodynamic Wattmeter
Variation of calculated inductive correction with load power factor
Corrections to be added for leading current; subtracted for lagging current

Low phase-angles are, of course, very desirable but it is equally desirable that such as do occur be definite and amenable to calculation. Eddy currents induced in metal frame-work and certain temperature compensating circuits tend to give uncertainty both to sign and magnitude of the inductive errors. The multiple connection employed in the current winding to obtain higher ratings may add further complications, due to inequalities. Equality, which is necessary to avoid the presence of parasitic currents in the circuit, is more nearly approached with the multiple connection of two distinct conductors, than with two separate coils. Fig. 8 illustrates how equality is obtained in a high-capacity wattmeter current winding. Well designed series resistors are, for all practical purposes, both non-inductive and non-capacitive, though in some of the older forms capacitance predominated with the resulting complications.

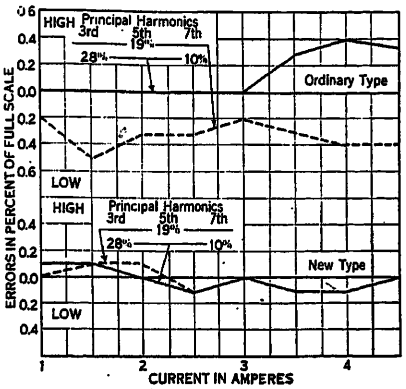

Fig. 10—Iron-Vane Ammeters
Variation in indication due to irregular wave form

A representative curve of inductive corrections for a wattmeter is given in Fig. 9. It is computed for 60 cycles.

Frequency and Wave Form

Except for induction errors, wattmeters are insensitive to variations in commercial frequency and wave form.

The relatively high self-inductance of voltmeters involves a careful consideration of their "time constants" if they are to be used interchangeably on direct- and alternating-current circuits. There should be no detectable variation in indication between mean reversed direct-current and an alternating-current of 60 cycles. In terms of 125 cycles, the variation ought to be no more than 0.05 per cent,—barely perceptible. Voltmeters of the electrodynamic type are unaffected by ordinary wave distortion, provided they are free of frequency errors.

The iron vane ammeter, though practically insensitive to variation in commercial frequency was, until recently, quite susceptible to changes in wave form. The use of new magnetic materials enables us to reduce errors from this cause from about 0.5 to 0.1 per cent. (Fig. 10.) These errors refer to wave forms having prominent third and fifth harmonics.

Hysteresis on Direct Current

Shielded wattmeters and voltmeters of the electrodynamic type show no differences in indication with reversal of direct-current if the shields are free of permanent magnetism. Extreme overloads may, however, give to the shields a definite magnetic polarity, and it is well to check the instruments occasionally for this condition.

Previously, the iron-vane ammeters were very susceptible to magnetic hysteresis, and the variation in indication with reversed direct-currents was great enough to prevent even a fair degree of accuracy. The magnitude of these errors depends upon the previous history of magnetization of the iron. Aside from the ordinary form of hysteresis, due to changing polarity and magnitude of the magnetic flux, the iron is also susceptible to changes in direction of the flux through it. We may call the latter "rotational hysteresis." Instruments having the irons mounted eccentric to the shaft exhibit effects of rotational hysteresis to a marked degree.

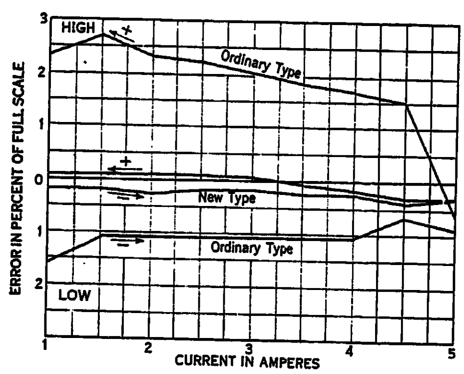

Fig. 11—Iron-Vane Ammeters

Variation in instrument indication with direct-current showing effect of magnetic hysteresis

New and specially prepared magnetic materials now enable us to construct iron-vane ammeters having little hysteresis error. Errors of two per cent so frequently observed in this type have been reduced to about 0.3 per cent (Fig. 11). For alternating-current work it would appear that the present-day iron-vane ammeter is a very dependable instrument. In view of the improved wave-form and hysteresis characteristics, this type is to be preferred over the low-torque and high-impedance type employing the shunted, moving-coil principle. The latter type is of course useful in the laboratory in making a-c. = d-c. comparisons. Laboratory standard ammeters are, therefore, of the shunted electrodynamic type.

Stray-Field Errors

High-grade a-c. instruments are sufficiently well shielded to prevent errors from stray fields under ordinary conditions. Possibility of error in instrument of high-current rating is remote if we use twisted conductors.

A field of 20 gauses "in-phase" is equivalent to about 100 times the horizontal component of the earth's magnetism, or the field 12 inches distant from a long straight conductor carrying 3000 amperes. In shielded instruments, this field should cause no error greater than about 0.4 per cent of full scale. With ordinary conditions of use, stray-field errors would than be undetectable. In general, we find that the higher-torque instruments are the least affected by stray fields, which is an argument for high torque.

To eliminate eddy currents and hysteresis, the shields are built of well-insulated laminations. Low power-factor errors in wattmeters have sometimes been traced to eddy currents in the shield. Improper methods of bolting the laminations together may be responsible for these errors.

The shunt compensating scheme of Fig. 1 in the paper is due to Swinburne (1887) and the series scheme of Fig. 2 was suggested by Dr. H. B. Brooks in his paper "The Accuracy of Commercial Electrical Measurements," (A. I. E. E. Transactions, Vol. XXXIX, part 1, p. 517). A complete and comprehensive treatment of the effects of self- and mutual-inductance is given in this paper of Dr. Brooks. Reference is also suggested to C. V. Drysdale's paper upon the subject of inductive errors and given in the *Electrician* (London), Vol. 46, pp. 774-8, 1901 and Vol. 76, pp. 523-5, 1916.

Discussion

C. G. Brown: As a-c. ammeters were previously made, the d-c. readings were so different according to the direction of flow of current that it was not feasible to calibrate on d-c. The metal in the moving system of the a-c. ammeter which Mr. Hoare has described has its direct and reversed d-c. readings so nearly alike that when necessary it can be checked on d-c.

B. W. St. Clair: One of the very important points of instrument construction mentioned in Mr. Hoare's paper that has a great deal to do with the dependability of instruments in service is that of instrument springs. The forces involved in indicating instruments are surprisingly small. The usual full-scale torque range is from 0.1 millimeter-gram to 10 millimeter-grams, which translated into more usual terms corresponds to 6×10^{-5} to 6×10^{-7} ft-lb. Despite the smallness of the forces involved, the spring does a remarkable piece of work, as in the better grade of test instruments the error of its indication is generally less than 0.1 of one small division, which is approximately one part in a thousand. Translated into other terms, the ordinary instrument spring on the better-grade instruments is dependable to about one minute of arc. Dependability of this high order is secured only by very careful choice of materials, unusual manufacturing facilities and by great care in the mounting of the spring in its final supports in the instrument.

I mention the springs as one of a number of very highly important members that contribute to the final dependability of the instrument. The magnets, the bearings, the constancy of shape of the windings, and many other factors are of equal importance.

The Measurement of Electrical Output of Large A-C. Turbo Generators During Water-Rate Tests

BY EVERETT S. LEE[1]

Associate, A. I. E. E.

Synopsis:—The water-rate of large a-c. turbo-generators is determined in place with the generator supplying power to the existing commercial load. Such procedure requires that the electrical output be accurately measured under conditions where the load is practically always varying slightly, and where it may be varying considerably. Portable test meters are frequently used for such measurement. The use of portable indicating wattmeters is absolutely feasible for such measurement even where the load variations are extreme, with the resultant accruing advantage that the superior operating characteristics of the portable indicating wattmeters, particularly as regards their permanency, are utilized.

Either the two-wattmeter or three-wattmeter method for measuring the power of a three-phase circuit may be employed.

Great care should be used in selecting instruments, particular reference being made to their past history. Comparisons against secondary standards should be made under conditions simulating those of the test.

Observations are made at frequent intervals depending upon the accuracy desired in the final result.

The accuracy of the final values of water-rate obtainable in practise is such that the per cent average deviation from the mean will be within ± 0.25 per cent. This means that practically all individual test results will fall in a belt 1 per cent wide, while the probably true value of water-rate will be located within a belt which will vary in width from 0.5 per cent to 0.25 per cent depending upon the conditions.

The results of a water-rate test on a highly variable load wherein the electrical output was measured with portable indicating wattmeters and the observations were obtained both with moving-picture cameras and by observers show the equality of the performance of the observers and the cameras under the existing conditions.

Introduction

THIS paper describes the methods used in measuring the electrical output in forty series of water-rate tests during the past five years on thirty-one machines located in twenty different power plants in this country. The machines tested ranged in rating from 10,000 kw. to 45,000 kw., and the test loads were the usual commercial loads supplied by the respective machines.

These tests were either guarantee acceptance tests or were for purposes of determining the improvement in water-rate produced by advance in machine design. Measurements of maximum possible accuracy were thus required and all means known to the art for attaining such results were available for use as far as they could be applied under the conditions imposed when testing on commercial loads.

Instrument Connections

The usual load being connected three-phase, the three-wattmeter method was used in practically all of the series of tests because of its symmetry. The connections are shown in Fig. 1. The generator neutral being available in practically all large turbo-generators, the connections for the three-wattmeter method are easily made, a set of instruments being connected into each phase. Values of phase voltage, current, and power are thus measured directly, from which measurements the phase power factor can be readily calculated. These values are required for making the necessary corrections to the readings of the wattmeters. Since the phase power unbalance is usually not more than two or three per cent, the three sets of instruments are operating under practically identical conditions which is an advantage both when comparing the instruments and applying corrections, and in operating with them. There is no disadvantage as regards measurement, however, if the phase unbalance is large, as the phase values are directly measured in each case. Since the phase power factor is the same as that at which the wattmeters are operating, and since the former is rarely

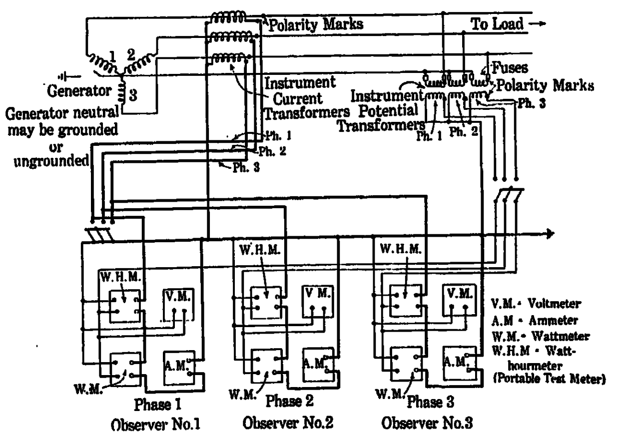

FIG. 1—DIAGRAM OF CONNECTIONS AND TABLE LAYOUT FOR MEASURING ELECTRICAL POWER IN A THREE-PHASE CIRCUIT USING THE THREE-WATTMETER METHOD

less than 0.8, the wattmeters are operating under their best condition which is near to unity power factor.

The two-wattmeter method was used in some series of tests. The connections are shown in Fig. 2. The two-wattmeter method requires less equipment and one less observer than the three-wattmeter method, but it is not symmetrical because the phase relation between the current and voltage supplied to the respective wattmeters differs from that of the load, and is different in

1. General Engineering Laboratory, General Electric Co., Schenectady, New York.

Presented at the Regional Meeting of Dist. No. 1, Swampscott, Mass., May 7-9, 1925.

the respective wattmeters. The actual conditions as regards the current, voltage, and phase relation between them for the individual wattmeters can be determined from the well-known relations existing when measuring three-phase power by the two-wattmeter method. These values must be known when determining the conditions under which the wattmeters are to be compared, and when correcting the wattmeter readings later during test. Except at unity power-factor load the indications of the two wattmeters will be at different portions of the scales; this requires that consideration be given the wattmeters individually as to the suitability of scale range. When the load power factor is 0.8, current lagging, and load balanced, the low-

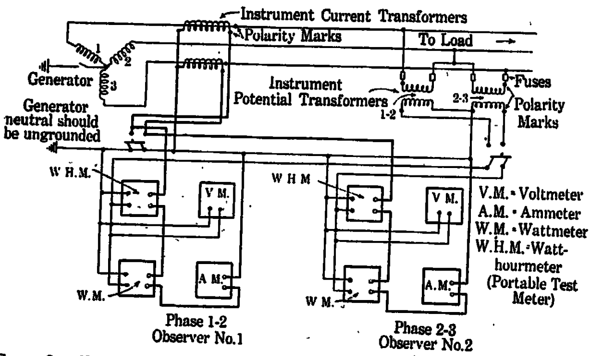

Fig. 2—Diagram of Connections and Table Layout for Measuring Electrical Power in a Three-Phase Circuit Using the Two-Wattmeter Method

reading wattmeter is operating at a power factor of 0.39. This is not at the best operating point of a wattmeter as regards power factor. If the generator neutral is grounded and a ground occurs at any other point on the system, the power may not be correctly measured. For this reason the generator neutral should be ungrounded during test.

Experience does not indicate that there is any real difference in the over-all accuracy of a water-rate determination whether the three-wattmeter method or the two-wattmeter method is used, provided that the existing conditions are determined and the proper corrections made for same in each method. Where a large number of series of tests are to be made under widely varying conditions, it is felt that these conditions can be determined and the necessary corrections applied more easily when using the three-wattmeter method. For this reason the latter method has been generally used, in spite of the increased equipment and additional observer required, and the uniformly satisfactory results obtained thereby have justified this selection.

Instruments

Portable indicating wattmeters have been chosen for measuring the electrical output because of their superior characteristics, particularly as regards their permanency. Portable test meters have usually been used in parallel with the indicating wattmeters as shown by the connections Figs. 1 and 2. This was done to study the operating characteristics of both indicating instruments and portable test meters.

For water-rate tests, where sustained accuracy is required, instruments exhibiting the most permanent calibration characteristics should be used. In order to select such instruments from any group available, they should be compared regularly with secondary standards and a careful record should be maintained of all such comparisons made. By means of such a record over a number of years the instruments of greatest permanency will be disclosed. Such a procedure is of greatest importance and should be regularly followed, especially with the wattmeters. Table I shows the results of successive comparisons made upon a portable indicating wattmeter thus selected from a group of similarly made instruments. The wattmeter was carried from laboratory to laboratory by messenger. The results show no difference practically greater than 0.1 of 1 small scale division. This is typical of the performance possible from selected instruments. From such a proof of permanency of calibration possible in high-grade portable indicating wattmeters, the surety for sustained high accuracy throughout a series of tests is evident.

Having selected the instruments, it is necessary that they be compared against secondary standards, under

0.1 of 1 small scale division is 0.5 watts

conditions simulating test conditions. Ammeters and voltmeters should be compared at major scale points, with preferably the same kind of current and voltage to be measured during test. Wattmeters may be compared using direct voltage and current by using the average of direct and reversed readings. This assumes that previous measurements have been made on the instruments and standards employed to assure the correctness of such procedure. The value of the voltage maintained on the potential circuit of the wattmeter during comparison should be the test value. The interconnections of the potential and current coil maintained during the comparison should be likewise maintained during test. The value of the phase angle of the potential circuit of the wattmeter requires consideration, though in all high-grade wattmeters this is quite small, such as three to five minutes, and may usually be neglected without error in final result.

Attention should be directed to the small scale divisions of the wattmeters to see that these are properly located. A scale wherein the small scale divisions are improperly located should be replaced with a scale properly made. As mentioned above, when using the two-wattmeter method, one wattmeter may be indicating at the lower end of the scale; it is necessary, under these conditions, that the scale be open at the lower end.

In order to be assured that there is no heating error in the wattmeters due to continuous operation during the water-rate test, comparisons should be made at the beginning and end of a heat run on the wattmeters at normal voltage and maximum current to be measured. If a heating error is found, correction should be made for same by using the comparison obtained with the instrument hot and then allowing the instrument to become hot before use in test. However, the best high-grade portable wattmeters have practically a zero heating error, and such instruments should be used during all tests where maximum accuracy is required.

If watthour meters are to be used, they should be calibrated and adjusted in the laboratory so as to have their best operating characteristics in the range of test values. However, the accuracy curve employed for correction during test, should be obtained "in-place" using the test current and voltage. This should be done with portable indicating wattmeters during the water-rate test. The connections shown in Figs. 1 and 2 allow for such "in-place" checks to be made. Two-minute runs, with the observer reading the indicating wattmeter as rapidly as possible, which will give 40 to 60 observations per minute, are suggested as necessary and sufficient.

A frequency indicator, or other instruments as desired, may be included in the instrument test circuit.

Instrument current and potential transformers of proper rating and accuracy characteristics should be chosen. Values of ratio and phase angle for the condition of loading equivalent to the instruments, meters and leads used during test should be obtained by recognized means to cover the range of test values of current and voltage.

All instruments should be compared immediately before and immediately after the test series. Intermediate tests at two-week intervals may be advisable if the test series is long. Instrument transformers usually need to be calibrated only once during the test series, preferably immediately preceding it. Watthour meters must be calibrated "in-place," preferably immediately before and immediately after each individual test.

Observations

The instruments having been carefully selected and compared for the test conditions, they are connected into the generator line leads as shown either in Figs. 1 or 2. After checking over connections, and comparing the test-instrument readings with the available switchboard-instrument readings to see that there are no major errors, everything is ready to run a test as regards the measurement of electrical output.

Testing on commercial loads requires that means be provided for determining the readings of the indicating wattmeters over a wide range of load conditions. The load may be extremely variable, as in some railway systems, or quite steady as in a large system of combined power and lighting. The means employed has been to take a large number of observations during the test on the theory that if the number of observations is sufficiently large, the average value obtained therefrom will be accurate to within the desired limit, and experience has justified this procedure.

The uniformly satisfactory results of many tests indicate that a test of one-hour duration is ample. Table II shows results to substantiate this conclusion. If it is felt that the conditions at hand warrant tests of longer duration, several tests should be run at the longer duration and the results for each hour of the run be calculated. Such results will indicate whether the necessity for tests longer than one hour is justified. If such is the case, it is quite possible that some of the test conditions are not right and should be altered. In this connection it should be remembered that three one-hour tests at any load point run non-consecutively, are of greater value than three one-hour tests run consecutively.

The observers for the indicating instruments should be men who are capable of comprehending the nature of the work they are doing and who recognize that their efforts should be directed towards obtaining an honest answer as to the value of the water-rate of the machine under test. Their contribution to this effort is recording the readings of the indicating instruments as they honestly believe them to be. Experience obtained with high school graduates, college undergraduates and graduates, and construction men of mature years, indicates that any of these types of men are equally suitable as observers during a test series including some

dozen or two dozen tests and continuing for one or two weeks. The instructions given to all observers are as follows:

1. Place yourself so that you are comfortable and can see the instrument scale without hindrance.

2. Study the appearance of the instrument scale, pointer, and mirror, and have these fixed so clearly in mind that you can look at them and see them with the same familiarity as you would a book or newspaper.

3. Read the position of the pointer on the scale over its image in the mirror just as you see it when you look at it at the designated signal with both eyes open. Read freely and without constraint. Record the value observed.

4. At all other times rest the eyes by looking around as desired. Do not try to average readings during an interval.

5. Do not allow your readings to be influenced by any preconceived ideas as to what the value is probably going to be. Record the result just as it appears to you at the time.

Each observer is assigned to one group of instruments. Each observer reads the indicating wattmeter at a given signal, such as a bell. Unless the observers are widely separated, no preliminary signal is necessary. Instruments are read in regular order, the wattmeter first, followed by the ammeter and voltmeter. The two latter instruments need be read only at every other signal, or in some cases, every fifth signal. Watthour meters are read at the beginning and at the end of every test.

A relief observer will be necessary. The relief can be utilized also to read the values of field voltage and current, which as a rule need be read only at five-minutes intervals during a one-hour test. A supervisor is necessary, together with an assistant who acts as calculator. There are thus required four observers, one calculator, and a supervisor. The supervisor will have to help the calculator after the completion of a days run when the observers are released.

The supervisor and the observers will have to cooperate in order that the supervisor may help the observers to do their work and to detect undesirable tendencies in making observations. Rotating the observers is good practise. A good way to compare observers is, unknown to them, to connect all of the

TABLE II

WATER-RATE FOR EACH HOUR OF TESTS OF LONGER THAN 1-HOUR DURATION

Water-rate for each hour is expressed in per cent of the water-rate obtained from the test, which value is expressed as 100 per cent

Turbo-Generator Designation Number	Test Designation Number	Duration of Test	Water-Rate (Expressed on basis of 100% for Test Value)				Maximum Difference From Test Value Expressed In Per cent	Type of Load

*Ammeter and voltmeter read every two minutes

instruments in series on one set of current and potential transformers. Then run for a convenient time interval, preferably an hour, as during a test, and compare the results obtained by the individual observers. Results from such a procedure are shown in Table III.

The frequency of observation necessary has been determined from the following rule: Readings shall be taken at such intervals during a test that the average of all the observations does not differ from the average of all the alternate observations by more than an assigned value depending upon the accuracy desired. For most accurate results under practical conditions a value of 0. 1 per cent has been adopted. For most commercial loads this value has been attained on one-hour tests by taking readings every minute. Table IV shows some results in this connection.

TABLE IV

DIFFERENCE BETWEEN AVERAGE OF ALL THE OBSERVATIONS AND AVERAGE OF ALL THE ALTERNATE OBSERVATIONS

Turbo-Generator Designation Number	No. of tests	Duration Hours	Time Interval between Readings Seconds	Load Conditions	Percent Difference between all Observations and all the alternate Observations, for the number of tests indicated			Method of Measuring
					Average	Maximum	Minimum	
1	27	4 tests, 2 hrs. 23 tests, 1 hr.	10	Rapidly fluctuating Railway load	0.20	0.72	0.01	3-wattmeter

6	11	1	60	Steady Lighting	0.20	0.62	0.02	3-wattmeter
3	3	1	60	Steady Lighting	0.18	0.39	0.07	3-wattmeter

CALCULATIONS

The average kilowatt output for any test is the sum of the corrected readings of the wattmeters. The corrected reading for each wattmeter for any test is equal to

$$W \times C.T. \times P.T. \times P_h$$

where: W is the average of all the corrected indications of the wattmeters, expressed in kilowatts. The correction used for each wattmeter is the average of all the comparisons which are made between it and the secondary standards.

$C.T.$ is the true ratio under test conditions of the current transformer to which the wattmeter is connected.

$P.T.$ is the true ratio under test conditions of the potential transformer to which the wattmeter is connected.

P_h is the combined correction factor for phase angle of the current and potential transformers and wattmeter.[2]

The kilowatt-hour output for any test is equal to the product of the average kilowatt output and the duration of the test in hours.

If, when comparing any wattmeter, the comparison at any point differs from the correction which has been used for previous corrections at this point by more than an assigned value (for most accurate work, taken to be 0.3 per cent of full scale value), an additional comparison or comparisons should be made immediately at this point until their results do not differ among themselves by more than 0.1 per cent of full scale value, and the average of these results will then be taken as the value of the point in question at the time of this comparison. In the event that the excess variation (0.3 per cent of full scale value) still remains, the new value found shall be taken as correct, and all tests in which this scale point may cause error should be investigated to determine the amount to which they have been affected. Such tests may have to be rejected. With the best, high-grade, portable indicating instruments now available, it has been found that the need for this procedure will be rare. However, a statement of such procedure is advisable for guidance if needed. Table V shows the results of successive comparisons of a wattmeter before, during, and after a test series including the suggested heat run. The test series was that described later in this paper (See Section entitled "Photographic Observation,") dated from Jan. 3, to Jan. 31, 1924, and the wattmeter was one of those read by observers. The performance of this wattmeter shows what has been found to be typical of high-grade portable indicating wattmeter performance during many test series.

ACCURACY OF FINAL RESULT

A value of accuracy of the final result of the electrical output alone may be arrived at from a knowledge of the precision of the wattmeters and instrument transformers used. However, a more satisfactory accuracy figure, is one which can be applied to the over-all measurement of the water-rate of the turbo-generator. This figure is the per cent averaged eviation from the mean, (defined below), and is applied to the results obtained from three or more tests at any given load point.[3] Enough tests can be run at any load point to

*Comparison made after a four-hour heat run at 400 watts, 100 volts

bring the value of the per cent average deviation from the mean within any desired value. It has been found that a value within ± 0.25 per cent can be attained in water-rate tests wherein the measurements of electrical output are taken as are described herein and where equal care is given in making the steam-input measurements and corrections. Any individual test at a given load whose value of water rate differs from the mean value of all tests at that load by more than 0.75 per cent may be rejected. It is assumed in the above discussion that all determinate errors have been eliminated and that only indeterminate errors remain.

The per cent average deviation from the mean is given by the formula:

$$\text{Per cent } A.\,D. = \frac{(d_1 + d_2 + d_3 + d_n)\,100}{A\,N\sqrt{N}}$$

where A is the average of the values of water-rate obtained from

N tests

N is the number of tests

and $d_1 = W R_1 - A$

$d_2 = W R_2 - A$

$d_n = W R_n - A$, etc.

where $W R_1$, $W R_2$, $W R_n$ are the values of water-rate obtained on the 1st, 2nd and succeeding tests. The absolute values of d_1, d_2, and d_n, are used regardless of sign.

Table VI shows accuracy data from several water-rate tests on large a-c. turbo-generators. The values in the column headed "Per cent maximum difference between values of water-rate obtained from tests at each load," show that practically all individual test results fall within a belt one per cent wide. The values in the column headed "Per cent average deviation from the mean," show that the probably true value of water-

rate is located within a belt varying in width from 0.5 per cent to 0.25 per cent depending upon the conditions.

Photographic Observation

This paper would not be complete without a description of the method whereby Messrs. Kidder and Hall of the Interborough Rapid Transit Co. of New York measured the electrical output of a turbo-generator by means of portable indicating wattmeters, the observations of which were made with moving picture cameras. The use of a second set of portable indicating wattmeters in parallel with the test wattmeters, and read by observers, gave opportunity to determine the effectiveness of the observers.

The photographic measurement was made by mounting an indicating wattmeter in a vertical position together with a moving picture camera so focused that the scale of the instrument covered the entire width of the film. The wattmeter was provided with a special pear-shaped target pointer, and was properly balanced for operation with the shaft horizontal. Three such

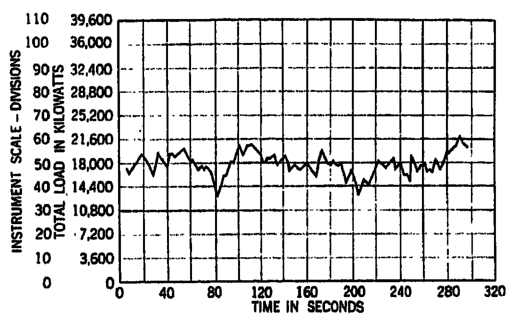

Fig. 3—Load Curve on One-Phase of Turbo-Generator Showing Fluctuations over Instrument Scale

Observations obtained photographically for five minutes of one-second intervals.

instruments and cameras were employed, one set for each phase. The shutter mechanisms of the cameras were operated in synchronism from a common motor-driven drive shaft. Number counters were so mounted on each instrument that the number appeared on the film, thus providing means for identifying all pictures. A watch was photographed on the film at the beginning and at the end of each test to obtain the rate of observation. Suitable illumination was produced from mercury vapor tubes. The entire installation was mounted in the generator room near the machine under test.

The shutter operating mechanism operated the shutters at one-second intervals for short-time duration. For long-time duration such as one-hour test periods, the fastest practicable rate was about one operation per seven seconds, which was the rate maintained during the water-rate tests.

Readings were obtained from the film after development by projecting the image on a screen through a projector and reading the value shown by the pointer. Readings were easily made to within 0.1 small scale division of the wattmeter scale, which is 0.5 watts.

The instruments were compared by setting up secondary standards at the instrument installation in the generator room. Holding scale values on the secondary standard, photographs were taken of the wattmeter indications. After developing the films, the readings were made from the projected image on the screen, and corrections thus obtained. These corrections were later used to correct the wattmeter readings during test. Comparisons were made of the instruments before and

after the test series, and intermediate to these at two-week intervals. A preliminary heat run was also made, as previously indicated. The comparisons were all made by the Electrical Testing Laboratories, New York.

The wattmeters used in parallel with the test instruments were compared at the same time as the test instruments except that they were read by observers. Observations were made during test following the principles as described herein. Readings were made at 10-second intervals. Tests were of one-hour duration,

there being three tests each day for nine days during a period of four weeks. At no time did the observers complain of fatigue.

Fig. 3 shows a typical curve of the Interborough Rapid Transit Company's load. This is a railway load, and the continual variation was the reason for employing photographic means for obtaining accurate observations. This load is undoubtedly the most variable of the large commercial loads in this country, and results obtained thereon may be taken as representative of the attainment possible under the worst of conditions as regards variable load.

The performances of the photographic method and the visual method are best shown by Tables VII, VIII and IX. These speak for themselves and show the truly remarkable results that may be obtained on a highly variable load with portable indicating wattmeters both as read with cameras and with observers. The equality of the results obtained by the two methods is evident. The art of electrical measurements is indebted to Messrs. Kidder and Hall for their persistent efforts in overcoming the difficulties in the photographic method, and in carrying it through to a successful conclusion.

Conclusion

The water-rate of large a-c. turbo-generators can be determined with such accuracy that the per cent average deviation from the mean, as defined, will be within ± 0.25 per cent. This means that practically all individual test results will fall in a belt one per cent wide, while the probably true value of water rate will be located within a belt varying in width from 0.5 per cent to 0.25 per cent, depending upon the conditions. Such results as these can be obtained on commercial loads, even when the load fluctuations are violent, by using portable indicating wattmeters read by observers following the methods herein described for measuring the electrical output, and with commensurate care in making the steam-input measurements and corrections.

The author wishes to acknowledge the helpful guidance of Mr. L. T. Robinson[4] in carrying on with the tests described in this paper, as well as the assistance received from Messrs. L. J. Cavannaugh and W. S. Vogel of the General Engineering Laboratory of the General Electric Company in conducting the electrical measurements in many of the tests. J. L. Roberts, of the Turbine Department of the General Electric Co., deserves great credit for his contribution to this work being in charge of the water-rate tests. The effective cooperation of the personnel in the Central Stations where tests were made was also most cordial and helpful, and their contribution to this work is hereby acknowledged.

Discussion

H. W. Oetinger: Reference is made to the checking of instrument transformers with equivalent secondary burdens. The usual procedure in determining this secondary burden is to calculate it from the published data of the instrument coil constants and the size and length of leads. Where test wiring is used exclusively, there can be no question regarding this procedure but where the test instruments are inserted in conjunction with station instruments and wiring, there is some question as to what is actually in the circuit. In one case it was found that coils of unknown and variable volt-ampere characteristics were left in circuit. In such cases it seems desirable to actually

4. See papers by Mr. L. T. Robinson as follows:

"Testing Steam Turbines and Steam Turbo-Generators," E. D. Dickinson and L. T. Robinson. Transactions A. I. E. E., 1910, Vol. XXIX, part II, page 1679.

"The Determination of Stray Losses from Input-Output Tests," L. T. Robinson. Transactions A. I. E. E., 1913, Vol. XXXI, part I, page 531.

measure the secondary burden and include all connections and instruments to be used during the test. A voltmeter, ammeter and wattmeter can be used in conjunction with a load box. The disconnection is made at the terminals of the instrument transformers and voltage applied to the leads at this point.

Under "Observations" mention is made of readings covering a wide range of load variations. For such load conditions it is important that the wattmeters used have practically no scale errors within the range of possible load swings. If the generator output is calculated strictly in accordance with the statements under "Calculations" this would not be necessary, but the usual procedure is to correct the average wattmeter reading only and not to average the corrected readings. The latter involves an immense amount of additional labor which can be eliminated by observing the above requirement.

With reference to "Photographic Observations," these have the distinct advantage of giving a permanent record of the instrument indications and any questionable data can be checked very readily by reading the film. There is, however, one point which should be recognized if speedy determination of the kilowatt output is required. By the visual method, final results of the test can be calculated within two hours. By the photographic method it is necessary to develop, dry and read the film which involves several times the delay required by the visual method.

J. A. Johnson: In the old days, when water was measured by means of weirs and piezometers we never had to worry much about the accuracy of our electrical measurements because the hydraulic measurements were so much worse. But within the last few years, there have been new methods perfected for measuring the water supplied to a turbine, so that we are now able to get hydraulic measurements so accurate that they have put the electrical engineer on his toes to produce electrical measurements of equal accuracy. We found that the discrepancies we were getting in our over-all results were apparently due to inaccuracies in the electrical measurements rather than the hydraulic. So I welcome Mr. Lee's paper showing that electrical measurements can be taken accurately by observers with indicating instruments, and that it is not necessary to use photographic methods, because it is always much easier to use apparatus which is available in any standard power company's laboratory than to have to develop special apparatus.

W. H. Pratt: Mr. Lee's paper shows what can be done by using instruments in a careful way, and it recalls to me work that I did about twenty-five years ago when we first had occasion to calibrate large watthour meters on very fluctuating railway loads. We found by averaging results on readings, simply taken as Mr. Lee describes, not attempting to average in the mind but putting down the readings as seen from moment to moment, that it was perfectly possible to get successive calibrations in agreement within a matter of a few tenths of a per cent, frequently within two-tenths of a per cent. So I think there is no doubt that this averaging of a moderate number of observations is an absolutely valid method.

In Mr. Lee's paper the use of a portable test meter is mentioned, and I think as a matter of record we should note that this is a use for which this meter was not originally intended. The accuracy that he seeks to obtain is higher than would be requisite when the meter is used as it is intended to be used. The meter in its proper field fully meets the conditions required.

F. V. Magalhaes: It is comforting, as well as interesting, to those handling tests involving the ordinary instruments and observations, to have the accepted methods of handling tests proved reliable by Mr. Lee's presentation of the use of the camera to check the readings of the instruments.

I should like to use Mr. Lee's paper as a vehicle for advancing a plea; and in advancing it, it is not intended as a criticism of this particular paper. The plea is for a careful consideration and statement of the necessities involved in any problem of measurement. These necessities or specifications, as well as the limitations of the instruments that may be selected for the test, should be clearly understood in the minds of those conducting the test.

The use of the rotating test meter for various purposes and its limitations have been quite actively under discussion during the past year or so and it is the use of this particular instrument that I wish to discuss. The uses which have been proposed or suggested for this instrument can be classified roughly into four necessities. The instrument was specifically designed to meet one of them but an effort is being made to use it for the other three. This effort has been attended with some lack of success and irritation on the part of those attempting it.

Firstly, there has been for many years a necessity for a convenient portable instrument for use in the field for making several hundred or several thousand tests a month of the house-type watthour meter installed on the lines of public utilities. For that purpose, experiments were started possibly twenty or twenty-five years ago, toward the development of a portable test meter or rotating test meter. The conditions to be met were primarily portability with a combination of as many ranges or scales within one instrument as it was possible to develop. The accuracies aimed at were, let us say, within 0.75 per cent.

Many are familiar with the successful use of the portable test meter in connection with the routine tests of service-type watthour meters in customers' premises.

The second problem is the one to which Mr. Lee's paper refers; namely, the measurement of energy during water-rate tests or acceptance tests on generators.

On tests of this character, the requirements for accuracy are more rigorous than for the field tests of commercial watthour meters and could probably be called $\pm$ 0.25 per cent rather than $\pm$0.75 per cent which was set up in case No. 1. Tests of this character would be made indoors in a station and it is at once apparent that the requirements for this test are different from the requirements which dictated the development of the rotating test meter for use in the field. There is no real necessity for using an instrument primarily designed for portability. Also the precision expected is much greater than that for which the portable instrument was originally designed.

The third problem that has arisen recently is the necessity for a reference standard to calibrate the watthour meters used for the interchange of power between large systems. These watthour meters are, as a general rule, very few in number and are always located within a power house. There would again be no necessity for the use of an instrument specially designed for portable use and an effort made to attain a precision of possibly $\pm$ 0.25 per cent.

A second variation of this same problem is the necessity for an instrument to calibrate the meters which sell energy directly to a small number of large customers, such as some of the utilities in the Niagara territory which have a total of possibly one or two hundred watthour meters, representing all of their customers as compared with other utilities having several thousand or several hundred thousand watthour meters. The instrument used to calibrate these relatively few watthour meters could properly be of different characteristics, possibly not quite so portable but providing a higher precision in the measurements. In this case a precision of possibly $\pm$ 0.20 per cent or 0.30 per cent might be required which again is much greater than the 0.75 per cent which the accepted type of rotating test meter now provides.

The fourth problem is the necessity for a reference standard of some description in the laboratories of public utilities or universities or public-service commissions as an instrument to certify the accuracy of the rotating test meters that are used in the field. Here again the conditions under which the instrument would be used are laboratory conditions so that there is no necessity for an instrument primarily designed for portable use

and the requirements for the precision of the measurements would be of the order of ± 0.20 per cent.

To sum it up, the present type of rotating test meter which is being used successfully by the utilities for making routine field tests of watthour meters very possibly will not meet the requirements of other forms of tests which I have just outlined. It is possible, however, that a different form of test meter may be developed which will meet all of these conditions satisfactorily.

To present an illustration from another field of measurement, I will refer to the subject of time measurements. The stop-watch was developed a great many years ago, primarily for the purpose of being carried around in a person's pocket to time races. Since this original development and use of the stop-watch, there have arisen the necessities of the electrical business with their incidental electrical and time measurements. An effort has been made to use this stop-watch in connection with more or less precise electrical measurements. The stop watch has continuously suffered from the comparison of the results which it can supply with the results obtained from good grade electrical instruments. If, precise measurements of time are required in the laboratory, it is quite obvious that some different form of measuring device should be used and this would undoubtedly be a device not primarily designed for portable use in a person's pocket.

The accuracy of the results which can be obtained from the stop-watch is probably adequate for timing a horse race or boat race, but no one should presume to use a stop-watch for the measurement of the time of flight of projectiles or the discharge of a condenser or other problems which have arisen since the stop-watch was originally designed. I am loath to class the rotating test meter with the stop-watch, but the comparison is only made to illustrate the difficulties which are being experienced with the use of the rotating test meter. These difficulties arise not with the instrument itself but from the use to which it has been applied.

C. G. Brown: There is one point to which I should like to call attention—probably a great many of Mr. Lee's readings are taken when the needle of the instrument is remaining fairly stationary. I think that if he were to have a large number of readings taken in every case when the needle is moving rapidly, (we shall say, up scale), he would find considerable difference in the observations from the different men. Some men would consistently read lower, while some would consistently read higher. It would also be interesting if, in an ordinary series of tests, those values that are taken when the needle is swinging rapidly up at the time of the observation could be marked, and then see how those results check up with the values obtained when the needle is swinging rapidly down.

B. W. St. Clair: Mr. Lee's suggestion that in making very important tests the previous history of the instruments involved should be investigated before putting undue dependence upon test results is a very good one. The demands made upon test equipment for constancy under unusual service conditions are very severe in the kind of tests referred to in Mr. Lee's paper. It is seldom in ordinary testing work that conditions as severe as these will be encountered. When consideration is given to the many factors that enter into instrument constancy it is really surprising that test equipment performs as well as it does under the adverse conditions often met with in turbine-room tests.

M. W. Leonard and E. J. Mommo (by letter): If any water-rate test is conducted throughout with the same care and attention to detail which Mr. Lee advocates for the electrical part of the work there should be no difficulty in obtaining a final accuracy of ± 0.25 per cent.

As the steam measurements are generally the greatest source of error, including not only these of initial pressure and superheat, but particularly that of weighed condensate, we should like to ask Mr. Lee if he considers the three-wattmeter method as most suitable for water-rate tests in general? Even where telltales are installed between double valves, and water lines are protected by blanks, there are still possibilities of error in calibrating weighing scales, measurement of gland leakage, condenser leakage, condensate from steam-jet pumps, etc.

The three-wattmeter method of measuring electrical energy is undoubtedly simpler than the two-wattmeter method so far as the application of the meter corrections is concerned. From a practical standpoint, however, we wish to point out that there are certain disadvantages to be encountered with either of these methods where indicating instruments are used. Under Mr. Lee's method three observers, one relief observer, and a computer are necessary. This means not only a multiplicity of instruments and high-test costs, but delay in computing and checking the increased amount of data. The eye strain on the observers, while not serious on a test of short duration, might well be a factor to be reckoned with on tests made every day for a week or so.

The polyphase-integrating-wattmeter method offers none of the above difficulties. Most of these instruments have a very constant calibration and involve very little difficulty in checking to within ± 0.1 per cent with a rotating master standard with 100 per cent power factor on each element. When equipped with a high-speed dial register ample precision can be obtained on tests of two-hour duration, readings of the dial being made at half-hour intervals. There is some question as to the advisability of running tests with a duration of less than two hours, not so much due to the precision of the integrating polyphase wattmeter but because of water levels, variations in condenser vacuum, and temperature changes in generator windings.

With the addition of a properly applied set of instrument-transformer calibrations it would appear that any further degree of refinement involving phase-angle corrections, etc., would be unnecessary with a single polyphase wattmeter because of the probably greater errors in the steam measurements. An over-all electrical accuracy of ± 0.25 per cent, including instrument transformers, may be reasonably expected even with the two elements of the polyphase meter checked at 100 per cent power factor. If greater accuracy is desired the wattmeter elements may be checked separately at 100 per cent and 50 per cent power factor, corresponding approximately to the electrical condition existing in the meter with generator loads at 85 per cent power factor, a value usually obtainable.

E. T. Brandon (by letter): I think that the refinements of measurement used would be justified only where a very large number of tests of first importance were to be made. Some of the corrections said to be accomplished are usually so very small that they are negligible no doubt in comparison with the error of observation of the meter reading itself. If the correction is made, I suppose it justifies itself by indicating that it has been accounted for, even if negligible.

The three-wattmeter method recommended has advantages, but would require temporary connection of potential transformers in some cases, and I think the advantage of having all wattmeters operating at high power factor is offset by the fact that three meters have to be read simultaneously, which is difficult. I think the trouble of having one wattmeter reading at low power factor, as is the case when the power factor of the load is much below 0.80 and the two-wattmeter method is used, could be overcome in most cases by an adjustment of power factor to unity before the test is started. We have been able to do this in our tests at all except light-load conditions for the generator under test.

No mention is made in the paper of the use of the polyphase wattmeter. This meter, in its portable form, usually has high accuracy and the additional advantage that it gives the total power on one meter, thus insuring the recording of a simultaneous reading. Adjustment of the load on the generator to approxi-

mately unity power factor would be necessary for the highest accuracy when the polyphase meter is used.

With reference to the electrical readings taken on the Gibson tests at Queenston, we have, in general, made corrections similar to those suggested and presumably used in the tests described in the paper. The Gibson test is different from the water-rate test in this respect, namely, that the power being delivered to the turbine is desired at the instant the gate starts to close. The quantity to be measured, therefore, is not the average power over a period of time, as in the case of the water-rate test. In correcting the meter reading obtained, we have taken account of the ratio and phase-angle errors of current and potential transformers, which have been previously calibrated, and the error in the meter itself. The wattmeter is always calibrated before and after test against our secondary standard, and is transported by messenger.

In noting that use was made of watthour meters, I might say that we have tried these, but were unable to get a very close check with the indicating wattmeter reading. This was due, no doubt, to the fact that the watthour meter would give the average kilowatts for the time immediately preceding the dropping of load, whereas the wattmeter gives the output at the instant of shut-down. The per cent error in the watthour meter is larger because the time during which it is reading is relatively short, not more than two minutes as a usual thing. In water-rate tests of an hour's duration, during which the load is held reasonably constant, this error would become very small.

I was interested to note the comparison between visual and photographic methods of obtaining the readings on the wattmeter. We have had this method in mind for some time, and expected that the extra cost of such a method would be justified by the increased accuracy obtainable. Apparently where the average of readings taken over a length of time is desired, competent visual observation can be depended on to give results as accurate as the results obtained with the camera. I still believe, however, that where an instantaneous reading is desired, greater accuracy would be obtained by photographing the position of the wattmeter needle.

E. S. Lee: With reference to using a polyphase integrating watthour meter as suggested by Messrs. Leonard and Mommo, the procedure, as described in the first part of the paper, regarding watthour meters should be followed. As regards the need for two-hour tests, the evidence submitted in the paper shows the sufficiency of tests of one-hour duration.

With particular reference to measurements of electrical power output from water-wheel units as mentioned by Mr. Brandon where the water flow is measured with the Gibson apparatus, conditions are quite different from turbine-generator testing in that the electrical power output is desired at a particular instant following a period of constant power output. The results of repeated tests will give the deviation. If the latter is too great, more refinements will have to be introduced into the measurement. Photographic observations would probably be of no advantage over the visual however, because of the steady conditions required preceding the observation which would allow the instruments to be read visually.

The use of a polyphase indicating wattmeter requires that the instrument be compared under the exact test conditions. The suggestion of adjusting the generator power factor to unity is not generally applicable as the generator must be tested at its rated power factor which is frequently less than unity.

The Engineer and Civilization

President's Address

BY FARLEY OSGOOD

The Institute

It seems fitting at this time to bring to your attention, very briefly, some of the outstanding results of the work of the membership of our Institute during the administrative year just closing.

I am sure most gratifying to all, is the increasing interest and activity in Institute affairs all over the country, the greater appreciation of the value of the Institute, professionally and practically, and finally the enjoyment of personal contact of scientists and engineers for the mutualization of thought toward the advancement of our art. These facts are clearly brought out in the statement of the number of meetings and attendance given in the Annual Report of your Board of Directors for the fiscal year ending April 30, 1925.

The work of our Standards Committee, which covers not only a revision of and additions to our Standards, but a rearrangement of their set-up, which will make for their much greater convenience for field use, is worthy of the greatest praise, as it required much untiring and unselfish effort on the part of a very large group of men determined to accomplish what has been done this year.

Our Meetings and Papers Committee has so coordinated its work with that of the Districts that regional conventions are now established on such a sound footing as to have made it desirable to abolish the National Spring Convention as such, which recommendation of the committee was concurred in by the Board of Directors at its meeting on May 15, 1925.

The revising of the constitution to bring it into line with the present scope of the Institute's activities, and the fast growing nationally spread membership has been accomplished, as was also reported at the Annual Meeting on May 15th in New York when the large affirmative vote by letter ballot was recorded.

The many Technical Committees have been even more active than usual, and through the Journal from time to time you have seen how well they have prepared the sessions of the conventions falling under their several responsibilities. Their following the electrical engineers into new fields of industry is particularly to be commended as it is bringing into our Institute many new groups, as members and authors, not previously interested in our possibilities. The detail of the constructive work of the committees will be recorded in the history of this convention, for it is now our practise to have their reports presented at this, the last and presumably the most widely representative convention of the administrative year, in order that their conclusions may be more far reaching in their orientation, and that through the discussion, views of members from the greatest number of sections of the Institute may be expressed.

The report of our auditors indicates a healthy financial condition, and that we have paid our way this year. The slight increase in income as provided by certain changes in our revised constitution, will be most welcome for the carrying forward in a broader way important activities as seen to be needed by the Board of Directors.

The excellent result from our Membership Committee is shown in the fact that on June 1, 1925 our list of members totalled 17,318—representing a very satisfactory continuous growth since the formation of the Institute.

The Reason

Now, the relation of these events concerning our activities and growth, which are not unlike those of our sister societies, should bring to our minds the thought that there must be a sound reason for it all.

There is a sound reason, and it is in the indisputable fact that the engineers have made the world what it is today; have brought to it industrial progress and economy; have given it the living comforts and, more than all, have shaped the very scheme of living of its inhabitants since civilization began.

History

The living in trees to escape the hazards of ground life, to the steel strengthened structure of many stories;

The dispatching of runners with messages, consuming days of time and covering moderate distances, to the instantaneous international transmission of intelligence and music by physical conductors and through the air;

The shaping of the business end of the club of the savage that the greatest destruction might be wrought on the head of an undesirable neighbor, to the sending through the air, accurately and speedily, tons of metal to a predetermined point;

The thought of the wheel bringing relief to transportation by hand or with manual carriers, with its evolution through all mechanical applications to the precision and delicacy of present-day timepieces;

The employment of steam as a mechanical agent to the point of mass energy for manufacture and transportation;

The development of highways, construction of bridges, furnishing of water supply, that humanity may dwell where it pleases;

The harnessing of electrical energy for nearly every purpose of industrial and domestic life;

The use of natural resources from the obtaining of

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, June 22-26, 1925.

raw materials from the earth to the practical application of water streams and storage, which for centuries have been idle in their help to man;

The understanding of many of the mysteries of chemistry with their application to industry, health and comfort; . . . . all seem long steps in our notion of periods of advance, but all find their foundation in science and engineering. No one can say that but for these, and the very many related achievements, would the progress of civilization, the groupings of the peoples of this world, their interests, their methods and comforts of living, be such as we now behold.

Although centuries have passed while our present scheme of life has been perfected, it is only very recently that the rapid strides of applied science and engineering have been accomplished. To note the fact that as late as 1852 was founded America's first national engineering association, that of the Civil Engineers, is sufficient to indicate the rapidity of development of the engineering arts. The founding of the American Society of Civil Engineers in 1852 was followed by that of the American Institute of Mining Engineers in 1873. Then came the American Society of Mechanical Engineers in 1880, and finally our own American Institute of Electrical Engineers in 1884.

The very many and rapidly increasing special fields of engineering endeavor seem to have been the reasons for the birth of these now so-called "Four Founder Societies." As each new field opened up, and its immediate development was hastened by necessity, there was not the realization of its possible and essential coordination with the work of those in distinct lines already established. Now, however, that there is a breathing time sufficient to review the situation as a whole, coordination is being established, as can be recognized in the forming of the American Engineering Standards Committee, the American Engineering Council, the Society for Promotion of Engineering Education, wherein the needs of all engineering may be comprehensively discussed.

The electrical engineers whose art has such universal application in all branches of engineering for nearly every industry and every domestic service, have had much to do in the bringing to one center all the arts of engineering. If for technical reasons this move toward general coordination has been started, it is all the more important for the presentation of a unified national opinion of America's engineers in matters pertaining to our own welfare, and that of the nation where the knowledge and training of technical men may be useful.

That engineers have brought all this about, by no means signifies that their responsibilities have ceased or even lessened, for in fact they have become all the greater; as through scientific knowledge and engineering experience, must not only the material side of life but its relation to human existence, go forward.

Engineers by training are taught to think straight, to seek the plain truth without bias, to deal with facts only, and to marshall them toward the goal of practical and beneficial accomplishment. Who, better than they, can turn the knowledge and experience which has brought us to our present state, to its application in the less technical activities of life with which it has such a close relationship.

The advancement of science and engineering for its own sake is not enough, in its control of the forces and materials of nature, for the organizing and directing of men, and all that this means in its broadest sense, becomes the obligation of engineers in order that the human race may be fully benefited.

No finer example of full accomplishment of this ideal could be cited than the life of the renowned French chemist, Louis Pasteur, an almost fanatical devotee to his science, yet never without the parallel thought of the benefit of his results to all living people.

Here in America today we have our distinguished Secretary of Commerce, the Honorable Herbert Hoover, an engineer of proven accomplishment, a worker for humanity, beloved by those European nations so much helped by him during the World War; now devoting his power of discernment of fact to practical application for the industry and comfort of the people of our whole Nation.

Engineers up to now have been all too prone to become so engrossed in their own technique as to give little or no heed to the development of life about them, or to have any thought that they are a part of that life and should give to it of their ability and experience and judgment, as other men do, who too have vital interests at stake from which some time must be taken for the good of all.

President George Fillmore Swain in his address to the Civil Engineers as far back as 1913, advocated a more human engineering, while our past President, Arthur W. Beresford in his address to us in 1921, warned against the belief by engineers that they can run successfully all the jobs in the world; but surely between these two ideas is a middle road to follow where engineers can and should help in matters concerning which they possess useful knowledge. President John Lyle Harrington in his address to the Mechanical Engineers in 1923, speaks very definitely on the subject, and I commend for your careful reading and reflection these three addresses mentioned, which so clearly point the way we should go, that from engineers the world may get the fullest measure it so rightfully demands, and the position of the engineer may be recognized as it so surely deserves.

Of course, just being an engineer does not qualify a man as an executive, nor as a legislator, for such work requires broad human vision, balanced perspective, ability to sense relationships and effects, all of which faculties would seem to have been more generously bestowed upon lawyers and business men generally than upon men of technical training. Is this, however, the

fact? Have not the technical men these faculties, but have neglected to develop them by special education and experience so as to bring them sufficiently to a prominent place in their mental activities and desires?

Faculty for other than technical work must be present in the engineer if he is to be a worker in the broad fields of life, but having such aptitude, his very technical training should make him a more useful, more forceful worker than those non-technically trained.

If you reflect but for a moment, you will realize that many, in fact most of the problems of our people are basically engineering problems, if not strictly so technically as many really are, at least so generally, as they have to be solved by analysis, and the weighing in the balance what is found to be the logical and practical result if one plan is followed, with similar results of some other scheme under consideration. This method of analysis is peculiarly that of engineers who by training are well fitted to lend a hand.

In few places where the engineers could be helpful, do we see their names listed. To be sure here and there we find them, and how well these few perform their duty is a matter of record. The names of these men are mentioned with pride, but it is the exception rather than the general rule to find our members in such activities. In our principal body of national representation, our National Congress, how many names of engineers do we find? This body is composed largely of lawyers, over 65 per cent, and politicians whose business at home is not engineering. These are the men who pass on the problems of the country so many of which, as we have endeavored to show, are such as could be more logically determined by our technical men.

Truly, by now we have come to the time when our experience must be turned to broader fields of investigation than those confined to our technique; and how is this to be brought about?

A new state of mind in the engineer must be born. Those most advanced in our art must appreciate their debt of service to the needs of the people not having our training in the determination of facts; our educators must be brought to appreciate that the training of young men in the technique of their work, is but a part of the training for a suitable graduating degree. Our college students must be made to realize that their particular training incurs an obligation of its service for the benefit of all our people, wherever it is possible to bring it to bear.

In so many of our commissions and political bodies we find the make-up largely lawyers, with a few other non-technical men, whose work deals primarily with projects based on engineering, and as a consequence many engineering experts are called to bring in the scientific and technical facts that proper decisions may be reached.

Why, now that the legal and financial bases of most of the investigations by our public bodies have been so well established, should not the personnel consist largely of qualified engineers, and when legal or financial advice is needed, call in the experts from those fields? Would not this seem more logical? Has the training of our scientists and engineers been such as to make them unfit for this duty? If so, it is high time that intensive study should be undertaken to correct such a condition.

It would seem reasonable for a well balanced committee of the four founder engineering societies to be formed, selected from many branches of industry and the world work to cooperate with the Society for the Promotion of Engineering Education, in order to determine most broadly on a proper curriculum for our students, to bring to them a correct blending of technical work and training in human engineering; that our profession may perform its fair share of carrying on the welfare of our people.

Even if much which is now taught is abolished from our present curricula, and the fundamentals of the technique of our art made more thoroughly understood, with training in expression of their application, both orally and in forensic, so as to be clearly understood by non-technical men of the business world, a much broader viewpoint of the engineer, and a much wider appreciation of what he can do in the world's affairs will result.

No longer should we be looked upon as "glorified mechanics," when in our combined mentality and our essential training in the discernment and arrangement of facts, exists such a potentiality for helpfulness to all mankind. If we so continue we can have only ourselves to blame, and now that we have come so far, what a shame to rest in a feeling of complacent satisfaction.

Of course every engineer in the country cannot be placed in public office, either municipal, state or federal, but all engineers can lend aid in supporting those chosen for the more conspicuous places. Each has his own field of usefulness, by training or by choice, and his feeling of reward should be his satisfaction of service rendered.

The Master Mind of all creation holds the key of all knowledge; to the scientists is entrusted the unfolding of the fundamental laws of nature, to the engineers their practical application for the benefit of the human race in every possible way; the road is open, our duty is clearly defined, that our obligations will be fulfilled there is no doubt.

Present State of Transmission and Distribution Developments

By Committee on Power Transmission and Distribution[1]

THIS Committee submits the following report on the progress made during the past year in the field of Power Transmission and Distribution. In accordance with the plan proposed, a number of subjects are offered at the end of the report suitable for topical discussion at the Annual Convention.

In high-tension transmission, the year has been notable for the first normal operation of the two long-distance 220-kv. lines in California and the concrete proof of the entire feasibility of lines of this sort. The importance of this fact is difficult to exaggerate. Already several other 220-kv. lines are projected; one now going under construction. The physical construction of these lines will soon be pretty well standardized and no longer a matter of serious controversy.

While the evidence as to the feasibility of 220-kv. lines is clear and convincing, there remains much uncertainty as to the limitations of the capacity of such lines when of great length. Much quiet work has been done, since the forceful presentation at the Philadelphia A. I. E. E. meeting last year of the dependence of very long lines on the rigid maintenance of line voltage and the weakness of commercial synchronous condensers for this purpose. The prospect is bright for better operation than would have been expected. At present, the work is largely in the hands of the designers of the various sorts of apparatus involved in line-voltage support and regulation.

It may be well to mention that the explanation of the many mysterious insulator flashovers on high-voltage lines in central California, which have baffled investigations for some time, has been established as the presence of large birds roosting on the towers and guard rings. This difficulty has now been, or soon will be, practically eliminated.

An old problem has come into unusual prominence in certain places, viz., the more or less severe vibration of highly stressed conductors, due to wind action causing the formation of standing waves and endangering the cable strands. This subject is being worked upon.

Little progress has been made in the discussion of the various aspects of the subject of flux control in very high-tension insulator strings. The well-known guard ring seems to be holding its position.

Much field work has been done on corona losses. It is to be expected in the measurement of these losses on long lines, subject to varying voltage and climatic conditions along their length, and sometimes of varying conductor size and configuration, the results are somewhat conflicting among themselves and to some extent at variance with the accepted formulas. While there is a difference of opinion on the subject, no clear proof as yet exists that there is any material error in the established formulas when applied to ideal simple conditions. However, it is clear that the actual determination of this loss for the practical case of long 220-kv. lines is a very complex and difficult matter, since the conditions vary so much both along the line and from day to day.

With the increased study of important tie lines which may carry power in *either direction* and with the proposals for the transmission with the aid of synchronous condensers of amounts of power on high-voltage lines near their *maximum capacity*, the importance and the complexity of the designers' task is just now being realized and the all-important rôle of power factor recognized.

In the field of lead-covered cables, we have to record a most active year of great progress. With the marked advance in 66-kv. cable joints; the successful operation of a number of high-tension cables in 66-kv. circuits in actual commercial service; and with the growing belief that cable for 132-kv. circuits will be feasible and may soon be available, the whole aspect of the transfer of large amounts of power underground in congested districts is changed. The possibility of the use of these voltages leaves very little to be desired as far as capacity goes. However, the costs are extremely high and the technical details are not yet developed to any final stage.

There has been no marked development, but it is believed that a steady advance is being made in the quality of high-tension cables and, therefore, in the voltage at which cable can be used. In addition to the use of single-conductor cable the principal elements contributing to this advance are greater care in the selection of materials, in the fabrication of the cable particularly the more thorough elimination of air and impregnation with the insulating compound. In the higher-voltage cables there is a distinct tendency toward

a fluid impregnating compound. For very high-voltage cables it is proposed that this compound by means of reservoirs along the cable, be kept under a hydrostatic head, the conductor cable being hollow or of open structure to permit flow of compound. Much work has been done on all phases of this subject during the last year and many notable papers have been presented before the Institute.

Development in high-tension insulators, lightning arresters, protective relays and oil breakers proceeds steadily but no especially conspicuous advances are noted.

In spite of the number of years in which electric-power systems have been in general use and the vast numbers of distribution networks, there still exists a lively discussion as to the best type of low-voltage local distribution system—whether two-phase with neutral wire or three-phase with one modification or another.

This brief review should not close without mentioning the closer and closer operating cooperation between the well-known groups of large utilities, such as those in the southeastern States, where many necessary details are being worked out. Much more intimate mutual support is being realized, also the rapid interconnection of utilities by high-voltage lines and the establishment of large base-load plants in the great industrial district east of the Mississippi and west of the Alleghanies. This sort of interconnection is developing interesting and difficult problems in the metering of commercial power.

In accordance with the plan for making the Annual Convention a forum for the informal discussion of topics of current interest without the labor of the preparation of formal papers and without the consumption of the time necessary to present them, the following topics are presented for discussion.

A. What capacity in lead-covered cable can a present-day designer count upon in laying out connections for the transfer of power from a large base-load generating plant in or near a large city to the principal distributing substations? On what voltage, what size of conductor, what operating temperature, etc., would this be based?

B. How much load can be handled over a 100-kv. tie-line connecting two large independent systems and carrying equal amounts of power in both directions with dependence placed on tap-changing devices for the maintenance of stabilized voltage in both systems? Can such tap-changing devices be relied upon where the interchange between the systems is to be automatic in accordance with the variations of load and with the conditions of most economic operation in the two systems combined?

C. What is the exciting cause for mechanical standing waves in a high-tension, long-span line conductor? Is tight stringing necessarily a cause of vibration? What is the relation to conductor size, weight and elasticity? What sort of remedy is theoretically effective?

D. Where a large block of power is to be distributed over a considerable area, is it feasible or desirable to use single-circuit interconnected feeders carried by different routes to accomplish distribution and transmission simultaneously. In such a case, what are the limitations on tapping the single circuit feeders for local loads, the questions involved being relay protection, cost of installation, reliability of service, etc.

E. What can be done to reduce installation cost of high-voltage transmission lines? Can transmission towers be further standardized? Can more mechanical devices be used in hole digging and erection? Is the use of extra high-strength conductors and very tight stringing desirable?

F. What can be done to reduce to reasonable proportions the cost added to a transmission line construction by the necessity of considering the effect of heavy sleet?

Live Problems in Connection With Protection of Electrical Systems

By Committee on Protective Devices[1]

IN accordance with a practise established over a number of years, the work of the Committee on Protective Devices has been delegated to a number of subcommittees, the division being made with reference to the nature of the subject covered. Complete reports from each of these subcommittees are appended.

It will be observed that one new subcommittee is reporting in addition to those reporting last year. By a ruling of the Board of Directors, the subject of automatic substations was assigned to the Committee on Protective Devices. The work of this subcommittee has been done in cooperation with other committees, covering the apparatus used in automatic substations, and while the report deals particularly with protective devices, it will be found to cover rather completely the situation in automatic substations as found today.

It is felt that the scope of work assigned to the Committee on Protective Devices is very well covered by the

activities of the following subcommittees and the Chairman would not suggest any radical change in the organization as it now exists. It is heartily recommended, however, that the work begun by these various subcommittees be continued during the coming year and that the recommendations made in each case be followed.

Automatic Stations

Fundamental Difference Required in Design of Devices for Automatic Application from Those for Manual Application

One of the things which differentiate devices used in automatic stations from those used in manually-operated stations is the question of inspection. The designers of devices for manual stations tacitly assume that all of the devices will either be continuously under the eye of an attendant or will be inspected several times each day. This tacit assumption is borne out by the fact that the usual manual station is provided with instruments and switches. A human intelligence is required to read the instruments and thus operate the switches in accordance with the story told by the instruments. As a result, the designers of devices for manual stations have paid more attention to the performance of the devices in response to a specific circuit condition than to their continued successful performance with inspections at intervals exceeding a week.

Another item differentiating the design of devices for automatic stations from those in manual stations is the relative life to be expected from the two. Devices for automatic stations require in some instances a successful life of several million operations. The only devices in manual stations called upon for similar services are probably the automatic generator-voltage regulators and some of the control apparatus used for steel mill service. In each of these latter cases, life has been an important feature of the design and as much attention has been paid to this as to the operating characteristic of the devices.

It will be seen, therefore, that primarily the attitude of the designers of devices used in manual stations contemplates an attendant who will supply any deficiencies in the operation of the devices, while the design of devices for automatic stations requires that the devices function correctly or else make the station inoperative.

Minimum Safe Protection for Power Apparatus in Automatic Substations

From the standpoint of railway applications, the amount of protection that is afforded automatic substation equipment by the use of various devices, relays, etc., is a direct function of the type of installation with respect to its application, importance and whether full-automatic or partial-automatic.

This statement may be amplified by considering a typical case. It is the installation of automatic equipment on large urban properties where the successful and continued operation of the substations is of prime importance. Here it is customary to install all the various types of protection that will prevent, as far as possible, either an interruption to power service or damage to equipment.

On the other hand, automatic substations installed on some small interurban or suburban railways do not require the refinements of protection afforded more important substations. This is due, in some cases, to lack of capital for initial investment. In other cases the continuity of service is not the controlling factor and the protective features may be kept to a minimum. These substations quite frequently take the form of the so-called partial-automatic type where an attendant or a time clock is used to start and stop the station. Upon the occurrence of trouble these substations are generally arranged to cease operation and remain out of service until restarted by an attendant.

For standard size 600-volt converters, feeding into a metropolitan railway-distribution network, the following minimum protection is recommended:

A-c. overload (lock-out); d-c. overload; sustained overload; a-c. undervoltage; d-c. reverse current overheating of current limiting resistors; failure of field circuit; overspeed (lock-out); overheating of bearings (lock-out); failure to complete starting cycle (lock-out); flashover (lock-out).

D-c. Edison-system automatics are called upon for a high class of service and the protective features must be so chosen and applied that the service must be maintained. There is a tendency at present to so protect the station that the machines are tripped off at times when the condition of stress may be far below the limit of the machine. This has had a tendency to prejudice prospective purchasers of automatic apparatus by apparently complicating the switching equipment.

It has been the practise in some heavy manual systems to tie the converters or motor generators solidly to the bus without protection on the d-c. end. Within reasonable limits it is felt that this could be approached in the design of automatics on the same class of system.

For 250-volt motor-generator sets and converters the following minimum protection is recommended:

A-c. overload (lock-out); d-c. overload; sustained overload; overheating of machine; overheating of transformer; overheating of current limiting resistors; a-c. undervoltage; d-c reverse current; overspeed (lock-out); failure to complete starting cycle (lock-out); overheating of bearings (lock-out); flashover (lock-out).

Various devices for the protection of the service may be applied; in fact it is felt that this feature cannot be overdone. Several equipments have temperature protection which reduces the load on the machine upon the temperature rising within a few degrees of the point at

which the set would be taken off of the system. In this way the system voltage is held somewhat above the value which would obtain if the over-temperature device disconnected the machine from the system. In most cases the machine will cool while operating at partial load. As practically all machines are arranged to limit their output by means of regulating devices, the overheating is usually caused by inadequate ventilation or a failure of ventilating apparatus. If the ventilation is only partly retarded by the failure, the machine would probably operate indefinitely at partial load; the voltage, of course, being somewhat low but at least some power being delivered to the system. The liberal use of thermostats, operating alarms over supervisory circuits in the Dispatcher's Office, will protect the service to a large extent. An attendant may be dispatched to the station upon indication of even slight over-temperature and may be able to alleviate the trouble in time.

Automatic A-C. Distribution and Transformer Stations

The protection to the service should consist of reclosing features applied to the outgoing circuits. Power supply to the station should be assured by proper overload, balanced, or reverse-current protection of the parallel transmission lines supplying the station, or by automatic transfer devices if not desirable to have transmission circuits paralleled. Differential protection should be provided for each transformer so that a defective unit will clear from the system without interruption to service. The matter of apparatus protection may be reduced to that of transforming and regulating devices; their protection should be against overheating and groundings. All outgoing circuits should, of course, be provided with overload protection and in cases of automatically reclosed circuits, lock-out features should be provided.

Oil Circuit Breaker Operating Duty as Applied to Automatic Reclosing Circuits

It is suggested that an attempt be made to get the manufacturers of switchgear to furnish ratings with oil breakers supplied for this class of service that will enable the operating engineer to apply intelligently these breakers to his circuits which are to be reclosed after tripping on trouble. Referring to distribution circuits in the 2200- to 6600-volt class, it seems to be general practise to reclose these circuits three times before final lock-out. There seems to be a little difference of opinion here and there as to just how much time should elapse between reclosures, but as a general average we might say that the first reclosure is made in from two to five seconds after tripping; the second reclosure in about 30 seconds from zero, (initial tripping) and the third in anywhere from 60 to 180 seconds from zero. It is felt that if the manufacturers were to establish a tentative standard somewhere near the above values and rate the breakers on this basis, that the operating companies would either accept the standard or their own idea of the values would be close enough to the standard to make an intelligent application. Even if this tentative standard were based on three or four reclosures at five-second intervals it would be a decided advantage over what is now available.

Nomenclature for Types of Automatic Reclosing D-C. Feeders

The following is suggested:

A. Types of Feeders

1. Stub Feeder. A Stub Feeder is one which, at the time of reclosing, receives energy for the testing circuit from one source only.

2. Multiple Feeder. A Multiple Feeder is one which, at the time of reclosing, receives energy for the testing circuit from two or more sources.

3. Stub-Multiple Feeder. A Stub-Multiple Feeder is one which, at the time of reclosing, may receive energy for the testing circuit either from one, two or more sources.

B. Methods of Automatic Test Prior to Reclosing

1. Continuous Testing by Current. Continuous testing by current is a method which continuously furnishes to the feeder a limited current which operates a device or devices adjusted to function at or below some predetermined value of current flow into the feeder to effect reclosure of the circuit interrupter.

2. Intermittent Testing by Current. Intermittent testing by current is a method which intermittently furnishes to the feeder a limited current, operating a device or devices adjusted to function at or below some predetermined value of current flow into the feeder to effect reclosure of the circuit interrupter.

3. Testing by Voltage. Testing by voltage is a method which employs a voltage-actuated device connected between the source of energy and the feeder or between two sources of energy to effect reclosure of the circuit interrupter at a predetermined voltage condition.

Remote Supervision

The handling of various switching and receiving indications of operations from remote points has received much attention. The larger operating companies are discovering that, even with manual switching, something of this nature is necessary to expedite operations in times of trouble. As soon as a system grows to a size where it becomes necessary to establish a central dispatcher to direct switching, it is at once manifest that when trouble occurs, the switching necessary to bring the system to normal can be carried out only as fast as the dispatcher can obtain information. The use of the telephone for this involves the chance of human error and retards action as an operator cannot manipulate his switchgear while telephoning. The use of supervisory systems to provide the dis-

patcher immediately with an indication of changed condition shunts out many minutes of valuable time. In automatic stations, indications may be given of lamost anything required and it becomes only a matter of how far it is desirable to go in a given case. In Edison system automatics, remote supervision is particularly helpful as there are many conditions which can occur without warning and if allowed to continue may result in partial service interruption. For the dispatcher to feel that he has his system well in hand he should have at least the following indications from each of his Edison system automatics.

1. Continuous indication of d-c. amperes on each unit in the substation.
2. Positions of all oil circuit breakers.
3. Alarm upon failure of ventilating system.
4. Alarm when predetermined high temperature value is reached at the air discharge from any unit.
5. Alarm upon the operation of the lock-out relay on any unit as he may not otherwise know that the machine will not restart upon demand.

He should also have sufficient supervisory apparatus to enable him to shut down and "hold off" any or all units so that he may, if desired, restrict the output from a given station. In addition to the above it may be desirable, although not necessary, to have supervision over the closing and opening of the oil breakers on the supply feeders and junctions in the supply bus, etc.

Supervision of a-c. distribution automatics is, of course, less elaborate due to the simple nature of the equipment in such stations. There are comparatively few indications that the dispatcher really has any use for and the balance is rather a matter of convenience.

It is sometimes desirable for the dispatcher to know when the lock-out relay on any of the automatically reclosed circuits has operated, although it is not necessary for him to be able to release the lock-out as it is generally necessary to make repairs before the circuit is again closed. It is observed in some communities that sufficient trouble calls from customers pile up in two or three minutes to indicate definitely that the whole circuit is dead and therefore, before the dispatcher can inform the proper persons in the Trouble Department of his supervisory indication, they have already made their deductions.

It is sometimes desirable to give the dispatcher control over the breakers in the incoming supply lines but it is better engineering to arrange them to take care of themselves.

In special cases where water-cooled or air-blast equipment is used, it is almost necessary to give the dispatcher a warning of the failure of the auxiliary apparatus involved but in average cases such detail is not met with. A-c. distribution stations are usually in outlying sections and at a considerable distance from the center of operations. In this connection the matter of rental of telephone pair mileage becomes quite an item of cost.

In general, a supervisory system is a very desirable asset to a system but it should never be forgotten that the reliability of the whole scheme can be made no better than the wires used in the circuit—experience has indicated that it is impossible to maintain 100 per cent service on such small circuits. The station should be arranged, if possible, to take care of all conditions automatically without the aid of the remote supervision.

Load-Limiting Schemes in Event of Overload (D-C.)

Load Limiting by Series Resistance (Fig. 1). Load limiting by successive steps of series resistance in the main circuit is probably the oldest type of load limiting scheme used in automatic stations. It is applicable to synchronous converters and all types of generators. For this scheme the d-c. machine is connected directly to the negative. The positive is connected to the bus

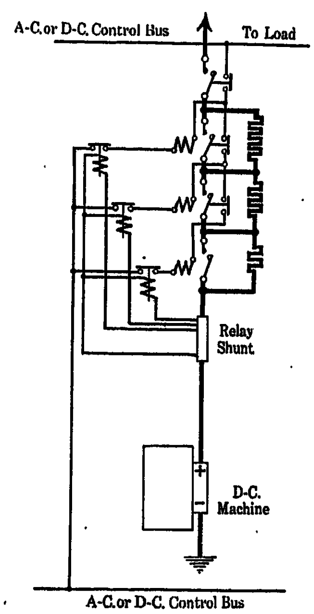

Fig. 1—Load Limiting by Steps of Series Resistance in the Main Circuit

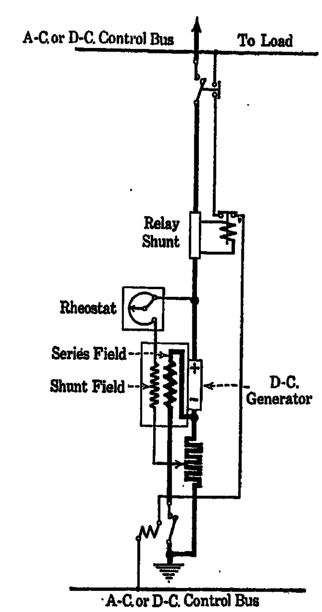

Fig. 2—Load Limiting by Accumulative Series, Field-Shunting Resistance

through a group of series resistors and a line contactor or circuit breaker. The usual design uses three steps of load limiting resistance with one shunting contactor or breaker for each step. The d-c. machine is connected to the bus with the shunting contactors open. Then the shunting contactors are closed successively; thus gradually making the bus and the machine pressures equal.

In case of overload, one or more steps of resistance are inserted into the line. If all the steps of resistance are inserted by means of the magnitude of the overload and if this overload persists for long enough time to overheat the resistors, then a thermal relay opens the line contactor and the machine is disconnected from the load until the load-limiting resistors cool. After

they have cooled, the machine is again connected to the bus through the resistors which are gradually shunted out, if the load permits.

Suitable interlocking is provided between the contactors to insure the correct sequence for closing and for opening.

Load Limiting by Accumulative Series Field Shunting Resistance (Fig. 2). Load limiting by accumulative series, field shunting resistance is used almost exclusively in connection with compound wound d-c. generators. The scheme is applicable with additional load-limiting resistors such as described above. It is permissable to eliminate such series resistors, however, if the characteristics of the load and the machine are within certain limits.

During normal operation the series field-shunting resistor has only a slight effect in reducing the amount of compounding. On overload a contactor is opened and this causes:

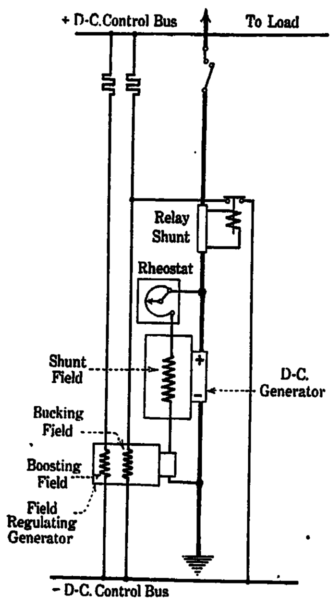

Fig. 3—Load Limiting by Counter E. M. F. Generator

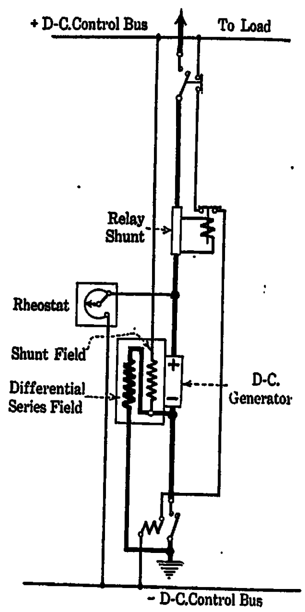

Fig. 4—Load Limiting by Differential Series Field

1. The generator to become a shunt machine.
2. The shunting resistance to be inserted in series with the machine.
3. The shunt field to be reduced due to voltage drop through the series field-shunting resistance.

On reduction in load to a predetermined value, a relay recloses the overload contactor as in scheme No. 1. Also, as in the previous scheme, interlocks are provided between the contactors to insure the correct sequence of opening and closing.

Load Limiting by Counter E. M. F. Generator (Fig. 3). Load limiting by counter e. m. f. generator is particularly applicable to shunt-wound generators. This scheme employs a small motor-generator set with the armature of the generator in series with the shunt field of the main generator. The small generator has two shunt-field windings. One is a comparatively weak boosting winding. The other is a stronger bucking winding. The boosting winding is used to supply a constant and practically separate excitation. The bucking winding is used to reduce the shunt field current of the main generator when it is inserted in the circuit by the opening of the contacts of a relay on overload.

The load is held at the setting of this relay by the regulating action of its contacts as long as the external circuit conditions require.

An excessive overload on the machine is prevented by control of the machine voltage up to a certain definite load beyond which the constant current relay in combination with the counter e. m. f. regulator makes the machine practically constant current.

Load Limiting by Differential Series Field (Fig. 4). Load limiting by differential series field is applicable to d-c. generators provided with a series field connected differentially. During normal operation, a contactor short circuits the differential series field. On overload, reverse current or short circuit, this contactor is opened by a suitable relay combination and thus inserts the differential series field into the circuit.

This method of load limiting is usually employed in conjunction with voltage and load regulating schemes, including a motor-operated shunt-field rheostat. Stability of operation on the differential series field characteristic is obtained through a constant amount of excitation from the d-c. control bus.

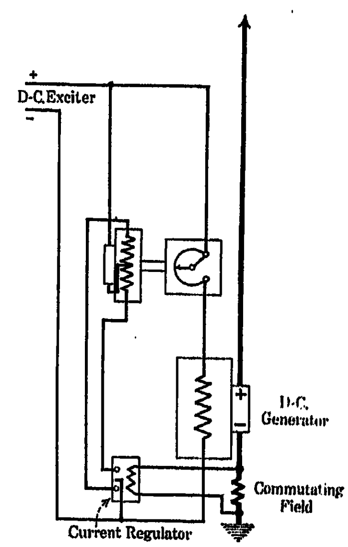

Fig. 5—Load Limiting by Current Regulator Controlling Shunt Field Rheostat

Load Limiting by Motor-Operated Field Rheostat (Fig. 5). Load limiting by motor-operated field rheostat is probably the simplest of all of the schemes employed. It is applicable particularly to d-c. generators and is suitable in general only for machines with separate field excitation, to insure stability at all voltages.

Essentially the scheme consists of a contact-making

ammeter or current regulator with a certain floating range. This device controls a motor-operated shunt-field rheostat which is operated to maintain definite voltage up to a certain load and then to reduce the voltage in order to back off from the load in case the load exceeds a certain given value.

Load Limiting by Step-Induction Regulator (Fig. 6). This scheme is applied to the transformer of a synchronous converter and affects the performance of the converter in the same manner as the well-known scheme of introducing an induction regulator between the a-c. supply and the rings of the converter, either ahead or behind the transformer. The old scheme, for various reasons, was limited to about 20 per cent range in voltage at the d-c. terminals of the converter, while this scheme is limited only by the ability of the converter to perform in a stable manner at low voltages. This limit is somewhere under 50 per cent of the rated voltage of the converter. The scheme consists essentially of an extended winding on the primary of the transformer with taps brought out at intervals. By means of a series of tap-changing switches coupled mechanically to an induction regulator, the steps of the winding are brought in or out of circuit. The various transitions are made at zero current in the tap-changing switch, the induction regulator acting as a booster to equalize the two points which are to be momentarily tied together during transition. The d-c. regulating range of the converter resembles a smooth curve. This scheme permits the use of a standard shunt-type converter, which is inherently a very stable machine.

Automatic Fire Extinguishment and Detection

Very little of a practical nature has been done along these lines except in power-plant work where the automatic liberation of inert gases into generator-cooling air has been more or less successfully carried out. There seems to be only two forms of extinguishing media which might be applied to automatic stations; inert gas and chemically-formed foam, the bubbles of which contain an inert gas. The objection to inert gas is the necessity for automatically closed dampers that will be tight enough to retain a sufficient amount of the liberated gas in the space affected. This method can best be applied to small stations using forced ventilation, as the whole station may be drenched with gas by closing the dampers at the intake and discharge openings. Stations provided with natural ventilation only are usually provided with a large number of openings both for intake and discharge and the problem of damper control would probably be too difficult. It is felt that this type of station, which is usually large in cubical capacity, can best be protected by the foam method, either in unit sections or by a system of sprinkler pipes. In this connection some experiments have been made in the application of a foam unit to a compartment or stall housing an induction regulator. The foam tank was suspended over the regulator and by means of a standard fire fuse, the chemicals were liberated into the tank where their mixing produces the foam. A section of the tank bottom was arranged to allow the foam as it was produced to drop down upon the body of the regulator. The effect produced was to cover the regulator with foam. In order to completely blanket the regulator it was necessary to close the open side of the stall with a screen which even of large mesh (½ in.) will cause the foam to be retained in the compartment. While this scheme indicated at least one good way of preventing a spread of fire from a regulator failure, it was felt that it could not always be applied in just this way. Fires generally originate in windings and except in cases of rotating equipment the devices possessing these windings may be installed in compartments or perhaps a group of such devices in an isolated chamber. This compartment or chamber may be protected by a foam unit or if the ventilating arrangement is just right by a gas unit. It was realized that wherever foam was used some method of heating the chemical tanks would be necessary to prevent freezing.

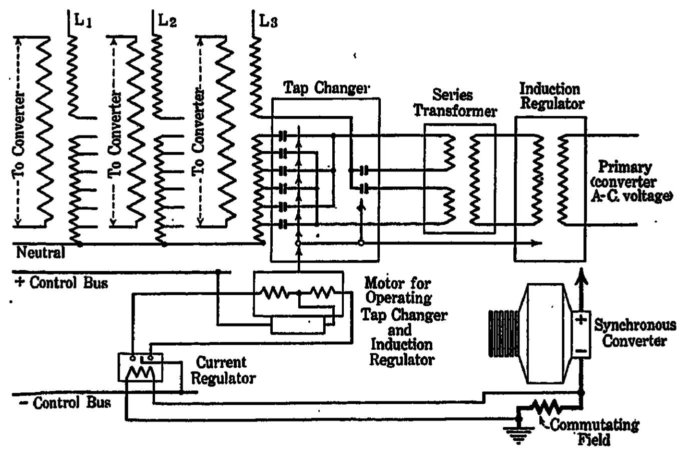

Fig. 6—Load Limiting by Step Induction Regulator in Transformer of Converter

A scheme was worked out for the protection of a compartment by gas where the nature of the device in the compartment was such as to necessitate one side of the stall being open for ventilation (this typical case being applied to an induction regulator). The use of the standard-roller, steel fire-curtain door was not thought advisable on account of its high cost and the fact that it was metal. A door of asbestos lumber, hinged at the top corners, was worked out. The door itself was hinged in the middle so that it could be hooked up to the ceiling in front of the compartment, jack-knife fashion. The operation of the fire fuse over the regulator released the gas supply and the door trigger at the same time, thus permitting the affected compartment to be flooded. It is necessary of course that an excess of gas be liberated in the stall as this type of door will have considerable leakage around it. It is felt that the use of the above door, even without liberating an

extinguishing agent, would be a step in the right direction and incidentally cheap enough to justify its use.

The matter of automatic fire detection has been given much thought. It is not very desirable to attempt to detect fire by temperature for more than one reason. First, the ordinary fire fuse used for building sprinkler systems has been known to liberate water when no fire has occurred at all. This sort of performance is, of course, unthinkable in automatic substations. Secondly, a fire such as we may experience first manifests itself in an odor followed by smoke and last by violent temperature rise. The most desirable thing to use to give the alarm would, of course, be the presence of a strong odor but as no automatic "smelling" devices have been produced, it is obviously impossible to consider this. Smoke, however, can be detected automatically and at present there is actually available a system, which by means of small suction pipes from various vital parts of a building, continually "samples" the air from these parts. This system is in use on shipboard and the indicating cabinet is located where some delegated officer can continually observe it. The smoke is made clearly visible by means of a properly directed light beam. It remains only to cause these light beams to act constantly on suitable devices to obtain automatic detection. This system in its present state of development is very elaborate and it is doubted if it can be justified in automatic stations at least for the present, but the manufacturers have indicated a desire to develop it further in the hope that it may be the answer to a good many of their problems.

Reactors

Since the most important feature of a current-limiting reactor is its reliability, the subcommittee has continued the collection of data on failures. The few reactors that have been called to its attention are mostly of the older design and the small number indicates that even in these, the weak points have been practically eliminated. Such failures which have occurred serve to keep before the manufacturers of reactors and engineers of power stations, the need for the greatest care in their manufacture and installation to the end that failures will be reduced to a minimum.

It is generally agreed that for medium and large size systems, reactors are a necessity not only because they reduce short-circuit currents and thereby lessen the duty on oil-circuit breakers and the electro-magnetic stresses on all equipment, but also maintain voltage on the rest of the system in the event of heavy short circuits in any one section of it. Were reactors omitted it is probable that an equal or greater cost would be involved in providing and installing oil circuit breakers of sufficient rupturing capacity to successfully open the very heavy short circuits that could flow, if indeed such oil circuit breakers could be built at the present time, and the system would still be without the stabilizing effect which reactors give.

Reactors being a protective device may be considered a form of insurance for which large premiums are paid in the form of losses and even more costly capital expenditures. Indicative of the extent of these capital expenditures is the fact that in one 200,000 kv-a. plant, the reactor installation (including compartments, building space, etc.), represents 15 per cent of the cost of the switchhouse. Another company, in order to add feeder reactors to one of its older plants, has had to erect a separate building for this purpose.

Thermal capacity continues to receive attention and the subject is being further investigated. There has been a distinct tendency towards increased copper cross-section. One operating company has increased the conductor size of its 3 per cent feeder reactors more than 100 per cent over that used about ten years ago, this increase being due to a desire for greater factor of safety, rather than the slightly greater duty imposed by the system's growth. The increased cost is but a small part of the total.

The smaller cross section of these older coils should receive the careful attention of all operating men. The increased use of reactors on outgoing feeders from substations offers a means of using these older coils advantageously, the newer coils being installed in the generating stations, where the short-circuit currents as well as the importance is usually less.

One or two operating companies have found it advantageous to order reactors with taps, so as to properly load parallel feeders of dissimilar characteristics (due to size or length, or both).

Recently attention has been focused on shielding the reactor leads so as to prevent damage from foreign magnetic material, such as bolts, nails, etc., from being accidentally dropped into the coils or drawn into them at times of short circuit. One American manufacturer has enclosed the coils in porcelain and in England a similar protection has been used. Another American manufacturer has designed coils with asbestos insulation around the copper conductors to avoid having the bare parts exposed to this danger. The committee expects to keep in close touch with this development.

The extension of the use of reactors is of interest. At first used in generating stations where their need is, of course, greatest, they are now being installed in substations on lines operating at generator voltages and also on the 2300- and 4000-volt distribution circuits. This latter application not only reduces the duty on the oil circuit breakers (a desirable step, especially where automatic circuit reclosing is employed), but also on the induction regulators, which on many systems would otherwise be subject to short circuits greater than those they are able to withstand.

At the last Annual Convention of the Institute, papers by Boyajian and Blake were presented on a new form of current-limiting reactor—the saturated core

type. The coils are wound on an iron core and the superimposition of a constant unidirectional flux (from coil-carrying direct current) gives a coil with low reactance on normal loads but high reactance at times of short circuit. The cost of such a coil will probably limit its use to special applications.

A paper on "Eight Years Experience with Protective Reactors" was presented before the Spring Convention (St. Louis) of the Institute by Lyman, Perry and Rossman.

In addition to points touched upon above, the Committee recommends that the succeeding Committee give consideration to two points which have recently been suggested, namely:

The question of the use of current-limiting reactors with static condensers, to—

1. Aid in smoothing out surges
2. Limit the fuse current
3. Increase the capacity of the condenser

The question as to whether the use of reactors actually increases the duty on oil circuit breakers.

Grounding of Systems

The principal activities of the subcommittee this year consisted in summarizing the information on grounding methods received in reply to an inquiry sent out in conjunction with the corresponding subcommittee of the National Electric Light Association, to thirty representative companies in the United States.

This subcommittee confined its study to the technical information gathered in this survey, paying particular attention to grounding methods used in a-c. substations of systems transmitting at higher than generator voltage. The prevailing practise of this class of systems is to dead ground the neutral, consequently in case of line to ground faults, large values of ground currents must be taken care of, which calls for a careful study of grounding methods.

The great increase in size of a-c. substations in recent years has forced attention to proper methods of grounding, because in large capacity substations ground fault currents attain such magnitude, that even when flowing through ground connections of only a fraction of an ohm will produce dangerous voltage gradients. In general, it may be stated that the problem of grounding is not so much that of obtaining individual grounds of low impedance, but rather one of obtaining a well distributed ground so as to approach an ideal equipotential area and thereby avoid dangerous potential gradients near ground electrodes when ground-fault currents flow. Another important requirement for a successful ground is the ability to dissipate, at times, large amounts of energy without a material change in the ground.

Grounding to Water Piping System. Water piping systems afford the best grounding systems obtainable and should be used wherever the necessary permission can be obtained. In fact, water systems have such comparatively low ground resistance that, where they are in proximity to other artificial grounds, a difference of potential will exist under fault conditions which will constitute a hazard to life unless the two are connected together. Unfortunately, water systems are available only in built up districts and generally can only be taken advantage of by indoor and moderate voltage substations.

Artificial Grounds. At high-tension substations in outlying districts, it is generally necessary to resort to artificial grounds such as plate or pipe grounds. It is interesting to note that the tendency is away from the use of plate grounds and toward the greater use of pipe grounds.

Although a single pipe ground has a higher resistance than a single-plate ground, a pipe ground of low resistance can be obtained by multiple grounding, that is, by connecting numerous pipes in parallel. In this way a ground of a given resistance can be obtained more economically with pipes than with plates. In addition, the multiple pipe ground will have the advantage of providing a well distributed ground which, as pointed out above, is a very important requirement. It may, therefore, be stated that the advantage of pipe grounds over plate grounds are that they:

a. Are more economical
b. Are more easily installed
c. Allow for convenient inspection and test
d. Provide a distributed ground over considerable area when used in multiple

The characteristics of ground pipes have been definitely determined in extensive tests conducted by the Bureau of Standards and others. Quantitative values on the properties of ground pipes may be summarized as follows:

a. The decrease in resistance with increased size of pipe is quite appreciable up to a pipe one inch in size, beyond which the curve becomes quite flat. From the standpoint of resistance there is, therefore, no economy in using pipe sizes larger than one inch.

b. Very little decrease in resistance is obtained by driving pipes to a greater depth than six feet. Pipes should, of course, be driven to a greater depth when the permanent moisture level is at a greater depth than this.

c. Ninety per cent of the resistance of a pipe ground falls within a radius of six to ten feet around the pipe. Pipes should, therefore, be spaced approximately six feet apart to keep one out of the dense current field of the other.

The effect of moisture and temperature on the resistivity of soils is surprisingly great below certain limits. Above a moisture content of 20 per cent there is very little variation in coil resistivity with variation in moisture content. Below a moisture content of 20 per cent, the resistivity rises very abruptly. With a moisture content of only 10 per cent, the resistivity

of red clay soil is 30 times as great as with a moisture content of 20 per cent.

The effect of temperature on resistivity of soil is not appreciable above 32 deg. fahr. Below the freezing point, however, the resistance increases very rapidly, being 50 times as great at a temperature of 5 deg. than at 32 deg.

In arid regions and in localities with sandy and rocky formations it is generally very difficult to obtain a good ground. In the West where such difficulties are frequently encountered, satisfactory grounds have been obtained by grounding to the steel casings of deep wells. Much benefit can also be obtained by treating the soil surrounding electrodes with chemicals such as ordinary salt, because, of the total resistance of a ground connection the most important part is contributed by the soil, the resistance of the electrode and contact resistance between electrode and soil under ordinary conditions being negligible. The electrical conductance of any soil is by means of the electrolytes formed by moisture combining with the soluble acids, alkalies, and salts, and where they are lacking, their artificial introduction will show excellent results. Such artificially treated soils require close attention and inspection as chemicals must be removed from time to time.

Potential Gradients. Because of the importance attached to the subject of potential gradients near ground electrodes, several tests were made to determine their values under normal operating conditions. These tests, which are reported in Appendixes A and B show that at least 50 per cent of the total voltage drop of a ground will fall within two feet of the ground electrode.

As reported in Appendix A, the potential gradient near the transmission tower when a line conductor becomes grounded to the tower is great enough to constitute a hazard to life. In this case the towers were near a highway and it was recommended that overhead ground wires be installed and carried back to the station ground, so as to improve grounding conditions on the line and eliminate potential gradient hazards.

In the test reported in Appendix B, heavy currents were used which, by heating and drying out the ground caused 80 per cent of the total voltage drop to fall within one foot of the ground electrode. This test emphasizes the importance of making ground connection capable of dissipating large amounts of energy without changing the character of the ground.

Value of Overhead Ground Wire. As pointed out in Appendix A, the overhead ground wire assists materially in reducing line and system ground resistances by connecting all tower and substation grounds in parallel. Several companies report improvement in relay action on grounded systems by connecting station grounds to the overhead ground wire on transmission lines. One company which formerly terminated overhead ground wire one or more spans away from substation reports that serious potential gradients were produced by returning ground currents when lines became grounded to towers, which hazard was eliminated by connecting the overhead ground wire to the substation grounds. It is evident, therefore, that in order to obtain the full benefit of overhead ground wires, they should be connected to the station grounds.

Petersen Earth Coil. Eleven months additional operating experience with the Alabama Power Company's Petersen Earth Coil is reported in a paper by J. M. Oliver and W. W. Eberhardt. The additional experience indicates that the high-voltage disturbances which were experienced when the coil was first placed in service have been entirely eliminated by making provisions to do all line switching, both hand and automatic, with the coil out of service—that is, with the system neutral solidly grounded.

From the experience to date, the application of Petersen Coils appear to be limited to comparatively low voltage lines (66,000 volts and less) of moderate length with a single source of power supply. On an interconnected network, where several sources of supply are maintained to all principle load centers, good service can be maintained without the use of flashover suppressing devices. In other words, the expense and complications of a Peterson Coil installation are justified only on radial feeder systems where it is desired to improve service to an important load center which is connected to the power source by only a single line. The Petersen Coil in such an application has the advantage over grounded neutral operation by reducing line outages due to flashovers, and over isolated neutral operation by eliminating arcing grounds.

Grounding at Generating Stations for Proper Functioning of Relays. In isolated phase installations, although the possibility of phase to phase short circuits are eliminated in case of two simultaneous faults to ground, the hazard of a fault to ground still remains.

Investigations have been made to determine the possibility, not of preventing ground fault currents, but of directing them into channels where they may be taken care of by connecting all metal parts, which are not normally at line potential but which are separated from parts at line potential by insulation, to a copper grounding system. The grounding busses of the three phases are joined together and taken through a current transformer to the station ground, the current transformer operating a relay when fault current flows to ground.

The application of this fault current relay scheme depends largely upon the arrangement of the grounding busses in which connection tests have been made to determine the proper arrangement and connection of the ground bus to various pieces of equipment. It is expected that further details upon this grounding scheme will be available at a later date and is one of the subjects which should be followed up by the grounding subcommittee next year.

Appendix A

Tests ot Determine Potential Gradients in the Vicinity of Transmission Line Towers

Object. To determine if the voltage drop along the surface of the ground in the vicinity of a 120,000-volt transmission-line tower would be dangerous to life at the instant when one line wire became grounded on the tower in question.

Method. One conductor of the line was grounded at

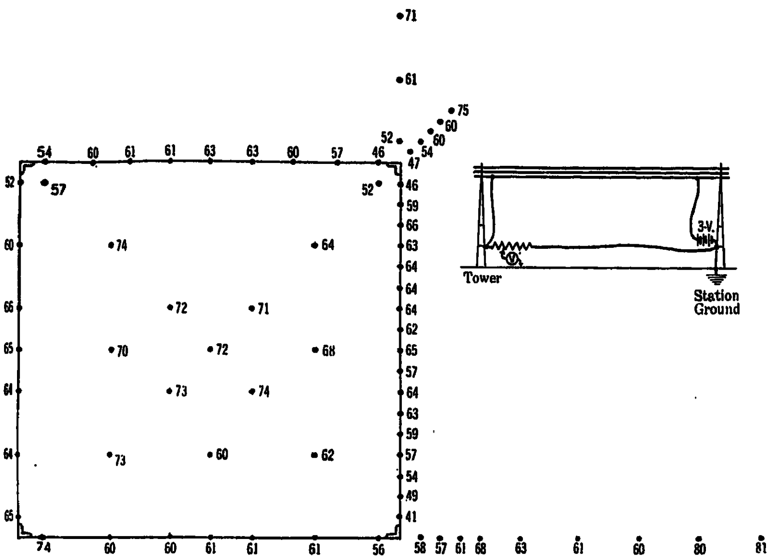

Fig. 7—Potential Gradient Test No. 1

Each number indicates the potential drop from the tower to that point in per cent of the total drop from tower to station ground
Ground resistance at tower = 0.467 ohms
Ground resistance at station = 0.147 ohms

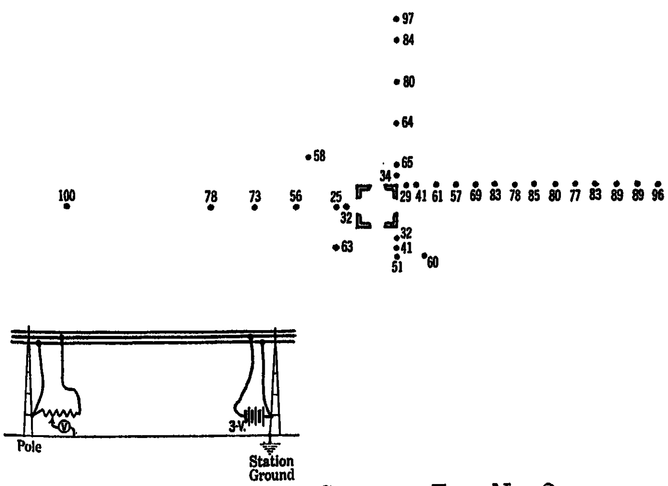

Fig. 8—Potential Gradient Test No. 2

Each number indicates the potential drop from the tower to that point in per cent of the total drop from tower to station ground
Ground resistance at tower = 3.40 ohms
Ground resistance at station = 0.147 ohms

the station, through a battery and the other end of the same conductor was grounded to the tower. A slide-wire rheostat was connected as a potentiometer, from the tower to the station ground, and the slide of the rheostat was at the same time connected through a millivoltmeter to a screw driver, as shown in diagrams 1, 2 and 3.

The screw driver was shoved into the ground at various points in the vicinity of the tower and the slide wire moved until the millivoltmeter read zero. A scale was placed on the rheostat dividing it into 100 parts, the position of the slide at zero reading of the millivoltmeter indicating directly the drop from screw driver to station ground as a per cent of total drop from the tower to the station ground.

Result of Tests:

Test Number	1.	2.	3.
Tower Resistance to Ground	0.467 Ohms	3.4 Ohms	2.6 Ohms
Potential Gredients	See Dia. 1.	See Dia. 2.	See Dia. 3.
Possible ground current in case a conductor becomes dead grounded to tower	5700 amperes	5700 amperes	2375 amperes
Computed voltage to ground	2650 volts	19,350 volts	6,175 volts
Voltage which person leaning against tower could be subjected to	1,590 volts	12,600 volts	4450 to 6175 volts
Voltage which person standing near tower would be subjected to from foot to foot	200 to 300 volts	3000 volts	1300 volts

Conclusion. These tests show that the potential near a tower is dangerously high at the instant a conductor becomes grounded to the tower.

In this particular case the towers were near a highway and the hazard was considered so great as to warrant the connection of the towers to the station ground with an overhead ground wire.

Appendix B

Ground Potential Gradient Test

The object of this test was to determine the potential gradient in the ground surface surrounding a driven ground pipe when a heavy current flow takes place to ground.

This test was made with the following equipment available:

1—6250-kv-a., 2300-volt, three-phase, 60-cycle turbine generator.

1—6300-kv-a., 22000/2300-volt transformer bank consisting of 3-2100 kv-a. single-phase units.

1—22000/110-volt potential transformer.

Switching equipment, instruments, insulator platform, etc.

Connections for the test were made as follows:

The test ground pipe was in a sandy soil which was the best location that could be found. Its measured resistance was 280 ohms.

The auxiliary ground, which was 300 feet distant, was in better soil and had a resistance of 53 ohms. By having an auxiliary ground of lower resistance than the test ground, assurance was made that no failure would occur in the circuit outside of the test ground.

The ground current was gradually increased from zero to a value which caused the test ground to steam. At this point the ground current was 30 amperes with an impressed voltage of 10,000 volts across the ground terminals. This value of current was considered the

maximum which could be maintained for any great length of time.

With the current held constant at 30 amperes, readings were taken of the voltage drop along the ground surface at one foot intervals in the direction of the current flow between the two grounds. The voltage readings were taken with a 22000/110 volt potential transformer and a 0-150 volt voltmeter; one

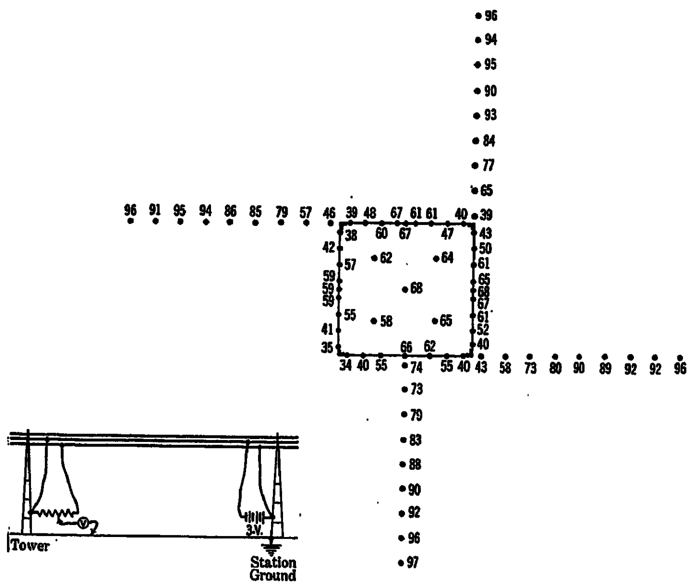

Fig. 9—Potential Gradient Test No. 3

Each number indicates the potential drop from the tower to that point in per cent of the total drop from tower to station ground
Ground resistance at tower = 2.6 ohms
Ground resistance at station = 0.147 ohms

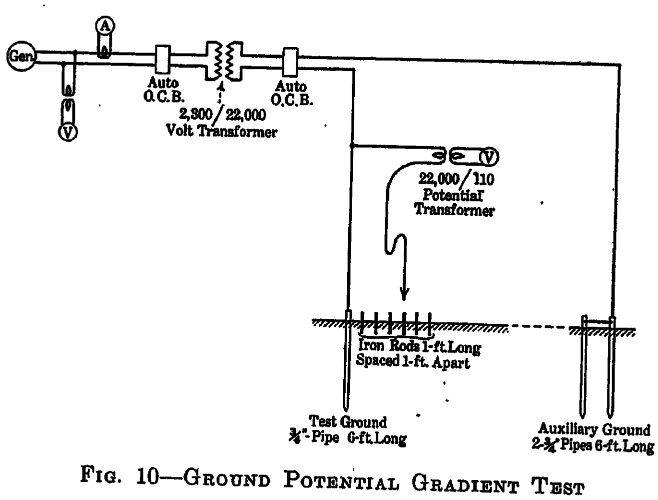

Fig. 10—Ground Potential Gradient Test

primary terminal of the potential transformer being connected directly to the test ground and the other terminal was successively touched to one foot iron stakes at various distances away from the test ground. This manipulation was done by an operator standing on an insulated platform and shifting the connections with a switch pole.

Following is a tabulation of the voltage readings taken:

Distance from Test Ground	Voltage Drop	Per cent of Total Voltage Drop at Test Ground
1 ft.	6900 volts	82.0%
2 "	7000 "	83.4%
3 "	7200 "	85.7%
4 "	7400 "	88.0%
5 "	7600 "	90.5%
6 "	7800 "	92.8%

These readings indicate that 82 per cent of the drop occurred within one foot and 92.8 per cent of the drop occurred within six feet of the test ground.

Another set of readings taken three minutes later averaged 700 to 800 volts higher than those shown above, indicating that the ground was baking out, which, was expected, since the ground was steaming in the vicinity of the ground pipe.

Tests made by the Bureau of Standards and reported in Technological Paper No. 108 showed that approximately 90 per cent of the total drop at a ground pipe occurs within a six-foot radius of the pipe. The Bureau of Standards tests, however, showed a much smaller drop within a one-foot radius of the ground pipe. The only explanation for this difference in results is that the resistivity of the soil around the pipe increased appreciably due to the baking out effect in this test. This emphasizes the importance of making grounds of sufficient current-carrying capacity to meet system requirements.

Lightning Arresters

The work of the Lightning Arrester Subcommittee this year has consisted almost entirely in an effort to list and evaluate the various electrical and mechanical features of lightning arresters.

In order to get an expression of opinion, the form given herewith was submitted as a suggestion in attempting the classification. Members of the subcommittee were requested to give their opinions as to the relative values of the listed features, proportioning each with respect to its importance in their own experience.

Electrical	Weighted Values
1. Spark-over Voltage..................................	
2. Dielectric Spark-Lag..................................	
3. Impedance—Normal Frequency....................	
4. " —200,000 Cycles..........................	
5. " —1,000,000 Cycles........................	
6. Discharge Capacity (amperes by time)..............	
7. Current Passed at Normal Voltage, Normal Frequency, with Gap Short-Circuited........................	
8. Time Required to Interrupt Dynamic Current........	
Mechanical	
9. Condition After Heavy Discharge..................	
10. Number of Heavy Discharges Arrester will take care of Without Repair..................................	
11. Attention Required in Service:	
(a) None..................................	
(b) Not More Than Once Per Season............	
(c) After Every Heavy Discharge................	
(d) Once a Day or Oftener......................	
12. Cost..................................	
13. Depreciation per year..................................	
Total..................................	100 per cent

This was sent out to members and was taken up for discussion at the midwinter meeting of the main committee. There was apparently quite a diversity of opinion among engineers as to the value and accuracy of such a classification. This diversity of opinion seemed to be, in a large measure, due to varying ideas as to the definition of the duty of a lightning arrester and of the various quantities involved.

The subcommittee was therefore, instructed to make an effort to state definitely the duties of a lightning arrester and to define clearly the quantities which make up the suggested classification. Following this, the subcommittee is to proceed with the classification along the lines suggested.

It is, therefore, possible to report progress only.

The measurement of some of the quantities necessary in making up the classification presents something of a problem. Particularly this is true of the measurement of dielectric spark-lag and the rate of discharge of lightning arresters. It is found that when discussing these quantities, there is a very great difference in the methods used by different experimenters. The different methods in use result in widely different readings of the quantities being sought. It seems that it is necessary to define very precisely, the size of the condenser to be used in measuring the discharge of an arrester; all the characteristics of the circuit to be used in measuring the voltage, and many other similar quantities.

It will undoubtedly be necessary to arrive at some standardization of these measurements before it will be possible to standardize or classify lightning arresters. In order to arrive at a definite method of determining these quantities, the Research Committee has been made acquainted with the problem, and it is hoped that through this cooperation some standard and practicable method of measurement may be obtained.

It is recommended that the succeeding subcommittee continue the work along similar lines.

Relays

Many difficulties have been encountered in the completion of the Relay Handbook. It is now in the hands of the printers and should be available for distribution in June.

This subcommittee is cooperating with the corresponding subcommittee of the Apparatus Committee, N. E. L. A., and plans within the next year to prepare the first supplement to the Relay Handbook. This supplement will be patterned after the Relay Handbook both as to form and size.

Although no new relay developments have been reported to date, several interesting installations have been received. One operating company has made an installation of protective equipment in a generating station, which is rather interesting in a number of respects, particularly in the matter of its completeness. A complete description of this installation appeared in the *Electric Journal* for April, 1924.

This same company has also made use of a variation of the split conductor scheme for the protection of a large frequency changer used for interconnecting 25- and 60-cycle systems. A description of this was given in a paper entitled "Use of Frequency Changers for Interconnection of Power Systems," by H. R. Woodrow, at the Spring Convention in St. Louis, April, 1925.

The problem of protecting generating station auxiliaries was investigated to some extent by this subcommittee, but the findings are not sufficiently definite to report more than progress. It is recommended that the succeeding subcommittee give this matter particular attention, and that the use of the so-called "Voltage Chaser" or automatic throwover switch be investigated. This latter gives some promise of considerable usefulness in assuring a continuous power supply to generation station auxiliaries, and it is felt that the subcommittee can do valuable service in coordinating experience and practise.

Oil Circuit Breakers

Progress in Standardization. Interrupting rating of oil circuit breakers was defined by the Protective Devices Committee last year. This definition has now received all of the necessary approvals and is before the Standards Committee for final adoption.

The proposed uniform procedure for testing oil-circuit breakers as prepared by this Committee last year has now been approved by the N. E. L. A. and is, therefore, in line to be used for future tests made by operating companies. Standardizing the methods of making system tests should make possible comparisons between tests on an equivalent basis so that maximum knowledge may be obtained from them.

The new edition of the A. I. E. E. Standards now being compiled will cover oil circuit breakers much more thoroughly than they are covered by the current edition. The most important new provisions are:

Conditions and Methods of Making Temperature Tests.

Tests of Dielectric Strength and Conditions and Methods of Making Same.

Protection from Voltage Surges.

Attention is called to the following definitions recently adopted by two prominent European technical societies covering certain essentials in connection with oil circuit breaker performance:

Working Voltage is the maximum potential occuring under any operating conditions at the point where the switch is installed in single and three-phase installations measured between the outer conductors. (Not including over-voltages).

Working Current is the effective value of the maximum current which flows through the switch continuously under any operating conditions (not including short circuit or over-current of short duration.)

Interrupting current is the effective value of the a-c. component which flows through the switch at the moment the contacts are opened during interruption.

Interrupting Voltage is the effective value of the potential which, at the interruption, occurs on the line that remains under voltage immediately upon the dying out of the arc of the interruption in all phases.

The present standard general definition of interrupting rating, paragraph 7090, A. I. E. E. Standards 1922, specifies the rating of current and voltage which the device will interrupt under "Prescribed Conditions." No attempt has been made to date to define prescribed conditions and much further study and experience will be necessary before anything could be done along this line. It appears, however, that sufficient knowledge and experience is available at least to begin studies to define the "Prescribed Conditions." In particular, the great difference in normal recovery voltage across circuit breaker contacts on systems with dead grounded neutrals, as compared with those whose neutral is free or grounded through resistance, makes it very desirable that the "Prescribed Conditions" be determined to the extent of covering this situation. Material economic advantage to many operating companies should result therefrom.

Standardization of interrupting ratings is in active progress at the present time by definite committees, which are now cooperating, to establish standard ratings, so as to reduce the number of circuit breaker designs which must be developed and the number of types of breakers required.

Recommendations. The following recommendations are offered:

a. Definite steps should be taken for a beginning, at least, toward formulating the "Prescribed Conditions" under which an oil circuit breaker is rated. First consideration should be given to the effect of conditions of operation of system neutral on interrupting rating of breaker.

b. Pending the working out of the above problem "Normal Voltage," in the present definition of interrupting duty should be defined so as to permit of no misunderstanding as to its relation to recovery voltage in any given case. Presumably for the present, at least, the breaker should be rated so that the recovery voltage is equal to normal voltage.

c. Definitions equivalent to those for Working Voltage, Working Current, Interrupting Voltage and Interrupting Current given above should be adopted by the A. I. E. E.

Latest Design and Practise in Power Plants

By Committee on Power Generation*

Introduction

PROGRESS in the art of steam station design and operation has been so rapid as to rather bewilder even the men who are giving their whole time and thought to this work. We have grown quite accustomed to seeing our dreams become actualities almost over night. The past year has witnessed the actual generation of power in an 80,000-kw. generating station at a coal rate of kw-hr. 20 per cent lower than any previous performance on a commercial scale. May we with confidence look forward to further gains of the same magnitude? May we expect that each new station built will establish a new record for operating performance? Why does each new steam generating station differ so radically from those already built? If we are to answer these questions, we must evaluate the present day tendencies, look backward a bit to see how far we have come, and attempt to look forward.

Important Technical Achievements of the Last Year

1. The operation of the two 40,000-kw. General Electric single-cylinder turbines, in the Philo Station of the Ohio Power Company: The steam is delivered to the turbine throttle at a pressure of 550 lb. per sq. in. gage, and a temperature of 725 deg. fahr., the steam being withdrawn from the turbine after being expanded down to a gage pressure of 155 lb., returned to the boiler room, reheated to a temperature of 725 deg. fahr., and then expanded through the remaining stages of the turbine to a pressure of approximately ½ lb. per sq. in., absolute at the turbine exhaust. This marks the consummation in this country of Ferranti's dream of a reheating cycle. The two units in this station have been in operation since October 14, 1924, and February 24, 1925, respectively. The water rate, corresponding to a load of 40,000-kw., steam conditions being as indicated above and no steam bled from the turbine for feed water heating, is reported to be approximately 8 lb. per kw-hr. In normal operation, steam is bled from two stages of the turbine for feed-water heating. The feed water then goes through economizers before

being delivered to the boilers. The air for combustion passes through a preheater before going to the wind box of the chain grate stoker. The flue gases pass through the preheater on their way from the economizers to the stack. The heat consumption for this station has over a week's time been as low as 13,715 B. t. u. per kw-hr. of net station send-out, this performance corresponding to a load factor of 81 per cent for the week.

2. The initial operation of the Crawford Avenue Station of the Commonwealth Edison Company in Chicago: The turbines in this station are designed for substantially the same steam conditions as the turbines in the Philo Station. The three turbines in the Crawford Avenue Station are of the cross compound type and were built by three different manufacturers—

a. 50,000-kw. unit—C. A. Parsons
b. 60,000-kw. unit—General Electric Company
c. 50,000-kw. unit—Westinghouse

Two surface condensers with vertical tubes connect direct to the exhaust casing of the low pressure element of each of these turbines. Each of these three turbines was built on a new design and they present many interesting features. Due to the new design of low pressure exhaust nozzle and condenser, new features have been embodied in the turbine foundations, the building layout and the arrangement of auxiliaries. The Crawford Avenue Station has been in operation only a few months and as yet the single stage of reheating of the steam during its expansion has not been used.

3. The construction by the General Electric Company of a 3000-kw. turbine, running at 3600 rev. per min., for operation in the Weymouth Station of the Edison Electric Illuminating Company, with a steam pressure of 1200-lb. per sq. in. gage and a steam temperature of 700 deg. fahr. at the turbine throttle: This turbine will exhaust against a back pressure of approximately 350-lb. per sq. in. gage, its steam being first returned to the boiler room to be reheated to 700 deg. fahr. and then discharged into the main steam header of the station. Only one boiler for operation at 1200-lb. per sq. in. gage has been installed at the present time. This high pressure boiler and the turbine which serves as its reducing valve will soon be completely erected and ready for operation.

4. The operation in the Colfax Station of the Duquesne Light Company in Pittsburgh, of two 35,000-kw. Westinghouse turbines, with four-stage bleeding of steam to raise the feed water to a final temperature of approximately 350 deg. fahr. before it is returned to the boilers: This marks the extreme development of the regenerative cycle in turbine room operation.

5. The operation of four 30,600-sq. ft., double-ended Stirling boilers, with 22,464-sq. ft. economizers in the Lake Shore Station of the Cleveland Electric Illuminating Company: These boilers and economizers, equipped with pulverized fuel burners and furnaces—each of the latter having a volume of 29,150 cu. ft., have shown on test an efficiency of 92.9 per cent at 140 per cent of normal rating, and an efficiency of 89.8 per cent at 270 per cent of normal rating. These same boilers have operated at an average gross efficiency of as high as 90.4 per cent for a month's time. These results have been obtained with coal running as high as 11 per cent in ash and as low as 12,600 B. t. u. per lb. in heat value. The sulphur was as high as 3.5 per cent and the coal ash melted at approximately 2150 deg. fahr.

Operating efficiencies in connection with the 29,085 sq. ft. double-ended Stirling boilers in the Trenton Channel Station of the Detroit Edison Company, have been only slightly lower than the results quoted above for boilers installed in the Lake Shore Station in Cleveland. Each of these boilers in the Trenton Channel Station is equipped with two 9492 sq. ft. economizers. The coal is fired in pulverized form, and the furnace has a volume of 25,140 cu. ft. These operating results in the Lake Shore Station and the Trenton Channel Station, with the unburned fuel loss reduced to a small fraction of 1 per cent and the temperature of flue gases reduced to from 230 deg. fahr. to 250 deg. fahr., present an achievement undreamed of a few years ago.

6. The operation of the 18,010 sq. ft. Babcock & Wilcox cross-drum boilers in the Cahokia Station of the Union Electric Light & Power Company of St. Louis: These boilers are twenty tubes high in the main tube bank and are not equipped with economizers. The coal is burned in pulverized form. The furnace has a volume of 12,850 cu. ft. Burning a most inferior grade of southern Illinois coal, these boilers have shown on test an efficiency of 85.9 per cent at 148 per cent of normal rating and an efficiency of 82.1 per cent at 260 per cent of normal rating. The average gross boiler-room efficiency in the Cahokia Station has run as high as 81.2 per cent over a month's time. These results are remarkable for two reasons:

a. They were accomplished with very low grade coal.
b. They were accomplished without the use of economizers or air heaters.

7. The successful operation in the Chester Station of the Philadelphia Electric Company, of underfeed stokers, with air delivered to the stoker wind box preheated to a temperature 550 deg. fahr.: A 15,000 sq. ft. boiler, equipped with a 15-retort, 22-tuyere, Taylor stoker with clinker grinder has operated for extended periods at ratings in excess of 300 per cent of normal boiler rating, with air delivered to the stoker wind box at a temperature of approximately 550 deg. fahr. The fuel bed has been free from large clinkers and is as easy to maintain in good condition as in connection with other boilers not equipped with air preheaters. It appears that stoker maintenance will not be greatly increased by use of preheated air. It does appear, however, that furnace walls designed along conventional lines will not withstand the effects of the high furnace

temperatures which obtain in connection with the use of preheated air.

8. The further developments in use of water-cooled furnace side walls as exemplified in connection with the boilers installed in the Hell Gate Station and Sherman Creek Station, of the United Electric Light and Power Company in New York, and the boilers installed in the Zilwaukee Station, of the Consumers' Power Company in Michigan.

A novel wall has been in operation since November in connection with one of the stoker-fired boilers in the Lake Shore Station in Cleveland. By water cooling, the inner refractory lining having a thickness of less than 1 in. is maintained at a temperature of less than 2000 deg. fahr., but still at not too low a temperature to slow up combustion adjacent to the wall.

9. The successful use of Cottrell precipitators in the Trenton Channel Station, of the Detroit Edison Company, for the removal of fine ash from the flue gases before they pass out the stack: The ability of this equipment to remove 75 per cent of the solids in suspension in the flue gas has been demonstrated.

10. The successful operation of 70 in. Fuller air-separating type of pulverizing mill in the Cahokia Station, of the Union Electric Light and Power Company of St. Louis: This mill has pulverized 28 net tons of Illinois coal per hour, with a combined power consumption of 294 kw. for the motors driving the mill and the exhauster fan. Coal was pulverized to a fineness so that 65 per cent passed through a 200 mesh screen. This mill and its driving motor occupy a floor space of 13 by 21 ft.

11. The development by the Fuller-Lehigh Company of the "well type" furnace for burning coal in pulverized form: In an experimental furnace 8 ft. square by 8 ft. high, 32,700 lb. of coal per hour have been burned. Such observations as can be made, in connection with a furnace open at the top to atmosphere indicate that the coal is completely burned.

12. The successful operation in several stations of automatic combustion control equipment: Notable installations are those in the Lake Shore Station in Cleveland, Sherman Creek Station in New York, and Devon Station, of the Connecticut Power and Light Company, in Devon, Conn. Reference has already been made to the close agreement between average monthly operating efficiencies in the Lake Shore Station, and the efficiencies obtained under the most carefully made tests. It appears that equipment is now available which will enable elimination in large measure, of the losses incident to the lack of constant vigilance by the firemen.

13. The efficient operation of large single-pass condensers in the Waterside Station, of the New York Edison Company, and the Trenton Channel Station, of the Detroit Edison Company: In these installations less than 1 sq. ft. of surface is installed per kw. of turbine capacity. Ample provision has been made, however, for the penetration of steam into the tube bank. These installations point the way to possible reductions in the cost of condensing equipment without appreciable reductions in station economy.

14. The placing in operation of five 30,000-kw. and nine 20,000-kw. turbines of the new Westinghouse multi-exhaust Baümann type.

15. The construction by the General Electric Company of two 50,000-kw., 62,500-kv-a., 1800-rev. per min., tandem compound turbo-generators, for the new Richmond Station of the Philadelphia Electric Company, and two 60,000-kw., 60,000-kv-a., 1500 rev. per min., single cylinder turbo generators, for the Fourteenth Street Station of the New York Edison Company.

16. The use of three new methods for insuring the reliability of the power supply for the auxiliaries in large steam stations:

a. In ten new stations recently placed in operation or now in the course of construction, the generator which supplies power for the essential auxiliaries is directly coupled to the main generator and driven by the main turbine.

b. In the Trenton Channel Station, of the Detroit Edison Company, the power for the auxiliaries is obtained from separate turbo generators which operate as condensing machines and constitute a separate power plant within the larger power plant.

c. In connection with the Parsons turbine in the Crawford Avenue Station, Chicago, and the Richmond Station, Philadelphia, the power for the essential auxiliaries is to be obtained from a transformer which is tied direct to the leads of the main generator.

17. The extensive use of waste heat driers and steam driers for removing the moisture from coal before it is pulverized: This is best exemplified by the installations in the Cahokia Station, in St. Louis, and the Trenton Channel Station, in Detroit.

Important Developments of the Past Few Years

These things have come to pass within the last year. Looking back over a slightly longer period, we see the development of the steel-tube economizer for high pressure installations; the development of the inter-deck and radiant heat superheaters; the development of the air-cooled furnace for pulverized fuel, with a water screen for protecting the furnace floor; the development of the air preheater; the use of the closed system of ventilation with radiator type coolers for large turbo generators; the widespread use of deaerators and evaporators; the all but universal swing to the use of electric-driven auxiliaries; the newer developments in the design of boiler settings for chain grate stokers to insure a thorough mixing of the rich gas stream which rises from the front end of the stoker with the excess air which comes up through the rear end of the stoker, so as to enable a minimum of excess air to be used; and the development of the underfeed stoker for total furnace depths up to 19 ft. 8 in. All of these things were unknown as commercial achievements and most of them undreamed of five years ago.

The length of the strides which we have taken may be visualized by reference to the most interesting address

delivered by Mr. W. H. Patchell, at the time of his inauguration as president of the British Institution of Mechanical Engineers on February 21, 1924. As a result of a review of the situation in this country and abroad, Mr. Patchell presented the operating efficiencies for thirty-six stations in England, twenty-five stations in the United States, and one station—the Gennevilliers Station—in France. The heat consumption per kw-hr. for the most efficient station in England was given as 20,150 B. t. u. The heat consumption for the most efficient station in the United States was given as

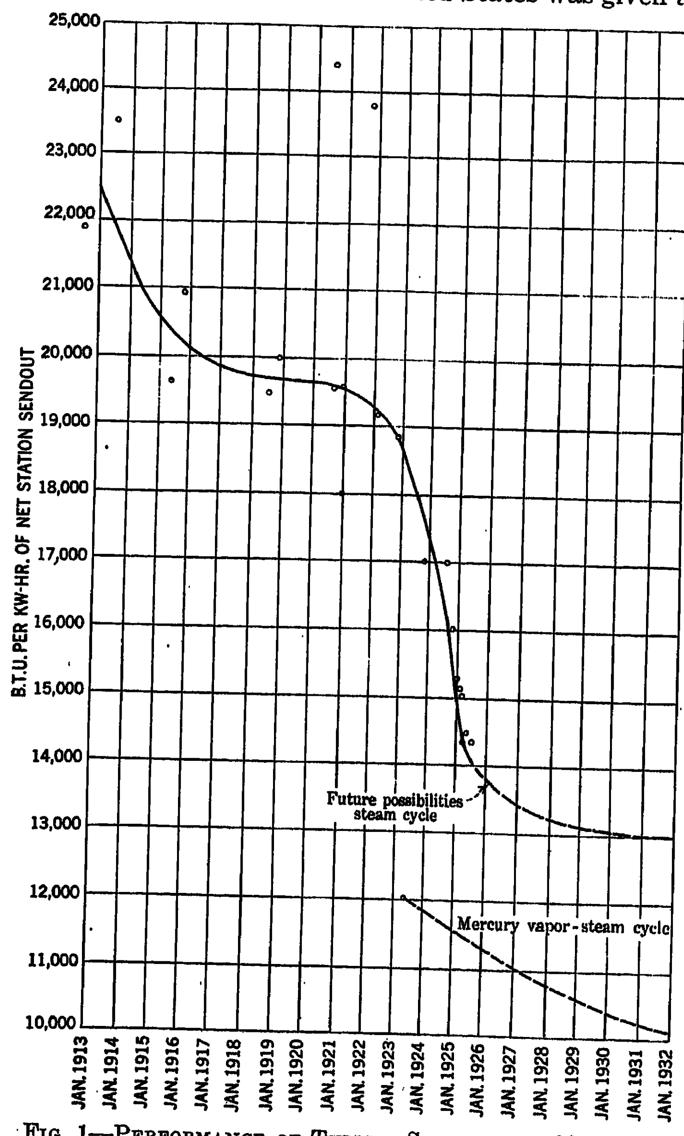

FIG. 1—PERFORMANCE OF TYPICAL STATIONS OF 60,000-KW. CAPACITY AND HIGHER PLOTTED AGAINST DATES OF INITIAL OPERATION OF STATIONS

18,030 B. t. u., and the heat consumption for the Gennevilliers Station in Paris was given as 22,240 B. t. u. We have referred earlier in this report to the remarkable performance of the Philo Station of the Ohio Power Company, which has been as low as 13,715 B. t. u. per kw-hr.

These same facts referred to in the preceding paragraph may be visualized by reference to the curves in Fig. 1, which show the trend of performance of typical stations plotted against the dates of initial operation of these stations. This curve is not the product of a disordered imagination, but represents the weighted average in connection with the performances plotted for twenty-two stations. At first glance, the curve appears to have a very peculiar shape. Further analysis indicates that there was a very definite reason for the slowing up of power-station development during the war period, and the extremely high prices of coal during the period from 1920 to 1922, inclusive, in no small measure account for the marked improvement in the performance of stations which have gone in service within the last six months.

The dotted extension of the curve shown on Fig. 1 is our estimate as to the future possibilities in the way of improved performance for a station designed to operate on the straight-steam cycle with a single stage of reheating. Obviously, this curve has to flatten out. We have also shown the over-all performance for a combined mercury vapor and steam station, which is indicated by the performance of the mercury-vapor turbine and boiler in the Dutch Point Station of the Hartford Electric Light Company, and we have shown by means of a dotted curve our estimate as to the future possibilities of the combined mercury vapor and steam cycle.

One might well gain the impression that the possibilities for further improvement in steam-station design have been almost exhausted. This is hardly the case. There are at least three major possibilities immediately ahead which will result in higher operating efficiencies for our steam generating stations:

a. The further development of commercial equipment for use in the application of the mercury vapor-steam cycle.

b. The development of superheaters, high-pressure steam piping, valves and turbines for operation in connection with steam temperatures of 800 deg. fahr. or higher.

c. The use of hydrogen or some equally suitable gas as the cooling medium in connection with closed ventilating systems for turbo generators, and the development of new generator designs which will take advantage of all the possibilities of this new cooling medium.

It is perfectly true, however, that while there has been a drop from approximately 18,000 B. t. u. per kw-hr. to 14,000 B. t. u. per kw-hr. in the last eighteen months, a further reduction from 14,000 to 10,000 B. t. u. per kw-hr. cannot be looked for unless use is made of the mercury vapor-steam cycle, with comparatively high pressure used in connection with the mercury vapor boiler and the most efficient possible layout in connection with the steam end of the station. As far as further reduction in the fuel cost in connection with large steam stations goes, work is being done on the law of diminishing returns. A point has already been reached where further gains are going to be very difficult of attainment.

The report thus far has dealt in large measure with the technical achievements and with the reductions in heat consumption in connection with our newer stations.

Our real function as power station engineers, however, is to deliver power on the station bus-bars at the lowest possible cost per kw-hr., and it is in the analysis of the elements which go to make up the cost per kw-hr. that we find the real answer as to the most profitable trend for future power station development.

The total cost of each kw-hr. delivered on the station bus-bars is made up of four major elements:

a. Operating labor and superintendence
b. Maintenance
c. Fuel cost
d. Fixed charges on the investment

The so-called operating cost which most of us talk

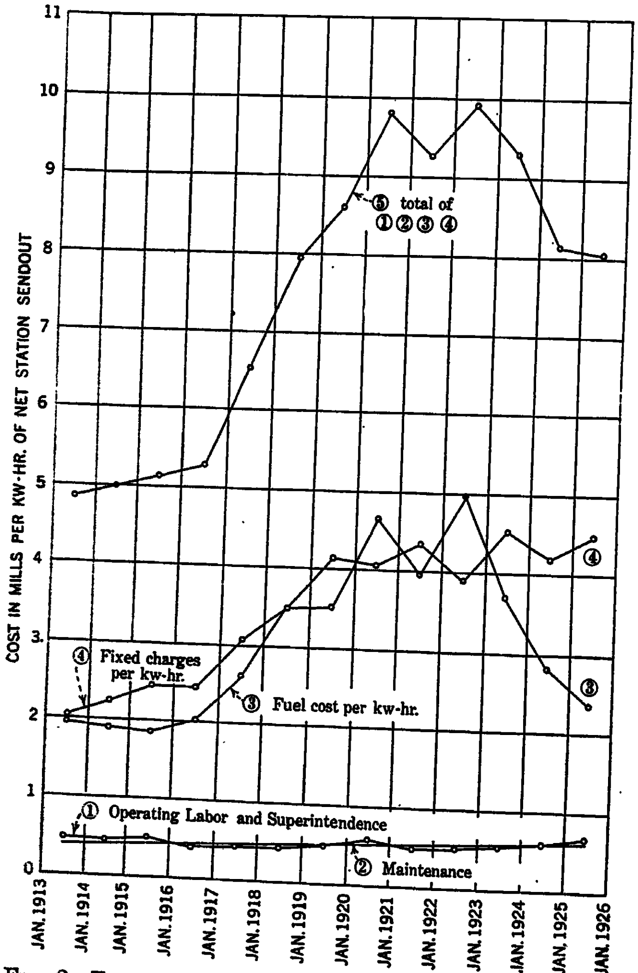

Fig. 2—Trend of Operating Costs and Fixed Charges for Typical Stations of 60,000-Kw. Capacity and Higher Plotted Against Date of Initial Operations of Stations

about when we discuss power costs, is made up of items a, b and c. Accounting systems commonly used do not spread fixed charges so as to allocate so many mils to each kw-hr. generated, and accordingly many of us lose sight of them. It is perfectly obvious, however, that the interest and the taxes paid in connection with an investment in power stations and the money which must be set aside each year to provide for renewals due to depreciation and obsolescence are just as tangible elements entering into the cost per kw-hr. as the money which must be paid for fuel to generate that same kw-hr.

In Fig. 2, is shown the trend of operating costs and fixed charges of typical large power stations plotted against the dates of initial operation for these stations. As in connection with Fig. 1, only power stations of 60,000-kw. capacity and higher are considered. An endeavor has been made to take into account all the

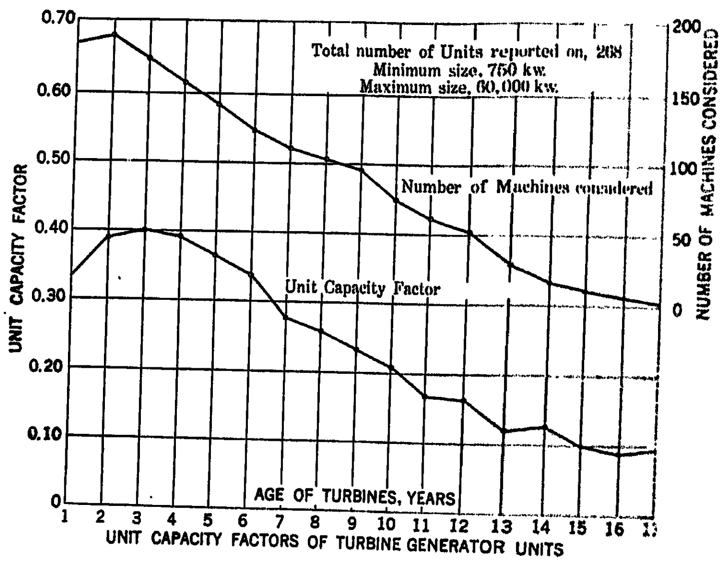

Fig. 3—Unit Capacity Factors of Turbine-Generator Units

different factors in the derivation of these curves. Some of these factors are as follows:

1. The variation in the cost of labor, both for operation, maintenance, and for construction work during the period from 1913 to 1925.
2. The variation in material costs and equipment costs.
3. The variation in coal prices (costs of coal delivered in the bunker for a power station in Baltimore has been taken as the basis).
4. The variation in the cost of new money in connection with financing which has been done during succeeding years.
5. The variation in taxes which have as their basis the investment in power stations.
6. The variation in the probable use factor of equipment placed in service during succeeding years. The average load factor of the system, the outages of equipment for inspection and repairs, and the amount of spare capacity considered necessary, are factors which go to make up the use factor in connection with the station.
7. The decrease in man hours of operating labor per kw-hr. incident to certain developments in power-station design.
8. The tendency towards the decrease in cost per kw. of installed capacity due to certain trends of power station design, and the conflicting tendency towards increased power station costs due to other trends of power station design.

The thing which stands out from an inspection of the curves in Fig. 2, is the relative trend of the fuel cost and the fixed charges during recent years. There has been a marked reduction in fuel cost due to the improvements in power station design and due to the declining price of coal. There is a definite upward tendency, however, in connection with the fixed charges per kw-hr., and as the matter stands at the present time the fixed charges

are 4.5 mils per kw-hr. as compared to a fuel cost of 2.4 mils per kw-hr. For those stations which are located in closer proximity to the coal mines and have the advantage of lower coal costs, the fuel costs will be still further reduced, assuming, of course, the same modern power station design for the best possible economy. The fixed charges, however, will remain at 4.5 mils.

The indications are that if we strive for lower fuel costs by the use of more efficient stations, the fixed charges per kw-hr. will rise still higher, and the increase in fixed charges per kw-hr. will more than offset the decrease in fuel cost per kw-hr.

The real job which the power station engineer has ahead of him is to decrease the fixed charges per kw-hr. and to reestablish the proper balance between fuel costs and fixed charges.

Certain executives and engineers will, no doubt, state that the fixed charges per kw-hr. in the newer stations which they are placing in operation, are very much lower than the curve indicates in Fig. 2, this being for the reason that these newer stations are carrying the base load for their system and are operating at an extremely high use-factor. Our answer is that this is a transient condition. Each new turbine or station operates on base load only for so long a time as it constitutes the most efficient turbine or the most efficient station generating power for that particular system. The curves given in Figs. 3 and 4 tell this story in a very striking manner. They show that the generating unit is heavily loaded during the second and third years of its life, but that from then on the loads carried during succeeding years gradually decline. These curves given in Figs. 3 and 4* constitute the actual operating history as regards kw-hr. generated during succeeding years by 268 turbines ranging in size from 750 kw. to 60,000 kw.

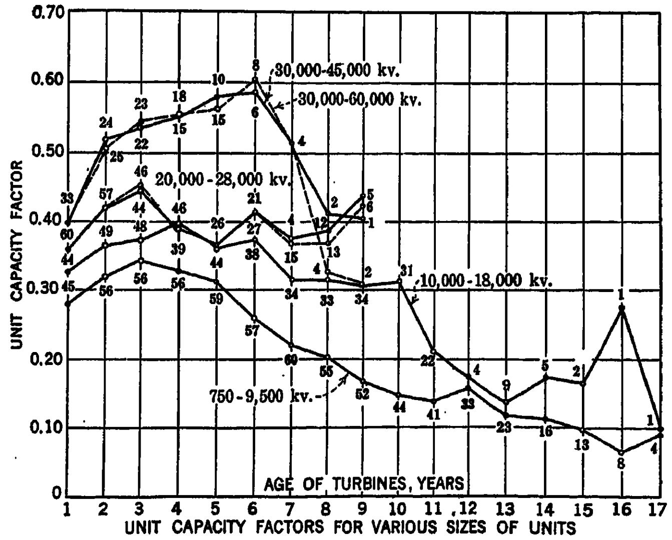

Fig. 4—Unit Capacity Factors for Various Sizes of Turbine-Generator Units

*The data given in Figs. 3 and 4 was compiled by the Turbine and Generator Committee, Association of Edison Illuminating Companies, and embodied in the report of that Committee for 1923.

It is perfectly obvious that fixed charges per kw-hr. must be determined by taking the total fixed charges on a piece of equipment or on a station during its life and spreading them over the total number of kw-hr. generated by that particular turbine or station during its useful life.

It is of interest to note from Fig. 3, that the average unit capacity factor during the 17-year period on the 268 turbines is approximately 25 per cent. The curve of fixed charges given as a part of Fig. 2 was based on the assumption that for generating stations placed in operation in 1913, the average unit capacity factor during their life would be 31 per cent, and for stations placed in operation in 1925, the average unit capacity factor would be 36 per cent. The evidence would tend to indicate, therefore, that if error has been made, it is on the side of showing the fixed charges per kw-hr. too low rather than as too high.

Tendencies in the design of steam generating stations may be classified under four heads:

1. Tendencies which improve the reliability of the power station, increase its cost, but do not appreciably affect the operating efficiency; for example:

a. The use of house turbines, auxiliary generators, and storage batteries for insuring the auxiliary power supply.

b. Isolated-phase layout and the use of reactors and other protective devices in the switchhouse.

c. The duplication of auxiliaries, and provision of excessive amounts of spare capacity in boilers and turbines.

2. Tendencies which decrease the coal consumption per kw-hr. and increase the cost of the power station; for example:

a. The use of excessively high steam pressures taken together with a single stage of steam reheating during its expansion.

b. The use of pulverized fuel-burning equipment.

c. The use of adjustable speed motors for driving auxiliaries where saving in power consumption at light loads is the consideration.

d. The use of air heaters or economizers usually falls in this classification.

e. The use of an excessively large amount of surface in the surface condensers for the main turbines.

3. Tendencies which decrease the coal consumption per kw-hr. and also result in a reduction in the cost of the power station and perhaps in the cost of operating labor; for example:

a. The use of electrically-driven auxiliaries.

b. The use of moderately high steam pressures without reheating.

c. The use of the highest steam temperatures which are possible with existing materials.

d. The use of large turbines and large boilers.

e. The use of three or four-stage bleeding for raising the temperature of feed water to within 75 deg. or 100 deg. of saturated steam temperature.

f. The use of large mills for pulverizing coal.

4. Tendencies which add to the cost of the station without improving either its reliability or appreciably decreasing its coal consumption; for example:

a. Insufficient care given to grouping of equipment and waste space in power station building.

b. Too many architectural frills.

For a particular set of operating conditions, some of the examples which have been cited above as falling in one classification may really classify themselves under an entirely new head. An inspection of the curve given in Fig. 2, however, presses home the conviction that every tendency which makes for an increase in the cost of steam generating stations, and correspondingly increases the fixed charges, must be viewed with suspicion. The burden of proof should be on the designing engineer to show why the particular feature should be embodied in the design. The same line of reasoning indicates that the designing engineer should give intensive study to those tendencies of power station design which hold forth promise of giving lower first costs and lower fixed charges, as well as lower fuel costs.

Now, turning to the field of hydroelectric plant design and operation, we find somewhat different conditions obtaining and no such revolutionary changes taking place as there are in connection with steam station design. There is one definite tendency in hydroelectric plant design very similar to that which has made itself evident in recent years in steam station design, namely, the trend toward the use of larger water-wheel turbines and larger water-wheel generators. In the main, the objective is not higher efficiency, but lower cost per unit of installed capacity. The tendency seems to be toward using as large water-wheels as the turbine manufacturers can build in single runner vertical turbines for the operating head that is to be developed. An effort is then made to match this water-wheel turbine with a generator which will permit delivering the full output of the water-wheel turbine to the station busbars. Water-wheel type generators of 65,000 kv-a. have been built. It is true, however, that these generators have been built for special plants, and that only in a few cases has a maximum rating of 35,000 kv-a. been exceeded. However, the size of generators is entirely economically dependent upon the individual case and its relation to the size and charging current of the transmission lines, if not limited by the maximum possible output from the water-wheel turbine.

In the future, it is going to be even more important than in the past to build water-power plants with a low first cost per unit of capacity. This must be done if the power from water-power plants is to compete with power from the larger and more efficient steam generating stations. The use of larger generating units is the one means that holds forth most promise for decreased station costs. Further, with the greatly increased total loads in connection with the big power systems, it becomes perfectly feasible to install generating units of large capacity. The tying of a number of plants into the transmission network of a large system makes single unit water power developments practical, and combined with remote or supervisory control, such developments permit a simple layout, resulting in low operating expense. This is particularly the case with some of the smaller power sites which are relatively close to existing developments. Simplicity of layout is very desirable, as it has a direct effect on reduction of costs, both capital and operating. The importance of this trend toward the use of larger generating units in connection with hydroelectric plants has made it seem worthwhile to prepare a symposium of the views of the engineers of the several different manufacturing companies on this particular subject. These statements are quoted herewith:

Statement by W. M. White. There are five principal factors which limit the maximum capacity of hydroelectric equipment. These reasons are given below:

a. Shipping facilities
b. Material size limits
c. Economical generator speeds
d. Manufacturing limits
e. Strength and life of parts

Shipping facilities are an important factor on many developments, the runner being the item most frequently affected. Runners for medium and low heads may be sectionalized, but this is expensive, and for high heads it is doubtful whether sectionalized runners can be made sufficiently strong. Other parts of the turbine can usually be sectionalized to accommodate shipping, but the runner is usually the limiting factor.

The sizes of available material is another important limiting factor. Shafts must be forged from steel ingots. At the present time, the largest ingots obtainable are about 80 in. in diameter, so that the shaft flange must come within a reasonable margin below this diameter. This factor seems to be one of the important points and limits size to about 100,000 h. p. at 200 ft. head, or 110,000 h. p. at 300 ft. head.

Economical generator speed is the most important factor for low head developments. The cost per kw. of generator equipment increases rapidly for speeds below 80 or 90 revolutions. Seventy rev. per min. is about the minimum for economical generator construction and this fact places the limit at about 12,500 h. p. at 20 ft. head and 30,000 h. p. at 40 ft. head.

Incidentally, the runners for large low head developments are usually larger than can be shipped in one piece, but propeller-type runners can readily be made in several sections so that shipping is not the most important factor for low heads.

Manufacturing limits are another important factor, that is, there is a maximum height and diameter of parts which can be handled with present shop tool equipment. Larger tools can be designed and constructed, but with the limited use for such equipment there is a question as to whether or not this is economical. At the present time, most of the manufacturers of hydroelectric equipment are able to handle diameters up to 28 or 30 ft. and heights of from 10 to 12 ft. Without exceeding these limitations, it is possible to build units for about 52,000 h. p. at 70 ft. head, 70,000 h. p. at 100 ft. head, and 90,000 h. p. at 150 ft. head.

Strength and life of parts is another important factor limiting the maximum capacity of hydroelectric units. For high head developments, the question of penstock material is sometimes a limiting feature and practically limits us to 100,000 h. p. capacity under 2000 ft. head and 60,000 h. p. capacity under 1000 ft. head. These turbines would be of the impulse type. For heads between 800 and 400, the question of strength and life of the runner is an important factor. Pitting occurs more frequently under these high head conditions and it is, therefore, advisable to make the diameters larger in order to decrease the relative velocities in an effort to decrease this pitting. Smaller runners of higher specific speeds could deliver the same h. p., but their life and strength is questionable and in all probability they would pit seriously in a short time. These factors seem to

indicate that 110,000 h. p. is the upper limit for heads of 400 to 800 ft., using the reaction type of runner.

These limitations are based not on a consideration of either hydraulic equipment or electrical equipment alone, but on a combination of the two as a hydroelectric unit. Undoubtedly, turbines of larger capacity could be constructed for heads below 100 ft. and generators of larger capacity for the high heads, but considering the combined hydroelectric unit, the values given represent the upper economical limit.

Statement by E. V. Gibbs. The curve shown on Fig. 5 indicates the maximum h. p. capacity for which it is possible to build water-wheel turbine units for heads ranging from 20 ft. to 600 ft. The specific speed, corresponding to the different heads, is also shown in this same figure—No. 5, and the formula for the specific

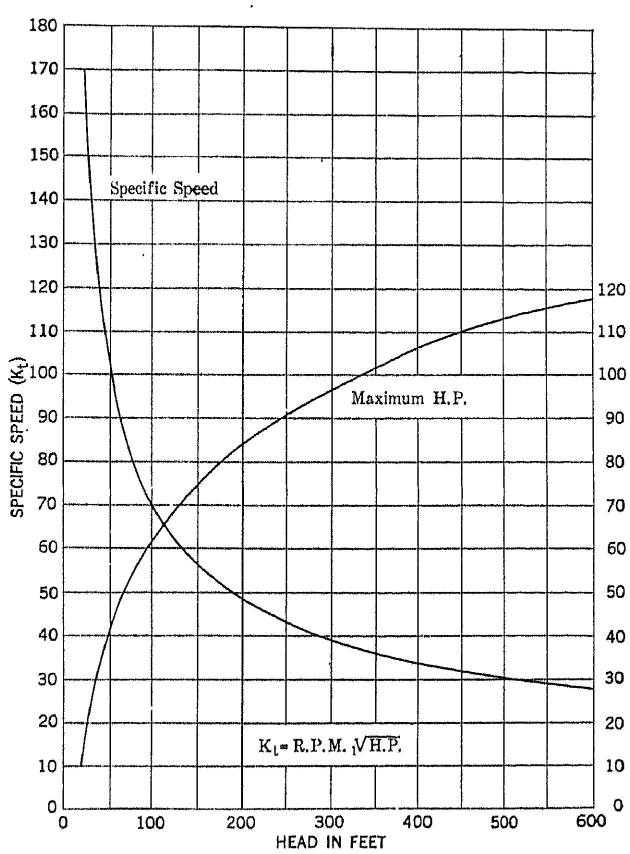

FIG. 5—CURVE SHOWING SPECIFIC SPEED AND MAXIMUM CAPACITY FOR WATER-WHEEL TURBINES DESIGNED FOR DIFFERENT OPERATING HEADS

speed at 1 ft. head is given. At the present time the maximum h. p. curve is considered the maximum output of a single runner turbine unit under the corresponding turbine head.

From any given head up to 600 ft., a specific speed from the curve can be found, thus leaving two unknown factors in the formula to be determined, viz., the speed and power. Either one of these unknown factors will have to be assumed under the given head, and this reduced to an equivalent at 1 ft. head by using the formula for speed which varies as the square root of the head.

The h. p. under the given head can be reduced to the equivalent at 1 ft. head by the formula that h. p. varies as the square root of the cube of the head. If it is desirable to obtain the speed of the maximum unit under the given head, take the h. p. from the curve for maximum h. p. shown on Fig. 5, and figure the same way to obtain the proper speed. While it is possible to build a turbine to operate under a 1000 ft. head, the field for pressure turbines under this high head needs further exploration before it would be wise to recommend them.

Statement by R. V. Terry. Relative to maximum h. p. of hydraulic turbines, the Newport News Shipbuilding and Dry Dock Company is prepared to build for different operating speeds and heads:

Since specific speed, $N_s = \dfrac{N\sqrt{P}}{H^{\frac{5}{4}}}$, the maximum power ($P$) for a given speed ($N$) and head ($H$) will depend upon the maximum specific speed selected for the particular head in question. The so-called Experience Curve, $N_s = \dfrac{5050}{H+32} + 19$ has been used in the past. This curve gives values of N_s too low for heads from 10 to 450 ft. and too high for 450 to 1000 ft. Specific speed should not be used as an absolute basis for the selection of the maximum head; other factors, including the draft head, should be given due consideration. However, for a number of years the formula, $\dfrac{632}{\sqrt{H}}$ has been used for the maximum specific speed to which it is possible to go, except under expecially favorable conditions as to low draft head. A few installations of the propeller type have been made with specific speed beyond values given by the latter formula, but they may be considered experimental installations. Therefore, in working up data for this report, a maximum specific speed for a given head equal to $\dfrac{632}{\sqrt{H}}$ was used.

Fig. 6 shows the maximum specific speed, maximum power and maximum speed for a given power that is proposed, using the head as a starting point. If the maximum power for a given speed and head is desired, this can be obtained from Fig. 6 or directly from the formula, $P_{max} = \dfrac{632^2\ H^{3/2}}{N^2}$. Fig. 7 shows the formula in graphical form. In using the formula, one must, of course, bear in mind the limitation of power for a given head due to physical dimensions and shipping facilities. This Company is prepared to build turbines as physically large as can be conveniently transported and erected.

A lower value of specific speed than that given above may be assumed for a given head. This simply means that for a given unit there is a certain choice of speeds. However, as stated previously, the power for a given head and speed will be higher, the higher the specific speed selected.

Statement by T. A. Worcester. With the larger units, the first cost, including building and operating cost, is less per kv-a. than with the smaller units. There is a physical limitation, however, to the size of units which can be built with present day materials and types of construction; and the kv-a. capacities vary with the speed of the units. These maximum size units are approximately as follows:

10,000	kv-a.	at	720	rev. per min.
20,000	"	"	600	"
30,000	"	"	514	"
55,000	"	"	400	"
80,000	"	"	300	"
110,000	"	"	200	"

This table might be carried to lower speeds and larger sizes. For instance, it is theoretically possible to build a 130,000 kw. machine at 100 rev. per min., but it is questionable if it is at all desirable to put so much capacity in a single unit.

Statement by F. C. Hanker. The 1924 water-power devel-

opments have been characterized by studies and investigations of a number of very large water-power developments in the north and northwest parts of the country. These developments have involved consideration of water-wheel generators approaching the limits of commercial design. The following gives an approximate tabulation of the economic design limitations of vertical water-wheel generators at the present time:

5,000 kv-a.	at 720	rev. per min.
12,000 "	" 600	"
40,000 "	" 514	"
45,000 "	" 400	"
70,000 "	" 300	"
100,000 "	" 200	"
75,000 "	" 100	"

This tabulation assumes that the more usual conditions of 60 cycles, 13,200 volts, 80 per cent overspeed, and normal flywheel effect apply and that standard commercial material is employed. At speeds below about 300 rev. per min., the physical dimensions of parts became a limiting factor. Low speed water-wheel generators are probably the largest pieces of material with which the electrical industry has to deal. When the dimensions become so great that special shop space and shop tools must be provided for the machine operation, the entire expense of this special equipment must be borne by such a relatively small number of machines that the cost becomes prohibitive. At the present time, the largest machine tools in this country will accommodate a frame bore (which is the same as the outside diameter of the armature punchings) of not more than 37 ft. This limiting dimension has been approached by the ratings given in the above table for speeds below 300 rev. per min. It appears quite probable that these limiting conditions will be reached by a few water-wheel generators in the near future. In general, machining limitations are reached before the transportation limitations become a serious factor since the generator can be separated into parts and a large amount of the assembling done in the power house location if necessary without greatly increasing the over-all expense.

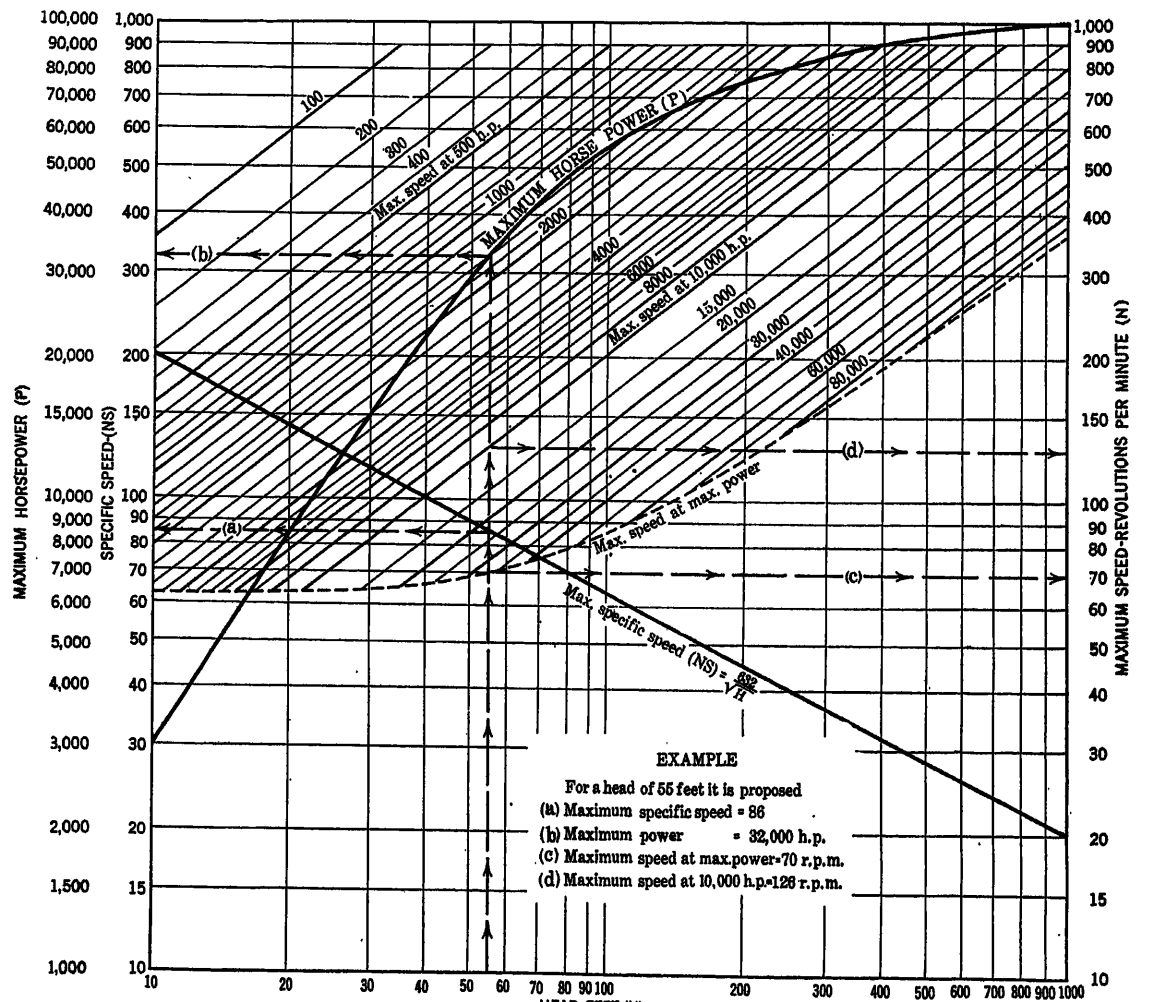

FIG. 6—CURVE SHOWING MAXIMUM SPECIFIC SPEED, MAXIMUM CAPACITY AND MAXIMUM OPERATING SPEED FOR WATER-WHEEL TURBINES DESIGNED FOR DIFFERENT OPERATING HEADS

TREND OF MODERN PRACTISE

The manufacturers seem to feel that automatic generating stations are growing in importance, but they, together with the majority of the operating men, feel that the complete automatic hydroelectric station is limited to the smaller sizes, there being two different reasons for this: In the first place, as the size of the installation increases, the complexity of the operating conditions determining the amount of power to be supplied from the station also increases, this being something that is controlled, *not* by the station itself, but rather by system conditions; also in important

installations, considerable judgment on the part of the load dispatcher is required for the best system operation, which cannot be supplied by any automatic station equipment. In the second place, there is no entirely satisfactory way of supplying the initial starting impulse for the control of the full automatic station. Voltage conditions which are satisfactory in railway stations will not do; drop in frequency is not satisfactory; so that, generally, the water level appears to be the most satisfactory means of control, and this very materially limits the scope of the automatic station.

mittee, who points out the advisability of having a unit or units in a given power plant controlled by a gate mechanism of another unit or units in the same station. In other words, the plan of operation consists in starting and stopping units automatically and from the gate motion of other units, so that the gate controls of all units are kept within the efficient range and probably within narrow limits where maximum efficiency is obtained, depending upon the number of units under such control.

While there has been a definite movement toward

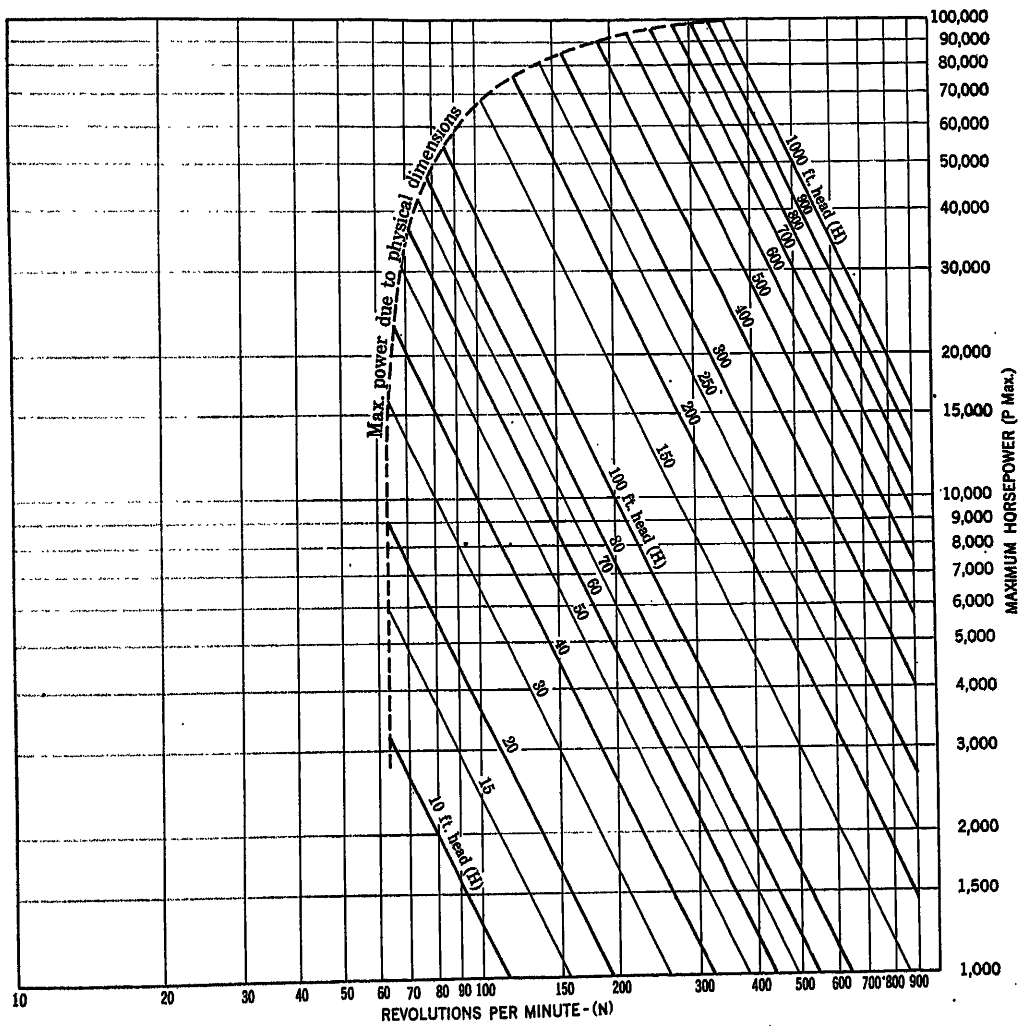

FIG. 7—CURVE SHOWING MAXIMUM CAPACITY FOR WATER-WHEELS DESIGNED FOR DIFFERENT OPERATING HEADS AND OPERATING SPEEDS

However, automatic stations with supervisory or remote control are quite different and developments along this line have been very rapid. Stations with three generating units and with capacities up to 10,000 kv-a. are now so controlled; several stations of 25,000 kv-a. with this type of control are under consideration. This type of control permits the operation of stations with fewer men and gives these men greater freedom to leave the operating floor to attend to duties at the head gates or in the switch yards.

A somewhat different phase of automatic operation has been proposed by one of the members of this Com-

outdoor substations and the location of all oil switches and transformers outdoors, progress in the matter of putting generating equipment outside has been very slow, the difficulty being, apparently, to provide suitable housing in case it is desired to dismantle a generator. However, several stations have been built with a very low superstructure with an outside gantry crane and with movable roofs over the individual generators, which can be rolled back so that the gantry can be used to dismantle any particular unit.

A noticeable tendency in connection with hydroelectric plants constructed in the west during the last

two or three years, has been the trend toward more permanent construction. Many of the earlier installations used open conduits. On all important developments now being made, these open conduits are being superseded by tunnels. Pipe lines that were formerly placed in trenches are now being placed entirely above the ground and carried in concrete saddles. The larger amounts of power that are being transmitted call for higher voltages, which in turn call for types of construction that are far more lasting and dependable than the wooden pole lines formerly used.

In the matter of station auxiliaries, there is considerable tendency to get away from direct-connected exciters on the main generator shaft, making the main generators easier to dismantle and reassemble. In the matter of excitation, many stations use a combination of a waterwheel and a-c. motor coupled to the same d-c. exciter, so that if one of the prime movers fails the other will continue to drive the exciter.

Several new European types of high-speed turbine runners are coming on the market in America. These appear to have considerable promise on account of their high efficiency.

There are instances this year of the use of babbitted bearings on vertical shaft turbines in place of lignum-vitae bearings to reduce maintenance expense.

Increased use of motor-driven, flyball governors is noticeable.

A subject which has received special study by both operators and manufacturers during the last year is the pitting of turbine runners, both as to the exact nature of the pitting, cavitation or corrosion itself, and as to the causes thereof. The three principal causes of pitting are believed to be excessive draft head, excessive specific speed and poor design. There is considerable difference of opinion as to the relative importance of these causes. The drive for high specific speeds in the last few years is blamed by some for the recent increase in pitting troubles.

A subject that has occasioned considerable discussion is the omission of governors from hydroelectric units, particularly when operating in large interconnected systems. The suggestion that governors be omitted in such cases except as safety shut-down devices, has met with considerable opposition among operating men. The proper design, characteristics and functioning of governors for hydroelectric units operating in parallel with steam electric units, are questions which are now receiving intensive study.

In the case of low head-water power developments on streams with widely fluctuating flow, there is an increasing tendency to secure the maximum possible output under existing limitations of property and flowage rights by the use of crest gates or movable dams of various types.

A considerable amount of experimental work has been done on draft tubes, but there does not seem to be any general agreement as to which type is the most satisfactory. Those which apparently indicate the highest efficiency are usually very much more expensive to build. It is in connection with the low head installations that the greatest care must be taken in the design of the draft tube. The great activity in draft tube design in connection with low head plants has been brought about by the increased specific speed of units wherein a greater percentage of energy is discharged from the runner. It seems unlikely that lower specific speeds will be adopted, but, on the contrary, more likely that an effort will be made to adopt higher ones, so that the problem of the draft tube will be with the Committee for sometime to come. It seems inevitable that some type of draft tube providing radially expanding passages must be adopted to best preserve the whirling energy from the high specific speed runners. It is important, however, that methods be developed whereby these draft tubes may be installed at moderate cost.

Conclusion

Much of the subject matter of this report falls more specifically within the scope of the American Society of Mechanical Engineers than of the Institute. We feel, however, that the members of the American Institute of Electrical Engineers should have called to their attention the trends in the art of power station design and operation. With this thought in mind, this report has been prepared, and deals not with details of design and operation, but with tendencies and trends. We had this same purpose in mind in scheduling one session of the Spring Convention at St. Louis for a symposium dealing with power station design. Certainly those of our members who are associated with companies generating large blocks of power, cannot afford to lose touch with the field of power station design and operation.

For those of our members who care to delve deeper into detailed discussions of the subjects briefly referred to in this report, we recommend a careful reading of the reports of the Prime Movers Committee, the Electric Apparatus Committee, and the Hydraulic Power Committee, of the National Electric Light Association. We also commend to your attention the wonderfully interesting series of papers presented at the World Power Conference in London. The papers presented before this Conference covered in an authoritative manner practically every problem of interest to the power station engineer.

A subcommittee of your Power Generation Committee, under the chairmanship of Mr. A. R. Smith, is working on a specific problem which we think is of very definite interest: There is a lack of common terminology and well-defined terms in the discussions which are heard, from time to time, dealing with power station operating costs and performance. It is felt it would be very much to the advantage of the industry that all should speak a common language. This Committee is

trying to set up a reasonable terminology and definition of terms which will have the best chance of acceptance by the engineers who have occasion to discuss the matters referred thereto. It is not the thought of the Power Generation Committee to attempt to impose any set of definitions on the engineers of other societies who also have very vital interest in discussions dealing with power station design and operation. It is our plan to call the importance of this matter to the attention of other committees working in this same field, and by cooperating with the members of these other committees, we hope to arrive at a set of definitions of terms which will be acceptable to all.

Iowa Railway and Light Co. gives results of tests of 15-stage, 3500-Kw. Turbo-Generator.

Drabelle, John M. Improving Steam Turbine Operations. *Power Plant Engineering*, Vol. 28, 1924, p. 478.

Drewry, M. K. Economical Loading of Turbo-Generator Units. *Power Plant Engineering*, Vol. 28, 1924, p. 887.

Pronounced turbine characteristics definitely determined most efficient operation of several units.

Electrical World. What the World Power Conference Showed About Modern Steam Turbines and Their Design. Vol. 84, 1924, p. 737.

Emmet, W. L. R. The Emmet Mercury-Vapor Process. This paper was presented at the Spring Meeting of the A. S. M. E. in May 1924 and will be published in *A. S. M. E. Transactions*, Vol. 46, 1924. *Mechanical Engineering*, Vol. 46, pp. 235-240 and 305, May 1924.

The author describes the Mercury-Vapor installation in the Hartford Plant of the Hartford Electric Light Company covering the possibilities of the process, the turbines, the boilers, etc.

Engineering. The Limits of the Steam Turbine. Vol. 119, 1925, p. 294.

Engineering. Turbine Troubles. Vol. 115, 1925, p. 305. Instances of actual turbine troubles developed at various stations.

Engineering. The Shanghai and Other Turbine Failures. Vol. 117, 1924, p. 18.

Engineering. Thirty Thousand Kilowatt Steam Turbo-Generator at Rotherham. Vol. 117, 1924, pp. 65 and 134.

Engineering. Condensing Plant for 20,000-Kw. Turbine. Vol. 116, Oct. 19, 1923, pp. 494-496.

Description of plant at Shanghai.

Eppelsheimer, P. C. Multiple Exhaust Blading in Steam Turbines. *Power Plant Engineering*, Vol. 29, 1925, p. 282.

Details of unit (35,000 kw.) installed at the Springdale and Colfax Stations.

Fiske, Rogers A. Piping for High Pressure and Temperature. *Power Plant Eng.*, Vol. 28, No. 8, April 15, 1924, pp. 424-427.

Gaster, George E. Jet Condenser Performance. *Power Plant Eng.*, Vol. 28, No. 21, November 1, 1924, pp. 1089-1092.

Detailed discussion of the various factors affecting the operation of jet condensers.

Guy, H. L. and Jones, P. L. Metropolitan-Vickers Rateau Marine Turbine. *Engineering*, Vol. 115, 1923, p. 186

Hermann, C. C. Factors in the Design of Steam Piping Systems. *Power Plant Eng.*, Vol. 29, No. 6, March 15, 1925, p. 348.

Important factors discussed—pressure drop, radiation relative location of equipment, reliability, etc.

Hodgkinson, Francis P. Relation of Pressure and Velocity in Various Types of Steam Turbines. *Power*, Vol. 59, No. 12, March 18, 1924, pp. 444-445.

Hodgkinson, Francis P. Large Steam Turbines. *Mechanical Engineering*, Vol. 47, March 1925, pp. 186-188.

The author discusses the economy reliability and the present trend in design of large steam turbines.

Hodgkinson, Francis P. Steam Turbines and Condensing Equipment. *Transactions of First World Power Conference*, Vol. 2, 1924. *Mechanical Engineering*, Vol. 36, pp. 628-31, October 1924.

Hubbard, C. L. Selecting Boiler Feed Pumps. *Power*, Vol. 60, No. 25, Dec. 16, 1924 Boiler Feed Pump Explanation and Calculations, Vol. 60, No. 26, December 23, 1924, pp. 1021-1024.

Characteristics and selection.

Jungren, O. F. Large Curtis Turbines. *Power*, Vol. 61, Feb. 24, 1925, pp. 290-295.

Author gives outline of development of large turbines by the General Electric Co. Some very good cuts accompanied this paper.

Kearton, Wm. J. The Possibilities of Mercury as a Working Substance for Binary Fluid Turbines. *Proceedings I. M. E.*, Vol. 2, Nov. 1923, pp. 895-952.

Discussion of the paper pp. 953-976.

Kerr, Wm. A Note on Jet Action in Turbine Blading. *I. M. E.*, Vol. 2, No. 4, 1924, pp. 673-686.

Paper deals with a special aspect of the problem of jet action in turbine blading.

Kerr, Prof. W. On Turbine Wheel Friction. *Journal Royal Technical College* No. 1, December 1924, pp. 103-120.

The author deals with the subdivision of the steam friction losses in turbine wheels (blading losses and disk losses).

Levit, L. G. Stage Efficiencies of Impulse Turbines. *Power*, Vol. 60, No. 21, Nov. 18, 1924, pp. 809-810.

Approximate manner of plotting condition curve so that pressures to be expected might be determined.

Livingston, R. T. Determining Pump Characteristics. *Power Plant Eng.*, Vol. 28, No. 20, Oct. 15, 1924, pp. 1063-1065.

Graphical determination of approximate pump characteristics from given data.

McLeod, R. J. Turbine Reduction Gearing and Its Production. *Proceedings I. M. E.*, Vol. 2, No. 4, 1924, pp. 633-659.

Discussion of general questions governing design of turbine reduction gears, and the methods of production, from a manufacturer's standpoint.

Mechanical Engineering. The Efficiency of Steam Turbine Nozzles. This is the second report by Steam Nozzles Research Committee of the Institution of Mechanical Engineers, Vol. 46, pp. 148-150, March 1924. First report published in the *Proceedings I. M. E.* No. 1, pp. 1-22, 1923. Third report in *Proceedings No. 5*, pp. 715-735, 1924.

Deals with coefficients and efficiencies of steam turbine nozzles.

Mellanby, A. L. and Kerr, W. The Pipe Loss in Steam Nozzles. *Journal Royal Technical College*, No. 1, pp. 67-102, December 1924.

This paper very fully discusses the losses occurring in steam nozzles and contains valuable information for those interested in the design of nozzles for steam turbines.

Naylor, C. H. Heat Transmission in Surface Condensers between Steam and Water. *Beama*, Vol. 12, 1923, pp. 206-214, 287-293, Vol. 13, 1923, pp. 37-44, pp. 104-108.

Subject is treated mathematically with the addition of experimental data, and as a final check comparison is made with what obtains in practise.

Nordstrom, V. Extra High Pressure Turbines. *Transactions of First World Power Conference*, Vol. 2, 1924.

Noyes, Edward W. & Sturtevant, Harold V. Size Selection of Dry Vacuum Pumps. *Mechanical Engineering*, Vol. 45, 1923, pp. 103-104.

Power. Steam Turbine Blading. Vol. 59, Feb. 5, 1924, pp. 200-204; Vol. 59, Feb. 12, 1924, pp. 251-254; Vol. 59, Feb. 19, 1924, pp. 293-296; Continued in Vol. 59, Feb. 26, 1924, pp. 329-330.

Power. Fifty Thousand Kilowatt Compound Parsons Turbine for the Crawford Ave. Station. Vol. 60, Nov. 4, 1924, pp. 728-730.

Machine built in England and thermal efficiency of 27.8 per cent from coal to steam expected.

Power. Five Hundred Thousand Horse Power in Ford Turbines for River Rouge Plant. Vol. 61, Jan. 20, 1925, pp. 88-94.

This article gives a complete description of turbines and auxiliaries installed in the River Rouge Plant of the Ford Motor Co., and built in the Ford shops.

Power. Steam Turbine Development Influenced by Higher Pressure and Reheating. Vol. 59, No. 1, Jan. 1, 1924, pp. 9-11.

Discussion of house turbines, small steam turbines and condenser developments.

Power Plant Engineering. Steel Case Turbines Designed for High Pressures. Vol. 28, 1924. p. 360.

Power Plant Engineering. New Crawfordsville Unit Shows High Economy. Vol. 28, 1924, p. 1128.

Municipally owned Public Service Plant in Indiana installs a new 3000-kw. turbo-generator which shows a steam consumption of less than 15 lb. per kw-hr.

Power Plant Engineering. Tendencies in Steam Turbine Construction. Vol. 28, 1924, p. 1183.

Trouble is not anticipated with operating pressures as high as 1200 lb. per sq. in. Temperatures will not go above 750 deg. fahr.

Power Plant Engineering. Use of Electrically Driven Auxiliaries Increases. Vol. 29, No. 6, March 15, 1925, p. 328.

Details of motors and controls, as well as source of auxiliary power. Shown by recent investigations of modern central stations.

Power Plant Engineering. The Steam-Jet Condensing Type Vacuum Pump. Vol. 29, No. 6, March 15, 1925, p. 334.

A description of the principals of the condensing type air ejector together with a study of its performance.

Power Plant Engineering. Electrical Features of Long Beach Station. Vol. 29, No. 6, March 15, 1925. p. 344.

Electrical auxiliaries supplied by separate shaft auxiliary generators.

Power Plant Engineering. Electric Power Systems for Auxiliaries. Vol. 29, No. 8, April 15, 1925, pp. 432-435.

Power Plant Engineering. Pipe Connections to Power Units. Vol. 28, No. 21, November 1, 1924, pp. 1093-1094.

Strains resulting from weight of pipe connections and pipe expansion.

Power Plant Engineering. Tendencies in Surface Condenser Practice. Vol. 28, No. 10, May 15, 1924, pp. 530-533.

Elimination of dead tube space, multiple air suction openings and variable water supply factors in condenser design.

Razek, J. The Regenerative or Stage Bleeding Cycle. *Power Plant Engineering*. Vol. 29, 1925, p. 323.

Reheating of the feed water in a number of stages has a decided effect upon economy.

Read, J. C. Steam Turbine Blading. *Jour. I. E. E.*, Vol. 61, 1923, p. 1109. Materials, thermo-dynamic design of blades, mechanical design of blades, vibration and method of manufacture.

Ross, M. O. The Multiple-Path Radial Ventilation of Large Turbo-Generators. *Electric Journal*, Vol. 21, No. 12, December 1924, pp. 540-545.

Discussion of the multiple radial system of ventilation and the limitations of other ventilating schemes.

Smith, H. W. Motor Drives for Turbine Auxiliaries. *Power Plant Eng.*, Vol. 28, No. 15, August 1, 1924, pp. 807-810.

Modern practise in the application and control of motors for auxiliary drives.

Smith, J. H. The Steam-Jet Condensing-Type Vacuum Pump. *Electric Journal*, Vol. 22, No. 1, January 1925, pp. 17-23.

The development and advantages, etc., of this type of vacuum pumps.

Smith, A. R. The Cooling of Turbine Generators. *G. E. Review*, Vol. 25, Dec. 1922; Vol. 26, 1923, pp. 83, 298 and 554.

Dealing with various methods of recirculation air cooling, heat transfer, physical consideration and design of surface air coolers.

Sprague, B. C. Method for Determining the Leaving Loss of a Steam Turbine. *Power*, Vol. 61, March 17, 1925, pp. 419-420.

Stork, Ir. C. F. Steam Turbines for High Pressures. *Transactions of First World Power Conference*, Vol. 2, 1924.

The Engineer. New Steam Turbine Design. Vol. 136, 1923, p. 76.

New features of two 5000-kw. Allis Chalmers machines dealing particularly with blading construction and materials.

The Engineer. The Gas Turbine in Theory and Practise. Vol. 135, 1923, pp. 466-468, 490-491, 515-517, 557-559, 583-584, 595-598, 630-632.

Dealing with the development of the Gas Turbines and giving characteristics of design and operation of Gas Turbines of various manufacture.

The Engineer. Development of Large High Speed Two Pole Turbo-Alternator and the Year's Production Record of C. A. Parsons. Vol. 137, 1924, p. 20.

Different types of machines briefly explained.

The Engineer. High Pressure Turbines. Vol. 137, 1924, p. 489.

Development in the field of High Pressure Turbines being done by Brown, Boveri & Co.

Thompson, Eustis H. Largest Straight Reaction Turbine. *Power*, Vol. 59, June 24, 1924, pp. 1016-1019.

Fifty thousand kw. reaction turbine installed in Hudson Ave. Station of Brooklyn Edison Company.

Von Freundenreich, Dr. J. Vibration of Steam Turbine Disks. *Engineering*, Vol. 119, January 2, 1925, pp. 2-4; January 9, 1925, pp. 31-34.

Problem of disk vibration solved experimentally as well as theoretically.

Wirt, H. Loring. The Turbine Designers Wind Tunnel. This paper presented at the Annual Meeting of the A. S. M. E., December 1924, *Mechanical Engineering*, Vol. 47, pp. 13-17, January 1925.

The determination of the efficiency of various types of nozzles is made by means of compressed air, measurements being taken with impact tubes, static tubes and angle measuring devices. Flow casts are used to determine the streamline and eddy flow through nozzle passages.

Woodwell, J. C. Efficiency Test of a 15,000-kw. Turbo-Generator. *Power*, Vol. 61, January 27, 1925, pp. 128-131.

Deals with tests on 15,000-kw. unit at Moore's Park Station at Lansing, Mich. (Municipal Plant).

World Power. Steam Turbines—Rateau Impulse Type, Vol. 1, No. 1 (New Series), January 1924, pp. 57-62.

This article deals with the design and operation of the Rateau Impulse Type Turbine as manufactured by tihe Metropolitan-Vickers Electrical Company, Ltd.

World Power. Recent Developments in Large Turbine Practise. Vol. 1, No. 4 (New Series), April 1924, pp. 243-248.

This article makes mention of the 18,750-kw. 1500 rev. per min. Metropolitan-Vickers unit installed in the Dalmarnock Station of the Glasgow Corporation. It also deals in general with the design of Rateau Impulse machines.

Boiler Plant Design and Operation

Bailey, E. G. Control of Boiler Room Operation. *Power Plant Eng.*, Vol. 28, No. 21, November 1, 1924, pp. 1095-1097.

Outline of instrument and control application from a paper read before the N. A. S. E. convention.

Bailey, E. G. Fundamentals of Combustion Control. *Power Plant Eng.*, Vol. 28, No. 20, October 15, 1924, pp. 1044-1048.

Rate of fuel feed, amount of forced and induced draft are essential controls for combustion process.

Bak, A. Kristian. Effect of Excess Air on Flue Temperatures and on Efficiency. *Power*, Vol. 59, No. 17, April 22, 1924, pp. 634-636.

Results of tests at Connors Creek to establish the relation between excess air and stack gas temperature for a particular boiler and setting.

Blomquist, Viktor. Steam Generation at Extra High Measures. *Transactions of the First World Power Conference*, Vol. 2, 1924.

Booth, C. A. Development of Mechanical Draft Equipment. *Power Plant Eng.*, Vol. 29, No. 2, January 15, 1925, p. 133.

Brownlie, David. The Ideal for Efficient Steam Generation. *The Engineer*, Vol. 135, June 22, 1923, p. 649.

The continuous measurement of air consumption.

Bruce, John. Boiler Room Practise. *The Electrical Review* Vol. 94, No. 2410, April 11, 1924; Vol. 94, No. 2410, May 9, 1924, pp. 736-738. Article concluded in issue of May 16, 1924, pp. 809-811.

Furnace efficiency, excess air analysis of operating results and the critical point of combustion.

Burke, R. F. Burning Oil Under Power Boilers. *Power Plant Eng.*, Vol. 28, No. 6, March 15, 1924, pp. 328-330.

Clarke, C. W. E. Present Status of the Air Preheater. *Power* Vol. 61, No. 13, March 31, 1925, pp. 486-489; *Mechanical Engineering*, Vol. 47, March 1925, pp. 175-184.

Historical summary of air preheating and recent operating developments in air preheating; giving interesting data in connection with present and proposed installation.

Clarke, C. W. E. Boiler Test Results with Pre-Heated Air, Colfax Station, Duquesne Light Company. *Transactions A. S. M. E.*, Vol. 45, 1923, pp. 567-605, *Mechanical Engineering*, Vol. 46, 1924, pp. 64-72.

This paper describes apparatus used and gives results of an extended series of tests carried out in the summer of 1923 on one of the units of the Colfax Station of the Duquesne Light Company, Pittsburgh, Pa., in which flue-gas air preheaters had been installed. Results obtained showed efficiency of unit increased by from 5 to 7 per cent by the use of the preheater.

Cotton, Alfred. The Determination of Chimney Size. *Mechanical Engineering*, Vol. 45, 1923, pp. 531-536.

A simple and orderly system, based on accepted characteristics for determining the size of chimneys.

Engineering. The Preheating of Air for Boiler Furnaces. Vol. 115, June 29, 1923, pp. 807-809.

Discussion of preheater and economizer.

Engineering. Water-lined Furnace Walls for Power Station Boilers. Vol. 119, January 16, 1925, pp. 71-74.

Boilers equipped with side wall cooling tubes, Hell Gate Station.

Erith, Charles. Preheated Air in Modern Boiler Plant. *The Electrical Review*, Vol. 94, No. 2, 462, January 30, 1925, pp. 164-166.

Discussion of preheaters and various installations.

Funk, N. E. and Ralston, Farley C. Boiler Plant Economics. *Transactions A. S. M. E.*, Vol. 45, 1923, pp. 607-641, inc.

The authors have applied themselves to the determination of a rational formula expressing boiler-plant performance. The paper shows how this formula may be applied, and also discusses the question of operating at minimum cost.

Hall, R. E. Investigation of Boiler-Water Treatment. *Power Plant Engineering*, Vol. 28, No. 16, August 15, 1924, pp. 843-845.

Written in cooperation with G. W. Smith and H. A. Jackson for the N. E. L. A.

Hall, R. E. Water Treatment for Continuous Steam Production. *Mechanical Engineering*, Vol. 46, 1925, pp. 810-817.

Water treatment considered in its relation to scale formation, corrosion, delivery of dry steam, and minimum blow-down.

Hunter, John and Cotton, Alfred. Methods of Ash Handling. *Mechanical Engineering*, Vol. 45, 1923, pp. 83-92.

Various methods are described and illustrated.

Jacobus, D. S. Development of High Pressure Steam Boilers. *Power Plant Engineering*, Vol. 28, No. 20, October 15, 1923, p. 1047.

Trend toward high pressures. Present day factors of safety not materially affected unless temperatures exceed 750 deg. fahr.

Jacobus, D. S. High Pressure Steam Systems. *Electrical World*, Vol. 82, No. 14, October 6, 1923, pp. 699-707.

Design and arrangement of boilers, economizers and superheaters in plants using these high pressure devices.

Johnstone, Taylor F. Foreign Practise in Vertical Water Tube Boilers. *Power Plant Engineering*, Vol. 28, No. 22, November 15, 1924, pp. 1140-1141.

Descriptions of a number of European Types of Vertical Water Tube boilers together with their relative advantages.

Johnstone, Taylor F. British Developments in Water Tube Boilers. *Power Plant Engineering*, Vol. 28, No. 3, February 1, 1924, pp. 173-174.

New design provides for independent circulation of water in tubes nearest fuel bed.

Jones, Charles L. Removal of Scale with Carbon Dioxide. *Power*, Vol. 60, No. 15, Oct. 7, 1924, pp. 578-579.

Applicable for the most part to special problems.

June, Robert. Tests of Mechanical Soot Blowers. *Power*, Vol. 60, No. 9, August 26, 1924, pp. 326-328.

Attempts to determine the savings effected by mechanical soot blowing.

Kemnal, Sir James H. R. Water Boiler. *Proceedings I. M. E.*, Vol. 2, 1923, pp. 579-586.

Construction and history of the water tube boiler.

Kershaw, John B. C. The Control of Boilers by Temperature and Draught Measurements. *The Engineer*, Vol. 135, April 27, 1923, pp. 437-441.

Directs attention to the interdependence of the test results for CO_2, temperature and draft.

Kriegsheim, H. Brittleness and Cracks in Seams of Steam Boilers. *Power Plant Eng.*, Vol. 28, No. 15, August 1, 1924, pp. 792-795.

Causes and prevention of so-called caustic embrittlement.

Lundgren, Edwin. Swedish Boiler Operates at Pressure of 500 lbs. *Power*, Vol. 57, February 13, 1923, pp. 238-241.

Steam generated in rotating tube with evaporation of 60 lb. per hr. per sq. ft. of surface.

Martin, S. C. Automatic Combustion Control. *Power Plant Eng.*, Vol. 29, No. 3, February 1, 1925, p. 182.

Theoretical considerations governing application to pulverized fuel installations.

McDermet, J. R. Possible Methods of Reheating Steam. *Power*, Vol. 60, No. 26, December 23, 1924, pp. 1014-1016.

Article points out the possibilities and disadvantages of such mediums of heat transfer as radiant energy, heated gas, oil, melted salt mixtures, organic liquids and mercury vapor.

Mechanical Engineering. Oil Burning Under Steam Boilers. Vol. 47, 1925, pp. 276-281.

Deals with atomizers, draft, oil characteristics, refractories, combustion data, etc.

Munzinger, Frederick. The Influence of High Pressure Steam on the Design and Economy of Large Steam Boiler Plant with Special Reference to Boiler Plant for Electric Power Stations. *Transactions of the First World Power Conference*, Vol. 2, 1924.

Peebles, T. A. Combustion Control. *Mechanical Engineering*, Vol. 47, 1925, pp. 193-196.

Advantages of combustion control—control of steam and air pressures—feed water control, etc.

Pigott, R. J. S. Combustion Control for Boilers. *Power Plant Eng.*, Vol. 28, No. 13, July 1, 1924, pp. 694-695.

Factors which influence control. Steam Flow, Air Flow and Fuel Feed should form basis of Regulation.

Pigott, R. J. S. Use of Combustion Control Devices Increases. *Power Plant Eng.*, Vol. 28, No. 23, Dec. 1, 1924, pp. 1199-1203.

Basic principles of various control schemes.

Pigott, R. J. S. Combustion Control for Boilers. *Mechanical Engineering*, Vol. 46, 1924, pp. 590-592.

Functions involved in operation, possibilities and methods of regulation, design, installation.

Power. Boilers and Boiler Auxiliaries. Vol. 59, No. 1, January 1, 1924, pp. 6-9.

Discussion of development changes in baffling and superheaters, novel furnaces design, Air heaters, etc.

Power. Bids on Boiler Auxiliary Equipment of Detroit Municipal Plant. Vol. 60, No. 16, April 21, 1925, pp. 605-607.

Power. Air Preheaters and Their Application. Vol. 60, No. 23, December 2, 1924, pp. 884-889.

Power. Boilers and Boiler Auxiliaries. Vol. 61, No. 1, January 6, 1925, pp. 3-8.

Developments in boilers, high pressures, status of economizers and air preheaters, superheaters, stage bleeding heat balance.

Power Plant Engineering. Evaporative Tests at River Rouge. Vol. 29, No. 5, March 1, 1925, p. 275.

Results of five tests, using pulverized coal for sustained boiler loads up to 285 per cent of normal rating.

Power Plant Engineering. High Pressures Affect Boiler Accessories. Vol. 28, No. 23, December 1, 1924, pp. 1191-1195.

High pressure feed pumps, water columns for 1200 lb. boilers and superheat control are a few of the problems which were solved.

Power Plant Engineering. Calculation of the Boiler Heat Balance. Vol. 28, No. 19, October 1, 1924, pp. 991-995.

Solution of a problem and an analysis of conditions which affect boiler economy over various periods of operation.

Power Plant Engineering. Boilers at Cleveland, Rate 3060 H. P. Vol. 28, No. 10, May 15, 1924, pp. 517-524.

Fired by pulverized coal. Automatic combustion control by steam pressure and flow meters.

Power Plant Engineering. Operation of Radiant Heat Superheaters. Vol. 28, No. 10, May 15, 1924, pp. 528-529.

Steam temperature varies slightly with percentage of CO_2. Two stage superheating has advantages.

Ricketts, Edwin B. Problems in Boiler Furnace Design. *Power Plant Eng.*, Vol. 28, No. 9, May 1, 1924, pp. 473-476.

Changes in stoker design, high ratings, high capacities, etc.

Ricketts, Edwin B. Boiler Furnace Design. *Mechanical Engineering*, Vol. 45, 1923, pp. 299-304.

The tendency toward larger combustion space. Factors governing furnace volume.

Savage, H. D. Water Cooled Furnaces. *Mechanical Engineering*, Vol. 47, 1925, pp. 197-200.

Description of several installations of fin-wall furnaces, pointing out their advantage.

Shadgen, Joseph F. Centralized Combustion Control in Lowellville. *Power*, Vol. 59, No. 18, April 29, 1924, pp. 676-679.

Simons, Gordon. Controlling Combustion by Temperature. *Power Plant Engineering*, Vol. 28, No. 17, September 1,1924, pp. 906-908.

Furnace and exit gas temperatures control dampers and fuel feed through thermocouples.

Smith, H. W. Motor Applications in the Boiler Room. *Power Plant Engineering*, Vol. 28, No. 13, July 1, 1924, pp. 700-703.

Recent changes in control of station heat balance.

Tenney, E. H. Water Treatment at Cahokia. *Power*, Vol. 59, No. 17, April 22, 1924, pp. 647-648.

The Engineer. Multi-flow Steam Superheaters, Vol. 136, October 5, 1923, pp. 376-377.

Conservation of fuel due to double use of steam.

Developments in Electrical Machine Design

By Committee on Electrical Machinery[1]

THE past year has shown a marked advancement in the art of electrical machinery, not only in the successful starting and operation of machines larger than any ever built up to this time, but also in the purchase and partial completion of machines still greater in size. Accompanying the trend towards larger sizes of units, there has been much investigation along the lines of ventilation, insulation, mechanical strength of materials, losses in iron and copper, the effect of expansion and contraction on the insulation of long armature coils, balance of the moving parts and the dissipation of heat from flat surfaces.

New applications of electrical machinery have been made in various industrial lines and transportation. The design of an electric locomotive having d-c. motors and operating from a-c. feeders was adopted. Diesel-electric drives have been applied to locomotives in sizes heretofore not attempted for this type of drive.

TURBO-ALTERNATORS

During the past year a number of 50,000-kw., 62,500 kv-a. turbo-alternators were successfully put into operation. These machines operate at 1200 rev. per min. and represent the largest single shaft generators yet put into operation. The large size and weight of the various parts of these machines represent a difficult handling and transportation problem. The largest 3600-rev. per min. generator yet to be built was successfully placed in operation during the year, it being rated at 12,500 kv-a., 80 per cent power factor. Machines having 60,000-kw., 60,000-kv-a. ratings, and operating at 1500 rev. per min. are under construction. Quotations are being requested on 75,000-kv-a., 1800-rev. per min. machines, and 83,333-kv-a. cross-compound machines are being considered.

The increasing demand for turbo-alternators of larger and larger sizes has necessitated much development on the part of the manufacturers. This development has been along the lines of improvements in construction and improvements in materials for given purposes, such as retaining bands of greater strength to hold the field end turns in place, iron for stator cores having better magnetic properties, decrease in strand loss by use of twisted conductors and different arrangements of coils, and improvements in the mechanical strength of materials which make up the rotor to allow higher peripheral velocities.

The 62,500-kv-a., 0.8 power factor, 1200-rev. per min., self-ventilated units installed have rotors weighing approximately 200,000 lb., stators, 200,000 lb. and the copper in the machine, 41,250 lb. The stators are wound with approximately 40 miles of insulated wire. The successful operation of the rotors of these large machines has been largely due to many inventions made during the past few years in machines and machine tools.

Tests made recently show that the temperature of the bare copper in commercial machines insulated for 12,000 to 14,000 volts is approximately 15 deg. greater than the temperature determined by a detector placed between the top and bottom coils when the latter is from 55 to 60 deg. above the temperature of the ingoing air; also that the temperatures shown by resistance detectors and thermocouples are about the same, and that the temperatures at the half-way location in the slot are approximately two degrees lower than at the quarter-way.[2]

The problem of self-ventilation is becoming more complex with increasing size of machines, which causes one manufacturer to recommend the desirability of external blowers being used for ventilating future machines. In the past, operating engineers have objected to the use of external blowers on the ground that they are added auxiliaries and therefore an added source of difficulties which may lead to shut-downs. This manufacturer states that the use of closed-circuit ventilation with air coolers, now coming into use, offers added advantages in the use of external blowers and makes their consideration justifiable at this time. The chief advantage of using external blowers in connection with recirculating ventilation systems is that the blower can be placed before the air coolers and therefore the temperature rise in the air passing through the blower, due to rotational loss, can be absorbed by the air coolers and air supplied to the generator at a temperature some five or six degrees lower than possible with self-ventilating systems.

In most cases ventilation is obtained by a multiple radial system in which the air passes radially in and out through the stator core. During the past year there were published results of experiments on this type of ventilation showing that the air is distributed in accordance with a simple hyperbolic or trigometric sine law. Knowledge of the balance state of flow when several branches of air meet and divide in a tube, the intake and discharge, occurring normally to the walls of the

tube, depends on the solution of a system of simultaneous transcendental equations. The total pressure required for a certain volume of air per unit time can be expressed by hyperbolic and trigometric cotangents of a certain argument which contains the geometrical dimensions of the air circuit.[3] Large models of turbo-alternators employing different types of ventilation were also set up and tested.

The use of closed ventilating systems has two distinct advantages, in that accumulation of dust on the windings is practically eliminated and fire can be easily extinguished by introducing an inert gas into the system. Several fire extinguishing systems have been installed during the past year. These consist of an arrangement for injecting carbon dioxide gas into the ventilating duct. The arrangement can be either manually operated or operated by the differential and balance relays used for protecting the machine against short-circuited turns or grounds. The results of exhaustive investigation along this line, published during the past year, show that the insertion of 25 per cent carbon dioxide gas, by volume, into the ventilating system will extinguish all flames.

Some of the inert gases have characteristics much better than air for use as the cooling mediums in high speed electrical machines with recirculating cooling systems. Many gases have been considered but the result of much study shows that hydrogen has the better properties if explosion dangers can be eliminated. The advantages which hydrogen offers for this use as compared with air are enumerated below:

Provided air can be excluded, hydrogen is a good fire extinguishing medium. The windage losses are greatly reduced due to the much lower specific gravity of hydrogen and its high thermal capacity. The temperature drop required to transmit heat through various parts of the machine is reduced. The temperature drop required to transmit heat from the hot surfaces of machine to the hydrogen and from the hydrogen to the coolers is less causing the hydrogen to return to the machine at a lower temperature.

Results of tests on generators filled with hydrogen show that it is possible to carry 30 per cent greater load on a machine with the same temperature rise when hydrogen is used as the cooling medium in place of air.

It would be comparatively simple to make a rotating machine hydrogen-tight if suitable shaft packing could be developed. Apparently shaft packing is at the present time, the largest obstacle hindering development of commercial hydrogen-filled machines. Nevertheless, this subject is worthy of further consideration and study.

Recent experiments show that there is considerable loss in the inactive magnetic parts and active magnetic parts of these machines. Miniature turbine-type generators were built for carrying out these investigations and the percentage losses were found to bear a similar relation to those of larger machines. Wood was substituted for various inactive parts and the magnitude of losses in these parts determined. Experiment showed that there is a high-frequency harmonic flux which causes considerable loss in the end structure and that these losses bear a relation to the magnetic loading of the field. These data together with the results of further study which is now being carried on, give rise to the hope that the efficiency of future machines will be still higher because the nature of losses in heads of machines will be definitely known.

Higher efficiency and lower temperature rises have been secured by grooving the surface of the rotor.

Synchronous Motors

A magnetic clutch has been applied to the synchronous motor allowing the motor to run at synchronous speed before the load is applied. By this means the motor can start heavy loads with a starting torque as high as the pull-out torque of the motor, and synchronous motors can therefore be used where good power factor characteristics are desired but where heavy starting duty is required.

The motor consists of a standard synchronous machine, having a rotor which is not keyed to the shaft, but free to move on a bearing carried by the spider. The field member of the clutch is bolted to the spider while its armature is fixed to the drive shaft. During the starting period, the rotor is brought up to synchronous speed and the drive shaft remains stationary. After the motor field is excited and line voltage applied to the stator winding, the magnetic clutch is excited, drawing its two halves together and bringing the load up to speed.

This motor has the advantage of being adaptable to full automatic, manual, or semi-automatic control. It is of sturdy construction, with desirable power factor characteristics, high load-starting torque and low starting current.

Another motor has been developed which accomplishes the above purposes in a different way. This motor is essentially a synchronous motor but differs mechanically from the ordinary type by having the stator mounted on auxiliary bearings. When the motor is started the rotor remains stationary and the stator comes up to synchronous speed. A friction brake is provided for bringing the stator to a standstill, thus causing the rotor to come up to synchronous speed.

By this method the relative speed between rotor and stator is the synchronous speed of the machine during the starting and running periods. In this motor, as in the one mentioned above, the starting torque available is the pull-out torque of the synchronous motor.

The other advantages are the same as enumerated for the motor above.

Induction motors have been arranged for operating at various speeds by being provided with armature windings which can be connected for various numbers

3. A. I. E. E. JOURNAL, March 1924, "The Multiple-Radial System of Cooling Large Turbo-Generators."

of poles, but until recently the synchronous motor has been inherently a single-speed machine when the frequency of power supply is constant. During the past year a synchronous motor has been developed, and a 5000-h. p. motor actually built, which has pole changing switches for both the stator and rotor windings.[4] This machine has pure synchronous motor characteristics for both speeds and requires no more attention than the ordinary synchronous motor. As the first cost of this motor is only slightly above that of the ordinary synchronous motor for the low speed, it is a practical machine which should broaden the field for synchronous-motor application.

The field poles are constructed so that they can be combined in groups of two having the same polarity, which gives the effect of one half the original number of poles and will therefore cause the machine to rotate at twice the speed when the stator winding is reconnected for the corresponding number of poles. The poles are shaped to compromise between the best shapes for each speed.

Frequency Converters

The year just past has seen not only the largest synchronous frequency changer yet built put into operation, but has also seen an induction-type frequency changer of the same capacity installed and successfully operated. The rating of these machines is 35,000 kw. A second induction frequency changer is now being built which will be rated at 40,000 kw. unity power factor for transfer of energy from the 60-cycle to the 25-cycle systems on which it is used and at 38,000 kw. unity power factor for transferring power from the 25-cycle to the 60-cycle system. This machine will be equipped with a phase-shifting device which will operate hydraulically.

The 35,000-kw. synchronous frequency changer rotates at 300 rev. per min. and has shown an efficiency of 96.1 per cent under operating conditions. This over-all efficiency represents an efficiency of each unit better than 98 per cent which is very high for rotating machinery. The machine is self-ventilated and has very good starting characteristics for a machine of its size. The induction frequency changer was put into operation with no difficulty and when used in connection with tap-changing switches in the air-blast transformer and reactors, showed a larger condenser capacity for power factor correction at reduced loads than could be obtained from a synchronous frequency converter of the same rating.

A new type of frequency converter was developed for tying together two systems, the frequency of each being susceptible to changes. This type is known as the Scherbius—controlled, load-regulating type of set. One machine is a synchronous generator and the other an induction motor having a Scherbius speed-regulating set. With this arrangement any desired amount of load can be delivered in either direction up to the limits for which the set is designed irrespective of the relative frequencies of the two systems. Two of these sets having ratings of 6000 kw. were installed during the past year. They form a tie between a 60-cycle and a 25-cycle system and are designed to operate with a total variation in frequency of nine per cent. If the 60-cycle frequency system is constant, the machine rotates at 720 rev. per min., the induction machine operating at above or below synchronism depending upon the frequency of the 25-cycle system.

4. Journal of the A. I. E. E., April 1925, page 339.

Transformers

The size of transformers installed and put under construction during the year represents a new high mark. Transformers were installed rated at 15,000 kv-a., 60 cycles, 7200-132,000 volts, three-phase, self-cooled, having a 12,470-volt tertiary winding. The efficiency of these transformers is better than 99 per cent and they have a regulation of 1.1 per cent. Since the largest self-cooled transformers constructed up to the year 1920 were of the order of the 10,000-kv-a., the above units represent a new level for three-phase transformers of this type.

Some 22,000-kv-a. single-phase, oil-immersed, water-cooled transformers, having 12,000-volt delta-connected primaries, and 39,500-volt secondaries, Y-connected to give 68,500 volts, were put into operation. These transformers do not have output ratings as large as other transformers now in service at 60 cycles, but, due to the fact that they operated on 25 cycles, the quantity of materials used in them was much greater than in any transformers of this type yet put into operation. Three-phase transformers, rated at 75,000 kv-a., have been built in Europe.

Improvements made in transformer design include a new type of ration adjuster switch by which the ratio can be altered while the transformer is carrying load. Potheads were developed for mounting on the side of transformers in order to provide a means for bringing underground cable into the transformer without exposing terminals or live parts. The pothead consists of two compartments, one in which the cable terminates and another in which disconnect links are provided. The lower compartment is filled with petrolatum and the other compartment with transformer oil. The conductors from the three-conductor cable are connected to lugs in the pothead which are arranged on the arc of a circle to make the reversing of conductors possible without splicing. A ground switch is now being designed to be located in the upper compartment and controlled remotely from the opposite side of the transformer. This switch will provide a convenient means for grounding the feeder connected to the transformer.

A new device has been developed for indicating the load on pole-type distribution transformers. This consists of two temperature detecting elements, one immersed in the oil and the other mounted in a case for

detecting ambient temperatures. These two temperature detectors are connected in series to a pointer which moves by the action of the temperature detector in the oil, which movement is modified by the action of the detector affected by the ambient temperature. When the temperature exceeds a safe value a target shows.

Several installations have been made of a transformer which is filled with nitrogen above the surface of the oil. The nitrogen used is automatically obtained from the atmosphere by passing the air breathed by the transformer through deoxidizing chemicals. The nitrogen, when formed, is conserved by a breathing regulator. The presence of nitrogen over the transformer-oil surface prevents the formation of sludges, (due to oil coming in contact with oxygen in the air), extinguishes fire, eliminates secondary explosions caused by mixture of the gases with air, and cushions primary explosive pressure from the sudden expansion of gases.

A radiator valve has been developed for use between the radiators and tank of large, self-cooling transformers, when it is necessary to remove the radiators for shipment. The valve consists of a tube projected into the radiator flange on the transformer tank and has a gasketed disk which is held against the end of the tube by means of a spring. It is operated by a handle. Rotating the handle 180 deg. in the proper direction opens or closes the valve. When the valve is open the handle may be removed to prevent unauthorized persons from operating it.

A new type of dehydrating breather for transformers has been developed, consisting of a screen basket suspended on a spring of large diameter. When the basket is filled with the proper amount of calcium chloride the spring is compressed and a pointer indicates the correct charge. As the calcium chloride absorbs moisture, the weight is increased and the spring is compressed until the pointer is opposite a refill designation. The calcium chloride is isolated from the humid atmosphere when the transformer is not breathing by means of check valves, and the device is designed so that the calcium chloride will not become saturated until after the refill designation has been reached by the pointer.

Synchronous Condensers

During the year, construction has been started on a 40,000-kv-a., 600-rev. per min. synchronous condenser representative of the largest machine of its type yet to be developed.

Spring Suspension for A-C. Generators

A new method has been developed for preventing the vibration of large a-c. generators from being transmitted from the stator to the supporting foundation. This arrangement consists of a spring mounted in the frame of the machine supporting the entire stator. The development of this device will aid in the successful operation of electric machinery in districts where vibration is objectionable, especially in the case of single-phase machines which have inherent vibration.

Water-Wheel Generators

The installation of the 65,000-kv-a., 12,000-volt, water-wheel generators, at Niagara Falls, has been carried on, and the first unit installed has already operated successfully for more than a year. These machines still represent the largest water-wheel generators built up to the present time. Among other large water-wheel generators about to be installed are a number of 32,500-kv-a., 12,000-volt machines, 23,160-kv-a., 13,200-volt machines, 18,750-kv-a., 6600-volt machines, and 19,500-kv-a., 6600-volt machines. The size of automatically-controlled, water-wheel generators has been advanced to 7300 kv-a.

Synchronous Converters

A number of synchronous converters have been developed for use in congested metropolitan districts. These are completely enclosed on the d-c. end and partially enclosed on the a-c. end. For cases in which systems of the same or different frequencies are tied together through the d-c. side of synchronous converters, a converter has been developed to incorporate special features for successfully withstanding current reversals feeding into a short circuit in either system.

Industrial Motors

New lines of single-phase, adjustable-speed, brush-shifting motors, having a speed range of two to one for constant-torque load have been developed. Single-phase, repulsion induction motors, having squirrel-cage rotor construction, without centrifugal devices, have been extended to include a reversing type capable of reversal from full speed in one direction to full speed in the opposite direction. Another new development in industrial motors is a new line of synchronous motors for driving ammonia and air compressors. These have double-bar, squirrel-cage windings, giving better control of current and torque under starting conditions and permitting the motors to be thrown on, full voltage. Induction motors of higher speeds with high-reactance secondary windings for full-voltage starting, totally enclosed motors with a special ventilation for operation in inflammable atmospheres and a new type of bearing which prevents air from getting into the bearing housing and oil from getting out, have been developed. Motors with enclosed collector rings have been put on the market for use in oil wells and similar service.

A New Self-Excited Synchronous Induction Motor[5]

The pure induction motor has characteristics which differ considerably from the pure synchronous motor. Each motor has advantages and disadvantages, the advantages of one being lacking in the other. A number of motors combining in part the advantages of both types of machines have been developed in the past and during the last year, there has been further development along this same line.

5. Journal of the A. I. E. E., August 1924.

A paper was recently published describing a new type of motor which has induction motor characteristics during the starting period and synchronous motor characteristics during the running period, the source of excitation when running as a synchronous motor being supplied from within the machine. The rotor of this motor carries a polyphase winding supplied with power through slip-rings and a commuted winding. The stator has an exciting winding displaced ninety electrical degrees from the axis of the brushes, and a neutralizing winding coaxial with the brush axis. Both these windings are connected to the brushes through separate variable resistances. A third variable resistance is inserted across the brushes to relieve the commuted winding under severe starting conditions.

When the polyphase winding is connected to the supply lines, a revolving flux is set up which revolves at synchronous speed when the rotor is at a standstill and is stationary in space when the rotor is revolving at synchronous speed. Since the revolving field cuts the two stator windings, displaced by ninety electrical degrees when the rotor is revolving at a speed less than synchronism, currents are set up in these windings which give a torque similar to that generated in an induction motor. These currents close over the brushes and the commuted windings and are regulated by the adjustable resistances which act in a way similar to the adjustable resistance inserted in the secondary of a slip-ring induction motor. As the rotor approaches synchronous speed additional torques are developed by the stator windings which pull the motor into step, at which time the magnetic field revolving with respect to the rotor becomes stationary in space and the brush voltage becomes unidirectional, thereby causing the magnetizations produced by the stator windings to be unidirectional.

Whenever the torque demand is greater than the maximum synchronous torque of the motor, the machine will drop out of step and become an induction motor in effect, giving the same asynchronous overload capacity as may be obtained from a corresponding slip-ring, induction motor. As soon as the torque demand is sufficiently reduced the machine will again fall into step. The motor is compounded to give power factor regulation by proper location of the brush axis with respect to the unidirectional magnetization of the secondary. All windings of the machine are utilized at all stages of starting and running.

A New Type of Single-Phase Motor[6]

Sometime ago a single-phase motor was developed which had series characteristics during the starting period and shunt characteristics during the running period, but as the motor contained a centrifugal device for decreasing the reactance of one of the windings, the motor was never adopted for production. However, this motor was a stepping-stone to a new type of motor having the same series and shunt characteristics and having no centrifugal device. The latter is termed the squirrel-cage repulsion motor and had been brought out during the past year.

This new motor consists of essentially a repulsion motor with a squirrel-cage winding inserted in slots which are located beneath the slots bearing the commuted winding. Since the induction motor winding is imbedded deeply in the rotor core, it has high reactance during the starting period, due to the relative high frequency of the induced current. However, when the speed of the rotor approaches synchronism, the frequency of the rotor currents is relatively low and the action of the squirrel-cage winding comes into play.

Since the reactance of the commuted winding is inherently low, the current flows mainly in this winding during the starting period, and torques are produced similar to those of a plain repulsion motor during the starting period. At full load the squirrel-cage and commutated windings deliver approximately equal amounts of energy.

Commutation is greatly aided by the action of the squirrel-cage winding due to the fact that it absorbs the energy which would otherwise cause sparking on account of induced electromotive force in the short circuited coil. To aid commutation further by absorbing the energy from the leakage flux which does not interlink with the squirrel-cage, a thin sheet of metal is inserted radially between the squirrel-cage winding and the commutated winding. This metal can be made of high resistance on account of the high frequency commutation and therefore does not materially interfere with the distribution of flux during the starting.

The motor has a very much better power factor, both at synchronism and below synchronism, than the plain repulsion motor. The commutation is practically perfect due to the action of the squirrel-cage winding in connection with the metal strips mentioned above. The efficiency is also considerably raised by the addition of the extra winding.

A New Alternating-Current General-Purpose Motor[7]

Another type of a-c. motor has been put on the market, which combines the starting characteristics of an induction motor with the good power factor characteristics of the synchronous motor, in a self-contained unit which needs no auxiliary machines for excitation. This motor will operate at unity or leading power factor and will carry very heavy temporary overload.

The motor consists of a rotor having a polyphase a-c. winding and a commutated winding, and a stator having a field winding and an auxiliary winding. The auxiliary winding is physically located at 90 deg. from the field winding and is closed upon itself. The field winding is connected to the commutator brushes. The power supply lines are connected to the polyphase winding on the rotor through slip rings.

6. Journal of the A. I. E. E., July 1924.

7. Journal of the A. I. E. E., April 1925.

The commutated winding does not appreciably affect the torque of the machine at standstill or low speed, but at higher speeds the commutator voltage enters into giving better synchronizing characteristics. When the machine is operating at synchronous speed a d-c. potential is present across the brushes, which serves as a direct-current source of supply for exciting the field. The machine, therefore, acts as an induction motor during the starting period and as a synchronous motor exciting itself during the running period. When the load reaches 150 to 200 per cent of full load, the machine drops out of step and continues to run as an induction motor. As soon as the load is again decreased to within these limits, the machine falls back into step and operates as a synchronous motor. The losses in this motor are comparable to those of an equivalent induction motor. However, the new motor has a tendency to be slightly less efficient at fractional loads and slightly more efficient at overload. The size of this motor is approximately the same as for the corresponding slip-ring induction motor.

Obviously there is a very large field for motors having the marked advantages enumerated above, not only for new installations where they can be made to operate at unity power factor, but also in older installations where a large number of induction motors have already been installed, in which case the lagging reactive kv-a. can be compensated by operating the new motor at leading power factor. However, the cost of these motors is considerably more than the corresponding induction motor, as may be expected.

A "Wool-Yarn" Oiling System for Small Motors

Many classes of service for small motors call for long operation of the motor without attention. Such service demands an oiling system for the motor bearings which is capable of supplying the bearings with the proper amount of oil for long periods without cleaning or the addition of oil.

A line of small motors has been put on the market which have a lubrication system called the "Wool-Yarn" System, consisting of a number of continuous strands of wool yarn placed over the shaft and projecting down into the oil in the well. In this system the oil is carried from the well to the shaft by capillary attraction instead of a revolving ring as is the usual practise. The compartment carrying the yarn and oil is practically dust proof, every precaution having been taken to prevent dust from entering around the shaft.

Even though this system is not applicable to motors larger than a few horsepower, it has marked advantages for small motors, in that the yarn acts as a filter for the oil and the oil in the well is not agitated which helps to confine it to the well. The oil capacity is increased by the amount held in the yarn and the motor will operate for long periods without re-oiling.

Surface Iron Losses with Reference to Laminated Materials[8]

Additional experimental work on surface iron losses with reference to laminated materials was carried on during the past year. The experiments were made on special test machines, the roters of which contained no windings other than exploring coils. The machines were rotated by direct-connected d-c. motors, which were calibrated in order that the losses in the test machines could be obtained from their inputs. The surface losses were obtained by separating the fundamental frequency losses from the total losses.

It was shown that the hysteresis and eddy-current components of the surface loss can be approximately separated graphically. Skin effect decreases the losses as the decrease in eddy current loss is considerably greater than the increase in hysteresis loss. In the case of salient poles the enamel on individual laminations decreases the surface losses only slightly, which would not justify the extra manufacturing expense in most cases, even though it may materially affect the relative hysteresis and eddy losses. It was stated that the hardening of lamination edges, due to punching, affects the hysteresis surface loss appreciably if the punchings are not annealed.

Repeated Thermal Expansions and Contractions Their Effect on Long Armature Coil Insulations[9]

During the past decade the length of armatures has been increased about five feet due to the increase in the capacity of machines. Since the coefficient of thermal expansion of the copper conductor in armature coils is about fifty per cent larger than that of the mica and paper insulation, there is a considerable difference in linear expansion of the two in armature coils. Recently much experimenting was done to determine the effect of this unequal expansion on long armature coils.

Experimental coils were placed in slots formed by stacking iron laminations in the same manner as they are placed in the slots of an alternator armature. Imitation vent ducts were situated at intervals in the iron so that the entire construction was comparable to a four-slot section of a large machine. The coils consisted of square brass tubes and were 118 in. in length. The insulation was standard for 13,200 volts. Thermocouples were placed at proper points for indicating temperature. The brass tubes were heated by passing current through them from a suitable transformer, and were cooled by passing them through air for certain experiments and water for other experiments where a greater change in temperature was desired.

Automatic equipment was used for heating and cooling the coils which consisted of time delay relays for putting on the current, starting the blower, etc. 7800 cycles of temperature changes of approximately 75 deg. cent. were given the coils, followed by 2512 cycles of

8. Journal of the A. I. E. E., August 1924.
9. Journal of the A. I. E. E., November 1924.

100 deg. cent. difference in temperature, 825 cycles of 130 deg. difference in temperature, and 400 cycles of 160 deg. temperature difference. The hottest temperature reached by the coils ranged betwen 150 and 180 for all tests.

After the coils were put through the above cycles, which were comparable to many years of service in a commercial machine, they were removed from the slots and inspected. The paper was somewhat darkened in color and was robbed of most of its mechanical strength. However, it was strong enough to retain its form about the conductor and to withstand the removal of the coils from the slot. The discoloration was greater at the imitation vent ducts than where the insulation was in contact with the stamping due to the fact that air could reach the paper more easily at those points. During the tests the coils were given a high potential test of 23,000 and 37,000 volts at intervals, and withstood these voltages without breakdown.

Tooth Pulsation in Rotating Machines[10]

Results of experiments have been published on the tooth pulsation in rotating machines, where both members are slotted. A method for checking the magnitude of flux pulsation was presented consisting of using metallic electrodes similar in shape to the machine teeth in connection with an electrolyte of mercury to represent air. Current is caused to flow through the teeth by applying voltage between the two members, with a magnitude proportional to the magnitude of flux that would flow under analogous magnetic conditions. The results obtained in this way are, in general, slightly lower than those shown by two methods of calculation; but the agreement is fairly good.

If the ratio of the mercury to electro resistance is small, corresponding to the effect of saturation in the iron, the effect of saturation may be experimentally determined. It was shown that for actual machines the effect of saturation on pulsation amplitude cannot be calculated by adding directly the air-gap and tooth reluctances, on account of the permeability of the iron not being constant.

Gaseous Ionization in Built-Up Insulation[11]

Experiments on the gaseous ionization in built-up insulation were conducted showing that the losses due to internal ionization caused a progressive deterioration of insulation, even though the absolute values of these losses in well constructed armature bars are small compared with dielectric losses of other types. The use of mica was shown to reduce the conductivity of the insulation and minimize the action of internal ionization. Even though the micafolium content can be somewhat reduced without seriously affecting the insulating properties over long periods, the use of high mica content appeared desirable due to variations in manufacturing process.

11. Journal of the A. I. E. E., January 1924.

Effects of Time and Frequency on Insulation Tests of Transformers[12]

The use of the induced potential method for testing the insulation of transformers has increased during the past few years. In order to keep the exciting current within a reasonable range during these tests, it is necessary to use frequencies higher than normal. Since the frequency used affects the dielectric strength of most insulating materials, the fair length of time during which high voltage is applied in the case of higher frequencies than normal is somewhat less than that for normal frequencies.

During the past year the results of experiments made to determine the fair length of time for higher frequencies were published. It was shown that the rupture voltage of oil is the same for both sixty and 420 cycles. Due to the fact that the behavior of oil alone is very erratic no well defined relation can be made between time and dielectric strength. However, for the first few seconds, time decreases the strength quite rapidly, after which the effect decreases and is probably entirely absent after two or three minutes. The momentary strength ranges from 25 to 30 per cent higher than the one-minute strength.

The strength of solid insulation decreases with an increase in frequency. The effect of time on the strength of oil and solid insulation in series is approximately the same as for solid insulation alone until the oil distance exceeds the solid insulation thickness, after which it begins to be the same as for oil without barriers.

When solid insulation is under considerable stress the breakdown by creepage is not affected by time nearly so much as is the puncture voltage of solid insulation. Frequency does not materially affect the creepage failure of solid insulation which is under no stress. However, if the insulation is under considerable stress the voltage for failure decreases with increased frequency in about the same order as the puncture voltage of solid insulation. The effect of frequency on the puncture voltage of solid insulation and oil in series is approximately the same as for solid insulation, where the thickness of the solid insulation is greater than that of the oil. When the oil distance exceeds the thickness of the solid insulation the effect approaches that for oil without barriers.

Obtaining Steady High-Voltage Direct Current from Thermionic Rectifier without a Filter[13]

The ordinary polyphase high-voltage rectifier gives a practical constant direct-current potential, which has a ripple superimposed on each side of the mean of approximately five to seven per cent of the total d-c. voltage. This ripple may be ironed out to a considerable degree by the use of a filter consisting of condensers and reactors which are somewhat expensive, especially for high voltages.

12. Journal of the A. I. E. E., February 1924.

13. Journal of the A. I. E. E., November 1924.

During the past year work was done on the development of a special type of a-c. generator having the proper low voltage wave form for giving a more nearly smooth rectified direct potential and provisions were made for manually or automatically varying the wave form to maintain a steady potential for varying load demands.

The Application of the Saturated Core Reactor and Regulator[14]

The use of direct-current saturation in the iron cores of static a-c. apparatus in radio work has been in vogue for sometime, and of late is being used commercially in voltage regulators and current-limiting reactors. However, due to cost and inefficiency, the saturated-core voltage regulator and current-limiting reactor are at present confined to specific uses in which speed of operation is desired in the case of the voltage regulator and increasing reactance with alternating current is desired in the case of the current-limiting reactor.

During the past year, saturated iron-core current-limiting reactors were installed in a large central station between the essential auxiliary bus fed by a house generator and a miscellaneous auxiliary bus fed by a house transformer. These reactors are designed to carry 660 kv-a. under normal operating conditions, at a reactance drop of fifteen per cent. The short-circuit reactance is approximately 38.5 per cent, which will not allow more than 1710 kv-a. to pass through the reactors at normal voltage. Should the house generator be carrying full load and supplying 660 kv-a. to the miscellaneous auxiliary bus through the reactors, a disturbance on that bus could not overload the house generator more than 42 per cent due to the action of the reactor.

The Transverter

A machine has been developed in England for converting polyphase alternating current into direct current and vice versa. Polyphase a-c. voltages of values low enough to be generated in large commercial alternators can be transverted into continuous potentials on the order of 100,000 volts.

The a-c. supply lines are connected to a series of transformer banks which transform the original voltage to the desired value and, in addition, convert the fundamental number of phases into a large number of phases, 36 for example. The 36 phases are then connected in the proper order to a commutator which remains fixed in space, the brushes being the rotating member. The brushes are mounted on a shaft and rotated inside the commutator instead of being placed on the outside as is the usual practise. If only two brushes were used and there were only as many commutator segments as phases, the brushes would have to be revolved at the synchronous speed of a corresponding two-pole motor. However by using more brushes and segments, properly arranged, the speed can be made to correspond to that of a four- or six-pole motor.

The transverter recently built and displayed in England used ten commutators in series to give 20 d-c. amperes at 100,000 volts, and was designed to be supplied with 50-cycle, three-phase current at 6600 volts. The speed of the brushes is 1000 rev. per min.

This device can be used for a number of purposes, such as obtaining high-voltage direct current from low-voltage alternating currrent, low-voltage direct current from high-voltage alternating current, low-voltage direct current from high-voltage direct current (by adding another set of windings and commutators), and a given alternating frequency from another frequency. All these processes are reversible.

The Subcommittee wishes to express to Mr. J. A. Brooks its appreciation of the valuable assistance which he has rendered to it in the preparation of this Report.

Committee Organization

The organization of the Committee on Electrical Machinery comprises a number of Subcommittees including the following;

1. The review and preparation of technical papers in the field of electrical machinery, H.M. Hobart, Chairman.
2. The preparation of a résumé of the year's progress in the electrical machinery art for the presentation at the Annual Convention, J. C. Parker, Chairman.
3. Preparation of short memoranda of timely interest relating to electrical machinery, for publication from month to month in the Journal, E. H. Hubert, Chairman.
4. Subcommittee on Electrical Machinery Research, V. Karapetoff, Chairman.
5. Subcommittee on Electrical Machinery Standards, C. A. Adams, Chairman.

Provisions are made for further subcommittees which can be described as Regional Subcommittees. Each member of the Committee on Electrical Machinery is invited to examine the practicability of establishing in his vicinity a Regional Subcommittee to deal with subjects in which he is especially interested. The member includes in the Subcommittee a group of fellow-specialists and he is free to go outside of the Committee on Electrical Machinery for this purpose.

As an example of one of these Regional Subcommittee's may be mentioned that organized by Prof. B. F. Bailey. It deals with induction motors and generators and research subjects relating thereto. As Professor Bailey is located at the University of Michigan he has associated with himself in this Subcommittee Professor James F. Fairman, Mr. Norman S. Yost and Mr. L. N. Holland, all of whom are located at or near Ann Arbor.

The studies and discussion leading to the above organization of the Committee on Electrical Machinery took considerable time and the Subcommittees have not made as much progress this year as had been hoped. However, the Electrical Machinery Research Subcommittee has held meetings in which several matters have been profitably discussed.

14. Journal of the A. I. E. E., July 1924.

Precision Watthour Meters and High-Frequency Measurements

By Committee on Instruments and Measurements[1]

IN selecting subjects which would become the major study of the committee during the year, an effort was made to choose those which seemed to be lagging in progress because of unorganized attention, or to be only imperfectly coordinated and recorded because of their relatively recent development. Two subjects were chosen, one on each of these bases, and subcommittees (with chairmen, H. B. Brooks and C. M. Jansky respectively), were appointed to make the survey.

One of these subcommittees has been assigned the task of promoting the development of a device or devices for the measurement of energy directly in terms of watthours under the condition of excessively fluctuating power, for averaging this variable power with laboratory precision, and to produce results equivalent in accuracy to those obtained with laboratory equipment now used for the measurement of volts, amperes and watts. The committee is not concerned with the watthour meter as used by the million in the vending of electric energy; that is the concern of other agencies, and it may well be agreed that the watthour meter, in practically all respects, surpasses the measuring devices through which the public purchases other services and commodities. But this device, or modifications of it, thus far produced and used as a precision standard of comparison in laboratory and field testing, and as a means of averaging variable power over an extended time (as in water-rate determinations of large turbo-alternators, for example) leaves something to be desired.

The subcommittee charged with this problem realized that one of the outstanding sources of variation in accuracy of watthour meters was the variation in temperature of their component parts, arising from two principal causes; (1) changes in temperature of the ambient medium; (2) heating from the flow of current through the coils, and from iron losses. There was presented at the Midwinter Convention an important paper by Messrs. Kinnard and Faus, in which temperature errors in induction watthour meters were analyzed theoretically and experimentally and a device described for the compensation of the major of the two principal classes of temperature errors. The subcommittee considered it of little or no value to assemble and coordinate data on the temperature performance of the meters in current use, which are not equipped with any such device, but that its concern should be with meters which include this or some equivalent compensation. When such meters are regularly available, the subcommittee will consider the feasibility of having exhaustive tests made by suitable authorities.

Meanwhile, there remains a number of other disturbing effects to be considered, such as the influence of frequency, voltage, and wave-form variations, and of low power factor. These matters, and the methods by which improvement may be realized, will be included in the work of the subcommittee. The program thus briefly outlined will obviously involve a considerable amount of effort over a long time, and the subcommittee looks with confidence to the experts of the manufacturers, and others who specialize in this field, for full cooperation in the task.

The watthour meter, in different forms, has not been found entirely suitable for measuring the power output of large turbo-generators during water-rate tests and there is a tendency to prefer the wattmeter for this purpose, even in spite of the necessity of taking a very large number of readings during the progress of the test. The scope of the subcommittee's work includes a study of this method also, and by request, a valuable paper on the "Measurement of Electrical Output of Large Turbo-generators During Water-rate Tests" has been prepared by E. S. Lee; this paper was assigned to the program of the First District Regional Meeting at Swampscott in May. It was hoped that this paper would serve to bring out discussion which would be of value to the subcommittee in its further study of the problem.

The phenomenal development of radio communication naturally focussed the attention of the committee on the subject of electrical measuring instruments for use with frequencies in the audio and radio ranges. It seemed to be an opportune time to make a survey of the available instruments for these fields, their operating principles, limitations, and scope of applicability, and a second subcommittee was appointed to conduct the survey.

The most extensive use of high-frequency measurements is undoubtedly in the field of radio communication. However, frequencies ranging from 20,000 to 50,000 are much used in wire telephone and telegraph communication and in the so-called "wired wireless" or "carrier current" communication over power trans-

mission lines. Another possible application of high-frequency measurements is the determination of the periodicity of transients and the measurements of higher harmonics on power lines and in electrical machinery.

Low values of inductance and capacitance are of great importance where high frequencies are involved. The power engineer has heretofore considered them negligible. With a better knowledge of high-frequency measurements, quantities that have been neglected may assume greater importance even in power engineering. These low values of inductance and capacitance are usually measured by some resonance method; that is, by "tuning" the circuit with the unknown inductance or capacitance to the frequency of another circuit with known inductance and capacitance and then calculating the unknown quantity in terms of the known values.

There are two common methods of measuring resistance at high or radio frequencies; the reactance variation method, and the resistance variation method. The application of the reactance variation method requires a knowledge of the frequency used. It is, therefore, more useful in measuring logarithmic decrement and sharpness of resonance. Bridge methods are but little used for the measurement of resistance at radio frequencies but a somewhat similar method, which utilizes a differential transformer, is coming into use. There is also the method employing a voltmeter designed for accuracy at radio frequencies.

Great need has been evidenced for the development of more accurate measurement of resistance, inductance, and capacitance at high frequencies, but there is greater need for the more general utilization of instruments of adequate accuracy for measuring the frequencies of the electromagnetic waves emitted by radio-frequency generators used in broadcasting and other stations. These frequencies are usually measured by means of an instrument known as a frequency or wave meter. The extensive use of certain radio-frequency bands requires that radio stations be assigned frequencies which are, in some cases, only 10,000 cycles apart. If there is to be no interference between stations, each must maintain its assigned frequency within a small fraction of one per cent; there is a call for the development and use of frequency meters having the degree of accuracy required for this purpose.

This subcommittee is also continuing its studies.

The Activities in Research

By Committee on Research[1]

Part I. General

Activity in the field of electrical research, as noted in last year's report, has continued unabated during the past year. The range of problems has been much the same, and while no striking research of outstanding importance may be mentioned, noteworthy progress has been made in many directions.

In the field of high-voltage transmission and power distribution there is an increasing tendency to investigate the performance of such systems through experimentation with models, miniature systems and equivalent net works. With these should also be included several important analytical studies of the transients occurring in such systems. Several accounts have appeared of experiences with 220-kv. systems based on special methods of observation and measurement, and these have brought forward facts and conditions sufficiently new to warrant their mention in this report. Important new data are available as to lightning disturbances and methods of protection; a new type of suspension insulator of great promise has appeared and further studies have been made of the properties of protective reactors. New data as to the law of loss due to corona have been brought forward and definite statements made as to the value of corona as a stabilizing, if not a protective measure for high-voltage systems.

In the wide field of magnetism much new material has been produced. Investigations have extended from studies of the core loss in induction machinery, the losses in laminated surfaces next to air-gaps, the influence of slot openings on wave form, and other similar questions in machinery, to the further study of the properties of magnetic materials in relation to their constituent substances. Noteworthy in this class is the substance permalloy and its adaptation to the submarine cable; a thing of great promise, but so far, upon this relatively little definite information is available. An important accomplishment in this field is the completion of a complete bibliography of the literature by the Core Loss Committee of the National Research Council. The bibliography embraces all branches of the field of core losses and is admirably classified and indexed. It is hoped that some one of our large research organizations will find it possible to publish this bibliography so that it may become generally available.

Among other studies in the general field of electrical engineering there may be mentioned as either completed or under way the following variety of problems: The

influence of impurities in storage-battery electrolytes; many studies of rectifying devices, including further methods of obtaining high, continuous voltage; the construction of an absolute electrometer for very high voltages; a redetermination of the unit of resistance, (these two latter at the National Bureau of Standards); the determination of the temperature errors in induction wattmeters, and other important developments in methods and instruments of measurement.

In the field of electrical communication special mention should be made of the increasing expansion of research work carried on by the Bell Telephone Laboratories. The range of problem handled in these laboratories is extremely wide and very noteworthy contributions are appearing at regular intervals. These are not confined to the immediate problems of conversion between speech and electric circuits and vice versa, but reach out into the field of pure physics on the one hand, and to studies of the performance characteristics of all types of electric circuit on the other. Of special note is our increasing knowledge, obtained through these laboratories, of the performance of all types of circuits under a very wide range of frequency, and the development of filters, relays, and other forms of auxiliary equipment for circuit control for special purposes.

Extension of range and improvement of methods, in radio, telegraphy and telephony is of almost daily occurrence. It is a highly specialized field, but one in which, many members of the Institute are nevertheless participating. Among the great number of improvements in transmitting and receiving equipment, there stand out as of recent, more conspicuous achievements, the control of static in transatlantic service; the increasing use of the shorter wave lengths; the control of "fading"; and the further perfection of generating equipment.

In the field of pure physics, principal attention appears still to be devoted to questions of molecular and atomic structure and the nature of the ultimate constitution of matter. Progress has been very rapid and the results obtained are of greatest importance as well as of absorbing interest. Up to this time, however, these studies do not appear to touch, in any close manner, the laws underlying the various arts in electrical engineering. It is an interesting fact that while much certain knowledge has been gained, as to the structure of the atom and the electrons therein, nevertheless it has not been found possible to adapt this knowledge in any certain way to explanations of the great fundamental phenomena of electric conduction, magnetism, and dielectric induction. For this reason, as well as because of the vast variety and quantity of material, only this passing mention is made of this great field of the highest type of scientific research.

PART II. ELECTRICAL INSULATION

This report has reserved for separate comment the subject of research in the field of electrical insulation. The year has seen a notable continuance of the general interest in this important problem. Numerous papers have been published giving new technical data, thus slowly increasing our knowledge. Among the subjects treated may be mentioned distribution of flux density in cables, the relation between breakdown voltage and times of application and rest, experimental data on the breakdown of cable insulation under standard tests with special reference to the duration of application of the test voltage, the influence of temperature on impregnated paper insulation, and ionization in impregnated paper insulation. Discussion of these papers has indicated the desirability of certain changes in present tests standard for high-voltage cables.

Particular mention should be made of the work being done by the committee of the National Electric Light Association on Cable Insulation Research. This committee has formulated a well considered plan and has raised sufficient money to pay for "whole-time" research assistants, the work to be carried on in the electrical engineering laboratories of Harvard University, Johns Hopkins University and Massachusetts Institute of Technology. Problems of attack are those bearing on the life of high-voltage cable insulation and the causes of its failure, the work is certain to produce results of value.

As indicated in last year's report, the Committee has had before it as its principal object the complete review and digest of the literature of electrical insulation. This work, formulated first by the Engineering Division of the National Research Council, in its Committee on Electrical Insulation, is being carried on largely by members of the Committee on Research of the American Institute of Electrical Engineers. The particular value of this work will be found in the summaries and conclusions to be prepared by the chairman of the several committees. The Committee hopes to include in these summaries statements as to the present problems under the respective headings, with suggestions for the most profitable lines of experimental attack. Steady progress has been made, although it can scarcely be said to be rapid; the character of the undertaking is such as to require considerable time and sustained effort. Surveys in the field of insulation can be made only by experienced and competent men, and under our present plan, we are relying entirely on the voluntary efforts of a comparatively small number. All of these are busy men with whom the work of the Committee must, of necessity, take a subordinate place.

The present state of the work is approximately as follows: The Subcommittee on Dielectric Absorption, J. B. Whitehead, Chairman, has practically completed its review of literature; Subcommittee on Phase Difference, Delafield DuBois, Chairman, has completed about eighty-five per cent of the literature; on Electric Strength, W. A. Del Mar, Chairman, has completed all the literature on solids, and its report is well advanced towards completion. The review of literature

on liquids is well advanced. The Subcommittee on Flashover Voltage, F. W. Peek, Jr., Chairman, has covered the field of the literature in English, and is making progress in foreign literature. The Subcommittee on Theories, J. B. Whitehead, Chairman, has practically completed the review of the literature. The Subcommittees on Dielectric Constant and on Resistivity have not been able to make any considerable progress.

The reviews of the literature referred to above consist of a separate report in standardized form for each paper reviewed. The results of this work therefore will constitute not only a valuable bibliography of the separate divisions of insulation, but also a most valuable concentration in one place of the important results of each worker, and, therefore, a combined picture of the entire problem which should prove of very great value. As the publication of this large mass of data will be a matter of some expense, the Committee hopes to make the more important results of its work available to all through the preparation of reviews and summaries by the respective chairmen.

PART III. THE ORGANIZATION OF RESEARCH

A general review of the work in electrical engineering research during the past year reveals two striking facts: First, the great amount of experimental research under way and the wide range of problem; and second, the lack of coordination among various workers in the same or allied fields. Obviously, a function of the Committee on Research should be the bringing about of such coordination if in any way possible. The difficulty here is in obtaining information as to the work undertaken in widely separated localities. Often the Committee's first knowledge of a piece of work is the appearance of the paper presenting the results. This state of affairs must continue so long as the original conception of the problem arises in the interest of some individual, in a university laboratory, or in the special needs of some manufacturing process.

The foregoing condition has been recognized for some time and the desirability for organization and coordination of electrical research has been frequently emphasized; in fact, the National Research Council in its Engineering Division, the Engineering Foundation, the National Bureau of Standards, and, to a less extent, the national engineering societies, all conceive it their definite function not only to stimulate but to coordinate research. The Committee on Research of the Institute acts as an advisory committee on questions of electrical engineering to the Engineering Division of the National Research Council, the body which initiated the work on electrical insulation. In addition to the Committee on Electrical Insulation, it has formed a number of other important committees, not only in the electrical, but also in other fields of engineering. If the purposes of these committees are carried out, they will result in authoritative statements of the problems in the various fields, will serve as important guides for future work, will avoid duplication of effort and, naturally, will result in a much more rapid extension of our knowledge in the respective fields.

The picture so presented is an inspiring one, but it has one serious and fundamental defect. On closer examination it will be found that the function of the comprehensive review of the field of any problem is relegated to volunteer workers. The men who are capable of making these studies and reviews, and of laying out subsequent programs, occupy important positions the duties of which must necessarily require most of their time; committee work of necessity takes a subordinate place. Money has been appropriated for particular research problems, but none for greater expert reviews of the entire field. This is unfortunate, the more so since it should not require any considerable annual expenditure to avoid it. The Committee on Research has spent nearly two years in accumulating data on insulation outlined above. This could have perhaps been done in one-fourth of the time by a single well trained man devoting his entire time to it.

The concrete suggestion, therefore, is that large organizations, the chief function of which is to promote experimental research, could, with profit, maintain as a part of their organizations a few competent men trained in science, engineering and in the methods of research, with their principal duty the presentation of the work of the past, problems of the present, and plans for concerted experimental attack for the future. The volunteer research workers would do the rest.

Developments in Applying Electricity to Industrial Uses

By Committee on General Power Application[1]

THE annual report of the Committee on General Power Applications has been divided into three parts, namely—an account of the Committee's activities in the past year and two appendices which are believed to contain data of interest and value to the membership.

Soon after its appointment, this Committee offered its services to all Institute Sections, in the preparation of papers or in locating speakers on any subject within its scope. In answer to an inquiry from the British Consulate General, the Committee conducted inquiry into the use of magnetic hoists in shipyards and at docks, with especial reference to their effect on the ship's compass, due to its possible derangement or the magnetization of the ship's frames.

A session of the St. Louis Convention was assigned to this Committee and five papers were presented as follows:

Load-Building Possibilities of Industrial Heating, C. L. Ipsen;

A High-Frequency, Induction Furnace Plant for the Manufacture of Special Alloys, P. H. Brace;

Electrically-Heated Lead, Solder and Babbitt Pots, J. C. Woodson;

Synchronous-Motor Drive for Rubber Mills, C.W. Drake;

Use of Purchased Power in Glass Manufacture, A. L. Harrington.

The Committee has given special thought to the manner in which the wide variety of subjects under its jurisdiction may be most suitably presented to the membership. The preparation and presentation of papers alone is not sufficient. The space available in the JOURNAL and the Convention sessions which may be devoted to General Power Applications, without unduly curtailing other subjects of equal or greater importance, leave the Committee embarrassed by a too plentiful supply of new and valuable material.

As a consequence, the Committee submits as Appendix A of this report, a brief summary of progress covering important developments in General Power Applications which have come to its attention during the past year. In Appendix B is submitted a bibliography of articles which have appeared in the technical press, on subjects related to the Committee's activities. It is believed that this bibliography will be found valuable by those who wish to investigate the subjects which have been included.

The Chairman wishes at this time to record his sincere appreciation of the efforts of D. H. Braymer, member of the Committee, and also the courteous and efficient help rendered by other members of the McGraw-Hill organization. Without their assistance, the appendices would have lost much of their value.

The Committee submits the following recommendations to its successor:

a. The annual preparation of a similar summary of progress and a similar bibliography, if the reception of these by the membership indicates that they are useful and desirable.

b. Suggestion of the subject of "Group Control of Motors, Sectionalized Drive" as one which should be developed in a group of papers.

c. The recommendation of subjects on "Power Factor and Load Factor, Their Control in Industrial Applications" for special development.

The Chairman gratefully acknowledges the interest shown by the members of the Committee and the Institute Staff in their cooperation in carrying on the work of the past year.

Appendix A

A condensed summary of general progress in power applications as recorded in engineering publications during the past year.

TRENDS IN INDUSTRIAL MOTOR APPLICATIONS

Through the cooperation of engineering departments of manufacturers, consulting engineers and electrical engineers in industrial plants, progress is being steadily made along the line of more efficient power drives and control equipment and drive arrangements better suited to the changing operating conditions or tending toward lower maintenance with improved operation from the standpoint of production in manufacturing operations.

Outstanding points in this connection are, improved motor construction; modifications in motor applications to speed up production; new types of control; improved resistors; new forms of limit stops and safety features in control applications; installation of automatic equipment in steel mill substations; extended use of electric heating, and the like.

Steel Mills. The most noteworthy feature of the electrification of steel mills has been the large number of installations of new equipment that were started during

Presented at the A. I. E. E. Annual Convention, Saratoga Springs, N. Y., June 24, 1925.

a year of comparatively dull times for the steel industry. This fact is a most striking indication of the economy and reliability of electric operation.

The Westinghouse Electric & Manufacturing Company reports that five reversing equipments have been sold, including two large reversing blooming mills, two roughing structural mills and one finishing structural mill. This company further states that one of the greatest advances in the art was made this year when the company placed in operation a 500-h. p., single-unit, reversing motor, receiving its power from two 2100-kw. generators operating in parallel. It has heretofore been considered necessary to drive one motor from a single generator, and if two motors were used two generators were required. By this new arrangement it is said to be possible to design both motors and generators to best meet their operating conditions, rather than to have the design determined by the number of units of which the equipment is composed.

A 40-in. and a 44-in. blooming mill are each being equipped, by this company with 7000-h. p., single-unit motors. These are said to be the largest single-unit, d-c. motors ever built. A 500-h. p., d-c. motor is being installed by this company to operate at 155 to 500 rev. per min., at any voltage from 220 to 250. This application is for a tire mill and constitutes a speed range of 3.7 to 1, which is exceptionally high for motors of this capacity.

The Allis-Chalmers Manufacturing Company of Milwaukee, Wis., reports that it has installed and put in successful operation three mill-type synchronous motors on main roll drives of steel mills. The motors are coupled to the mills without the use of a clutch.

By the addition of 45,350 h. p. (normal continuous rating) of main roll motors during the year, the total of General Electric main roll drives has been brought to over 700,000 h. p. This company reports that an installation of particular interest is a 14-in. continuous merchant mill at the plant of the Jones & Laughlin Steel Corporation. The nine stands of this mill are driven by seven, adjustable-speed, d-c. motors. This mill will roll a very large tonnage of diversified products and the employment of individual drives with a very wide speed range is said to enable it to do the work of two or three less flexible mills.

The 26-in. rail mill at the Sparrows Point Plant of the Bethlehem Steel Company was changed over from steam to electric drive by the installation of two 3000-h. p., 500-rev. per min., 660-volt, constant-speed, induction motors made by the General Electric Company.

The Reliance Electric & Engineering Company reports that one of its most important application developments is an individual wire block driven by an adjustable-speed, d-c. motor with special automatic control equipment.

Textile Mills. An application of the brush-shifting motor to the operation of textile finishing machinery, where the operation of several motors in tandem may be required, is reported by the General Electric Company. In each case the speed of the main motor is controlled by push buttons through the operation of a pilot motor, which actuates the brush-shifting mechanism, while the speed of the other motor is controlled either mechanically or electrically by the motion of a compensating gate or floating roll between sections of the machinery.

Rubber Mills. The Westinghouse Electric & Manufacturing Company reports that for the past two years, its mill drive using synchronous motors without clutches or brakes has proved highly satisfactory. This is said to be due to the use of dynamic braking as a means of making safety stops, which has proved thoroughly reliable and effective. During the past year further improvements and developments in the control have been undertaken with a view to obtaining even greater reliability and quicker stopping. This company states that the development of a three-pole, double-throw, gravity-operated contactor makes it possible to use dynamic braking with either manual or automatic starters, the braking feature being entirely independent of any external control circuit or relay operation.

The elimination of the use of low-voltage and other relays in the braking circuit, together with the use of gravity operation, is said to give a reliability exactly comparable with d-c. drive for calenders, which has been in use for so many years.

Lumber and Woodworking Mills. A variable-voltage log carriage, consisting of a d-c. motor and motor-generator set, has recently been installed on the Pacific Coast by the Westinghouse Electric & Manufacturing Co. The motor is rated at 35 h. p., and has a speed range of from 10 to 80 rev. per min. Power is supplied by a 30-kw., 320-volt motor-generator set.

The General Electric Company reports that small, drawn-shell type motors of unusual speed were provided for the operation of woodworking machinery. A typical application of this character consists of five small motors with operating speeds of 25,200 rev. per min., which are utilized by a single woodworking machine, the current for the small high-speed motors being supplied by means of a frequency changer. The motors operate on three-phase, 240-volt, 420-cycle circuits.

Paper Mills. A new rotary contactor regulator for sectional paper-machine drive is reported by the Westinghouse Electric & Manufacturing Company. This regulator is an improvement over past apparatus, in that great simplicity and a more flexible action is obtained.

By the same company there has been placed in operation a paper winder drive with automatic regenerative tension control for sheets, including automatic regenerative and dynamic braking for the winder and unwinder. This is said to permit much faster operation of the winder and much better control of the finished roll, as it produces a uniform tightness throughout. Thus is avoided the expense and annoyance of frequent replacement of friction brake linings on the unwinding roll.

Also by the Westinghouse Electric & Manufacturing Company an automatic speed regulation of the vibrating regulator type for single motor paper machine drive has been developed and placed in operation. The use of this device is said to make possible a degree of regulation not previously obtainable through inherent speed regulation characteristics of the motor and generator. This is a decided advance in the art and contributes in a marked degree to precision control, which is becoming of greater and greater importance in this industry.

An installation of a sectional paper-machine drive, for a 175-in., 1000-ft. per min., Kraft paper machine, has been placed in operation by this company. This is the largest Kraft paper machine built to date.

An installation of five automatic grinder load regulators for the control of as many 1800-h. p. synchronous motors driving pulp grinders has been placed in operation by this company. The control of the load on these machines is said to relieve the governors of the power plant of an enormous amount of work and to greatly improve the frequency and voltage regulation of the entire system.

Industrial Haulage. Induction motors designed to give a high starting torque with a relatively low current and a high efficiency when operating under load were applied for the first time to large systems of conveyers by the General Electric Company.

The first haulage electrification of an open-pit iron mine in America was effected by the adoption of three 60-ton, double-truck, 500-volt mine locomotives made by the General Electric Company at a mine of the M. A. Hanna Mining Company at Duluth, Minn. These locomotives are provided with auxiliary cable reels, and current supply is effected by means of an overhead trolley.

Machine Shops. With the improvement in cutting tools and quality of rails, has come a demand for more driving power for frog and switch planers. During the past year, the Reliance Electric & Engineering Company has developed and applied motors in sizes up to 100 h. p., 250-1000 rev. per min. to such planer drives. This company further states that reversing the motor drive with automatic control of such work means the elimination of belt troubles, ample power, accurate speed adjustments for a cutting speed range of 1 to 2, and a separate speed adjustment for return strokes from 50 to 100 ft. per min. Quick return strokes reduce the non-productive operating time to one-third that of belt drive.

A complete line of variable-voltage, reversing planer equipments has been developed by the Westinghouse Electric & Manufacturing Company. Each unit makes use of a separate motor-generator set; consequently, it is possible to install a variable-voltage equipment on a planer at any point in a plant having alternating-current service. Other outstanding features that this drive is said to have are a greater speed range, smoother acceleration and braking, and very simple control, combined with a power saving in service where reversals are frequent.

Elevators. The General Electric Company reports that radical improvements were made in the operating characteristics of its high-speed elevator equipment. One of the principal difficulties in the past has been that the speed, on any one speed position of the controller, is decidedly variable with the load, being slowest when the motor is hoisting the maximum load and fastest when the motor is being overhauled by the load. The improved system consists of a motor and motor-generator controlled on the Ward Leonard principle but with the novel feature of an auxiliary series generator by which a considerable degree of compounding can be successfully applied to the main generator to an extent entirely impracticable to apply in the ordinary manner.

A new gearless traction elevator motor for passenger service has been developed by the Allis-Chalmers Manufacturing Company. It is of the shunt-wound type designed for operation at slow speeds suitable for giving normal car speeds, using standard diameter sheaves. The system of control used is the Ward-Leonard requiring separate motor-generator set and variable-voltage control.

Elevator equipment and the necessary control has been developed to such a point of perfection that speeds of 1000 ft. per min. are now entirely possible, is reported by the Westinghouse Electric and Manufacturing Company. In fact, there seems to be no reason why speeds cannot be increased up to the limit prescribed by the speed at which humans can be transported, in vertical position, without discomfort.

Oil Wells. The Westinghouse Electric & Manufacturing Company reports that field tests of the Hild differential drive for oil wells have been made. Two holes, 3700 ft. deep, are said to have been completed successfully.

This drive is designed primarily for rotary drilling. Its function is the automatic regulation of the downward bit feed according to the resistance of the formation encountered. Essentially, it consists of a differential gear unit, two slip-ring motors and a rotary drawworks. One of the motors—the drill motor—drives the rotary table which revolves the drill pipe and at the same time drives one-half of the differential. The other—the regulating motor—drives the other half of the differential. The two motors operate the differential in opposite directions, the operating motor in a direction tending to raise the drill pipe and the drilling motor in a direction tending to lower it. By adjusting the speed of the drilling motor slightly higher than that of the regulating motor, a slow downward feed of the drill pipe is produced. If the resistance to the drill is increased due to change in formation, the increased load slows down the drill motor and a slower feed results. Conversely, a lighter load means a more rapid feeding of the bit. High resistance encountered in drilling through hard rock causes the bit to rise until it clears itself.

Automatic Controllers. Because of the very nature of industry and the years of study of application and performance of motor devices and control, there is always a certain amount of development and refinement in controller design and construction that is accomplished through the increased knowledge of the requirements of industrial power drives. The year 1924 was no exception with regard to progress and developments.

One of the outstanding developments is the inductive, time-limit controller devised by The Cutler-Hammer Manufacturing Company of Milwaukee, Wis. In the design of this time-limit starter the inductive principle is utilized to obtain the accelerating time, a transformer being used in place of relays, interlocks, dashpots or other moving parts to control the time of acceleration. The manufacturer states that, through the medium of the transformer, a holding-out current of transient nature is obtained in successive accelerating switches. Transfer of connections takes place automatically with the cutting out of successive steps of resistance without disconnection of the coil circuits. It is said that in this new development, the acceleration period is very uniform under ordinary conditions of load variations, the time being somewhat increased on heavy loads; thus the machine driven, whether reversing table, screw-down or other auxiliary machine, is always brought up to speed in the same period to insure the productive synchronism and plant efficiency desired.

Another development in time-limit acceleration is reported by the General Electric Company in the case of a 300-h. p., a-c. motor on the hoist and a 75-h. p., a-c. motor on the trolley of a coal tower at Clairton, Pa. Current-limit acceleration was previously used on this application and the change to time-limit acceleration was secured by using a suitable number of d-c. contactors and allowing them to close in sequence, each one being interlocked through the preceding contactor. D-c. contactors were used to secure a slow time of closing, so that fewer contact elements were required than would have been necessary with alternating-current contactors. No time element relays were used.

Two forms of resistor-type magnetic starters for a-c. motors have been produced by the General Electric Company; one for squirrel-cage induction motors, and one for slip-ring motors. Mechanically, these starters are very much alike, the difference being chiefly in their connections. They both employ a new type of time-element relay for the accelerating period, which can be adjusted to about six seconds. The relay consists of an armature that is drawn across the face of an a-c. magnet by a spring which is distended when the line contactor closes. The magnetism resulting from the alternating current intermittently attracts and releases the armature as it slides by the pole face, thus giving the desired time adjustment.

A great advance has been made in the control of blooming mill auxiliaries, by the installation of two entirely separate control circuits, either of which can be used at will, is the report received from the Westinghouse Electric & Manufacturing Company. Each master switch is plugged into a receptacle, and in case of trouble can quickly be replaced by a spare. A complete spare control panel is included which can be quickly transferred to any motor.

Similar information comes from the Rowan Controller Company of Baltimore, Md., in citing the case of a switchboard containing the necessary control equipment for the auxiliaries for a large blooming mill in the Cleveland steel district. A unique feature of this installation is that all the controllers for the front and rear tables and the screw-down are exactly alike. An additional spare control panel is provided so that by means of throwover switches this spare panel can be rapidly connected in place of any of the other similar controllers.

A new type master has been developed by the Cutler-Hammer Manufacturing Company for use particularly with Cutler-Hammer magnetic-type controllers. This master is a compactly enclosed structure with a contact cylinder mounted on a square shaft. Standard non-stubbing contact fingers such as are used in Cutler-Hammer drum controllers, are mounted on the stationary support, the leads to which they are connected also remaining stationary. Pyroplax arc barriers are placed between the fingers and the contact segments which are automatically lubricated by means of an oil wick which holds sufficient oil for about six months use.

A new automatic reversing planer controller has been developed by this company. The scheme of control employed plugs the planer motor in stopping and reversing the planer, and the company reports that this results in the fastest method of operation. Two shunt-field rheostats are provided in the control—one is for regulating the cutting speed and the other is for adjusting the return stroke speed.

For several years past it has been evident that the trend of safety regulations is toward the enclosure of all types of motor starters and speed controllers. During the year, the General Electric Company reports that work along these lines was practically completed, and the remaining open-type starters and speed controllers were provided with either self-contained enclosing cases with external handle or were redesigned to accommodate enclosing cases when required.

Monitor Thermaload starters, manufactured by the Monitor Controller Company, Baltimore, Md., are now being built with standard Monitor side-arm contactors instead of the special contactor previously employed. Hairpin-shaped thermal elements are also being supplied, instead of the coiled elements previously used.

The thermal relay of the Monitor Thermaload starter operates on the thermal expansion principle. The heat produced by the thermal element under overload causes a liquid confined in a tubular receptacle to expand and to elongate two expansion units. These expansion units in turn operate an arm containing two contacts which control the operating circuit of the

contactor. The liquid used is carbon tetrachloride, a non-corrosive and non-freezing liquid which is used extensively for fire extinguishing purposes. This starter is intended for starting small induction motors, both single-phase and polyphase, and is said to protect the motor against light overloads dangerously prolonged, yet permits the motor to carry heavy overloads momentarily.

A new steel enclosed, dust-proof drum controller is being marketed by the C. H. McCullough Engineering Company, of Pittsburgh, Pa. This company reports that the diameter of the drum of this controller is exceptionally large, giving a greater wearing surface and thereby increasing the arcing distance between points. This company also points out that due to its dustproof qualities the controller is especially adapted to foundaries, steel works, cement plants and similar dusty locations.

The Condit Electrical Manufacturing Company has announced that during 1924 it has arranged its type N-3 oil motor starters for push-button control, thus making them especially adaptable to industrial service. The type N-4 starter which was developed in 1923 is now equipped with thermal cutouts.

The Allen-Bradley Company of Milwaukee, Wis., has within the last year or so added refinements to its lines of across-the-line starters, automatic starters and semi-automatic starters, according to reports received from them. It also informs us that these lines have been standardized so that they can be made on a large quantity basis at a very reasonable price and yet keep the same standard of quality for which these starters have been noted.

Heretofore, fractional horse-power motors have, to a very large extent, utilized standard, wiring device switches, which were primarily designed for lighting circuits. A new design of single-pole and double-pole enclosed tumbler switches, assembled in boxes for conduit wiring for throwing small motors on the line, now gives these motors a class of control equipment comparable with that provided for large motors, reports the General Electric Company.

This company also informs us that a new thermal overload relay was designed to follow the heating and cooling curve of the average induction motor, and that this is particularly adapted to service where it is important for the motor to carry heavy, short-time overloads intermittently, without being tripped out by the overload device. It is said that this device will permit the motor to do any kind of work that does not run it above a safe operating temperature.

The company states that it has developed a definite time relay which was utilized for the first time in an automatic compensator, and is now used to provide the accelerating period. It consists essentially of a motor-driven train of gears, magnetic clutch and switching mechanism to provide for either opening or closing the contacts at the end of the time for which the device is set, being adjustable from a few seconds up to several minutes, and adaptable to many applications where a definite time adjustment is needed.

The Cutler-Hammer Manufacturing Company states that a complete line of control equipment for various sizes of Fynn-Weichsel, alternating-current motors (made by the Wagner Electric Corporation, St. Louis, Mo.) was brought out in 1924. For the smaller sizes, the face-plate type with the operating handle arranged for manipulating from the exterior of the enclosing case is used. A drum type starter is employed with the larger motors incorporating in its design non-stubbing fingers, a square steel shaft for carrying the contact segments, and blowout shields. In all of these starters the design takes care of simultaneously cutting out resistance in each of the two secondary windings found in this type of motor.

For the automatic control of motor-driven pumps, air compressors and the like, the General Electric Company has developed a new pressure governor for use in connection with automatic starters. This governor is of the Bourdon tube type, and can be used on any liquid or gas system which will not corrode the Bourdon tube. The equipment includes an "impulse" magnetically operated relay of a quick throwover type breaking its own operating circuit as soon as it functions.

Three, across-the-line, automatic starters have been placed on the market by the Sundh Electric Company of Newark, N. J., one having undervoltage release or undervoltage protection, the second in addition, having, inverse-time-limit overload thermal relay protection and the third being provided with inverse-time-limit overload relay protection. All these starters are manufactured in either the open or enclosed type, two-pole or three-pole, for motors up to and including 10 h. p., 220-440-550 volts.

Heretofore this company's principal activities have been more or less confined to furnishing control for large office buildings and pump concerns. This company now plans to enter the industrial market more intensively with the present line of equipment rounded out with the additions that have just been described.

Compensators. Two new automatic compensators have appeared on the market during the past year. One of these is a high-voltage compensator made by The Electric Controller & Manufacturing Company of Cleveland, Ohio. It is built for voltages of 2500 and below, is push-button operated and entirely automatic. With the exception of the overload panel, which is mounted on the top of the tank, the compensator is entirely submerged in oil and the tank is so designed that the compensator is said to be dustproof, weatherproof, vaporproof and fireproof. It may be installed either indoors or outdoors.

The power supply for the push-button circuit comes from an independent low-voltage circuit which is taken from a separate transformer so that there is no danger of the operator ever coming into contact with the high-voltage circuit. The compensator is so

designed that continuous torque is applied to the motor from the time the push-button is pressed until the motor has been brought up to speed.

A new automatic starting compensator for squirrel-cage induction motors, has been placed on the market by the General Electric Company. This motor starter is for remote control of constant-speed, two- or three-phase, squirrel-cage motors up to 600 volts and general applications driving lineshafting, pumps, compressors, blowers, conveyors and the like. With it, such equipment may from a distance be started or stopped by means of one or more small hand-operated push buttons or snap-switches located within convenient reach of the operator or automatically operated by a pressure governor, float switch, thermostat or similar arrangement.

Resistors. A ribbon-type resistor, wound on edge, has recently been developed by the Monitor Controller Company, Baltimore, Md., and is intended for service where cast-iron grids would otherwise be employed. It consists of a high-resistance alloy ribbon, wound on edge in helical form and mounted on a steel-reinforced, porcelain support which passes through the entire length of the unit, supporting and separating every convolution at two diametrically opposite points. This method of construction relieves the resistor ribbon from mechanical strain and permits of thorough ventilation. The maker states that the ribbon will operate at any temperature up to red heat without sagging or in any way injuring the resistor as a whole.

A system of terminals and taps enables a unit to be connected into a circuit, and to be interconnected with other units. Two simple forms of clamps provide all these facilities. These clamps may be placed at any desired point along the resistor and changed at will. This permits of accurate adjustment of the resistance steps. The maker reports that a saving of weight and space is obtained by the use of these resistors as compared to cast-iron resistors. These resistors are shown in an accompanying illustration.

The *EMB* grid resistor, manufactured abroad, is being introduced by the C. H. McCullough Engineering Company, of Pittsburgh, Pa. This resistor is made of drawn material and in one continuous length for an amount equal to one frame, or bank. The maker states that it is unbreakable, rustless, scaleless, of uniform section, jointless in the frame and is covered by a five-year guarantee. He also states that the weight of same is less than that of cast-iron grids of equal rating.

Safety Switches. A new, small safety switch has been placed on the market by The Trumbull Electric Manufacturing Company, of Plainville, Conn. This switch is now made in the 100-ampere, 250-volt size and will shortly be made in the 440- and 550-volt size. The maker reports that the switch is characterized by its small size, yet the parts are accessible since the switch may easily be removed from the box. The switch is constructed on the double-break principle, the blades being carried on a rotor made of molded material.

A new line of quick-make, quick-break, enclosed safety switches has recently been put on the market by the Westinghouse Electric & Manufacturing Company. This line was designed to meet the demand for a simplified enclosed switch without the full safety features.

This switch, known as the WK-60 switch, is unique in that the quick operating mechanism has been condensed into a few simplified parts, located inside the operating handle. The maker states that this feature alone is a marked advance in the design of safety switches, since it lends greater reliability, lesser maintenance cost, and at the same time, increases the ease of plant operation with regard to inspection testing and the making of repairs.

A new "Lumenized" finish has been added to the line of Bull Dog safety switches made by the Mutual Electric & Machine Company of Detroit, Mich. The company states that this finish involves the depositing of aluminum flakes, like tiny fish scales, upon the basic metal under high temperature. It is said that the result is giving the switch the following qualities: making it luminous in the dark; rust, acids, and alkalies resisting; easily grounded; and the last word in cleanliness.

A new type of cross-bar construction has been incorporated in safety switches made by the Square D Company of Detroit, Mich. A steel bar is heavily insulated with molded composition tubes, possessing not only superior mechanical strength but greater dielectric strength as well. This construction has an extremely low absorption of moisture, which is said to prevent warping and the consequent distortion of blade alinement. Wide fiber washers have been provided to prevent accumulation or adherence of dust, breaking up any continuous path of dust to ground. The insulating tubes have an offset at the ends so that dust cannot work in under the washers, thus causing leakage.

During the past year the Super-Safety Electric Company has developed a new design of safety switches of the larger sizes. Instead of the contacts being on the base of the cabinet, as is usual, they are placed on sides of the cabinet, thus leaving the base entirely clear. This constitutes the principal difference between the new switch and the more usual types of safety switches.

The maker reports that this type of construction results in the following advantages; greatly increased wiring space within the switch with, at the same time, a reduction in overall dimensions; double break—a break on each side of the fuse; greater flashover distance between polarities; and perfect and even contact between all contact members by reason of their tandem arrangement and their self-alining construction. This switch is shown in one of the accompanying illustrations.

Limit Switches. A new safety limit stop has been developed by The Morgan Engineering Company, Alliance, Ohio. This device consists of a cast-iron box in which are mounted two double-throw, single-pole switches. These two switches, when actuated by contact with the hook block, cause the limit switch to function. The maker states that this limit switch

differs from others in that a resistance is thrown in series with the armature as the limit switch starts to function, thereby slowing down the armature and greatly reducing the amount of current broken by the contactors. Complete stopping of the hoist motor is accomplished by an usual arrangement of dynamic braking. The maker also points out that another feature of this limit switch is that the lowering circuits are established immediately upon the reversal of the controller through the action of a solenoid; there is no waiting to lower through resistance. Other features cited by the manufacturer are: absence of external banks of resistance, for the limit switch is self contained; positive action, since an upward movement of the weight of even a fraction of an inch will actuate the limit stop; foolproof, having only one adjustment; the use of extra large copper to carbon contactors; having only one swinging weight, guided by one of the hoisting ropes; and sequence of operation of the contactors obtained by a single system of levers, with no cams, springs or counterweights.

The Cutler-Hammer Manufacturing Company of Milwaukee, Wis., reports a new development in safety limit stops which is said to be a compact, rugged unit with a number of features of great importance in the functioning of a safety device. The working parts are liberally designed and arranged to move freely, this ease of operation being still further insured by the provision of ball bearings.

Miscellaneous. A new quick-acting, electric, solenoid brake has been developed by the Whiting Corporation of Harvey, Ill. This brake was especially designed for application to crane service.

The maker points out that the brake arms are so pivoted that the shoes release equally at all points; leaving no chance for shoes to drag at the lower ends. This is said to be a great advantage in applying the brake as the shoes bear equally at all points, resulting in quick braking action as well as uniform wear.

Nichols-Lintern Company of Cleveland, Ohio, reports improvements in its electromagnetic sander. An electrically-heated chamber has been placed around the sand box, thus keeping the sand warm and dry, thereby greatly increasing the efficiency of the sander. These sanders are intended to replace dangerous and wasteful hand sanding methods and are said to save crane and runway maintenance.

The use of static condensers for power-factor correction in industrial plants has increased considerably. The Westinghouse Electric & Manufacturing Company reports that it has developed a new low-voltage unit which may be connected at the motor or place where the power is used, thereby reducing the line losses in the feeder circuits. This new line of low-voltage condensers is made for 220-, 440-, and 550-volt, 60-cycle service.

The National Electric Condenser Company of New Haven, Conn., is also putting out a line of low-voltage condensers for direct connection at the motor terminals.

Automatic Substations. The automatic station has become firmly established as an economic, operating necessity in the electrical industry. With its inherent advantages established beyond dispute a marked advance in the application of this type of control was made during 1924.

There were no radical changes in the design of automatic switching equipments. The tendency during 1924 was to produce unit equipment which might be easily handled and installed, standardizing wherever possible. The General Electric Company reports the progress of standardization to such an extent that complete automatic stations for mining and industrial service are now being stocked.

To meet the requirements for this class of service, the company states that one type of standardized design is so arranged that a single machine automatic control equipment may be used in either single- or multiple-unit stations with any number of reclosing feeders, thus giving maximum flexibility, since it allows of arranging converting units in any manner desired with a possibility of later re-arranging if called for by a change in load conditions. This may then be accomplished without modifications of the control.

Theater Dimmers. A combination stage dimmer and switchboard termed "Controlite" has recently been developed by the Ward Leonard Electric Company. A quick make and quick break switch opens the circuit after the lights are dimmed. This simplifies the control of the lights by reducing the number of movements which the operator has to make. It has previously been considered good practise to dim the lights with one lever and reach elsewhere on the switchboard to open the switch.

Space on the stage is limited and the control handles have frequently been placed eight and nine feet from the floor. *Controlite* by its simplification makes it possible to place all operating handles within easy reach of the operator.

Motor Driven Dimmers. There has been an increasing demand by the trade for motor-driven remote controlled dimmers to control the lights in the auditoriums of moving picture theaters, churches and masonic halls. The Ward Leonard Electric Company has developed several very efficient types of motor drive for their dimmers.

Control Equipment

A new line of motor and generator field rheostats has been completed by the Ward Leonard Electric Company. The smaller sizes are of the Vitrohm (vitreous enameled) type and the larger capacities are of the "Ribohm" (stamped metal grid type). Due to new developments in the art of enameled rheostat construction, the Vitrohm plates are made of stamped steel, instead of being of the former cast-iron construction. Many advantages are claimed as a result of this change.

This company has also recently placed a dead-front

type sectional battery charging panel on the market. It is especially adapted for charging electric vehicle batteries. The special features are compactness, ease of operation, and the total enclosure of all live parts. A unique design of enclosing cover renders all operating parts readily accessible when necessary.

The Ward Leonard Electric Company has also produced a line of totally enclosed contactor type motor starters which are unique in that the resistors form part of the enclosing case but are arranged so that all heat radiation takes place outside of the enclosure.

Electricity's Progress in the Iron and Steel Industry

By Committee on Applications to Iron and Steel Production[1]

AT the first meeting of this Committee held in the Schenley Hotel, Pittsburgh, Pennsylvania, September 17, 1924, every member being present, it was agreed that the Annual Report for 1924-25 should be a topical consideration of progress during the current year, and the field was duly apportioned to the several members of the Committee.

One of the papers secured by the Committee and deserving of special mention in this Report is that, prepared and presented by Mr. K. A. Pauly before the Annual Convention at Pasadena, California, September 1924, entitled "Contributions of Electricity to the Steel Industry."

1. Annual Report of Committee on Applications to Iron and Steel Production.

F. B. Crosby, Chairman
E. Gordon Fox, E. S. Jefferies, G. E. Stoltz,
Eugene Friedlaender, D. M. Petty, J. D. Wright.
A. G. Pierce,

Presented at the A. I. E. E. Annual Convention, Saratoga Springs, N. Y., June 24, 1925.

It was also agreed that each member of this Committee should actively interest himself in arranging for one or more joint meetings of the Local Sections of the A. I. E. E. and the Association of Iron and Steel Electrical Engineers (A. I. & S. E. E.).

Although many members of this latter organization are also members of the A. I. E. E., your Committee was of the opinion that closer cooperation and unity of interests might be brought about by the formation on the part of the Association of Iron and Steel Electrical Engineers of a committee empowered to act directly with your Committee in all matters relating to the mutual interests of the two organizations.

This matter was brought to the attention of your Board of Directors, who, on September 26, 1924—

VOTED: That the Board of Directors recognizes the importance of the work being carried on by the Association of Iron and Steel Electrical Engineers in the industry with which it is associated, and appreciates the desirability of closer cooperation between the Institute and the A. I. & S. E. E., and requests its

Committee on Applications to Iron and Steel Production to consider and report to the Board methods of cooperation between the two organizations and means of bringing it about.

This action on the part of the Directors was duly transmitted by this Committee to the Board of Directors of the A. I. & S. E. E., who, through an incomplete appreciation of the objects in view, at first rejected this suggestion. Further consideration, however, has resulted in the consent of the Directors of the A. I. & S. E. E. to give the proposition more thorough study before taking final action.

Every twelve month period shows the steady and truly remarkable, if not always spectacular, increase in the application of electricity in the manufacture of steel. The current year of 1924-25 has been no exception. Generally speaking, however, the growth has been along lines already well defined and presents little that is fundamentally new or novel.

I. Generating Units

The Steam turbine continues to hold first place as a prime mover in the steel plant. That there has been a substantial increase in the generating capacity of steel-mill power plants is evident from the fact that one manufacturer reports the sale during this past year of fourteen units ranging from 750 to 15,000 kw. and aggregating 111,000 kw.

It is an open question, however, as to whether the greater economies which are being sought throughout the industry may not, together with improved design of engines and gas cleaning equipment, bring the slow speed gas engine back into favor. The economic value of blast furnace gas is increasing, due to its successful use in various metallurgical processes, soaking pits, heating furnaces, etc. This increasing value will automatically necessitate its use at the highest possible efficiency and as a given quantity of gas can be converted into more kw-hrs. of electrical energy through a gas engine than when burned under a boiler, the return of the gas engine, in spite of its present high first cost and maintenance charges, is a possibility.

Very satisfactory progress is being made in the development and use of Diesel Engine units up to 5000-kw. capacity.

II. Distribution

No marked improvements in distribution have been reported, but the use of purchased power has rapidly increased as the size and reliability of commercial power systems has increased. Largely for this reason, 60-cycle current now predominates.

Automatically controlled railway and power substations have been in successful operation for several years, and during the past year there have been installed several such equipments in steel plants. One large steel plant has changed over all of its manual stations, involving five motor-generator sets and a large number of a-c. and d-c. feeders, to full automatic control. At another plant a full automatic substation has been installed to control two 1000-kw. motor-generator sets and all a-c. and d-c. feeders. A third plant has installed three equipments for the operation of motor-generator sets and feeders. This increase in the use of automatic substation control has been due primarily to the extreme reliability of operation, together with the operating saving that can be shown, as compared with manual control, to take place where power is used, thereby reducing the line losses in the feeder circuits.

III. Main-Roll Drives

To an even greater extent than usual, this past year has been marked by a replacement of existing engine drives by modern electrical equipment. The sturdy induction motor still meets, in some one of its several forms, most requirements for main roll drives, except for reversing mill duty where, of course, nothing is likely to replace the d-c. machine with generator field control.

The growing demand for high tonnage mills with great flexibility in range of product is, however, requiring more and more adjustable speed, d-c. motors and this in turn is giving more importance to the relative merits of motor-generators, rotaries and mercury-arc rectifiers as a means of transforming from alternating to direct current. For certain types of mills the synchronous motor is being considered very favorably, although no installations of importance have as yet been made.

The following tabulation includes only main-roll motors on a continuous rated basis in units above 300 h. p. as reported by the three principal electrical manufacturers in this country up to June 1, 1925.

	1923	1924	1925
60 cycle	452840	478390	543440
25 cycle	475825	490225	538450
Direct current	299670	324860	430610
Totals	1228335	1293475	1512500

It is interesting to note that out of 95,225 h. p. reported by one company as sold during the year units (13) totaling 23,750 h. p. or approximately 25 per cent of the total represents motors which have been purchased to replace existing steam engine drives.

For the operation of a continuous skelp mill there has been purchased a 7500-h. p. induction motor with Kraemer speed regulating set to adjust the speed of this motor from 250 to 134 rev. per min. This is the largest motor with Kraemer equipment that has ever been built.

Another manufacturer reports the construction of a 5000-h. p., 75/150-rev. per min. motor for reversing service built with a single armature and supplied at 700 volts from two generators in parallel forming a part of a three-unit set.

This is a distinct departure from the usual practise of having several armatures connected in series where

units of this size are involved. This motor replaces an engine on a 48 in. universal plate mill.

Other notable units reported by this manufacturer are:

2—3500 h. p.—50/120 r. p. m.—700 volt—reversing units
2—5000 h. p.—25/150 r. p. m.—700 volt—reversing units
1—5000 h. p.—50/120 r. p. m.—700 volt—reversing unit
4—7000 h. p.—50/120 r. p. m.—700 volt—reversing units
1—8000 h. p.—40/80 r. p. m.—700 volt—reversing unit

Physically, the 7000 h. p. motors are the largest single armature reversing motors yet built and the 8000 h. p. will be, when completed, approximately 50 per cent larger. This latter motor will drive a 54 in. blooming mill which is likewise the largest mill of the kind in this country.

Another notable installation is reported by the same manufacturer, namely, a tandem hot-strip mill driven by one 1500 h. p. induction motor and six individual adjustable speed d-c. motors with an aggregate rating of 10700 h. p. for the d-c. machines which are of the compensated type.

A strong and sturdy yet easily operated foot-master switch has been developed for the control of reversing mill motors. The use of a foot-operated master switch requires one less operator in the mill pulpit than with a hand-operated controller and some mills have also found that production is increased as the concentration of control to one man permits closer coordination of the various operations.

Two speed regulating equipments of the frequency converter type are being built for use with existing 600 h. p. motors.

Truck-type switching equipment is being used to a greatly increased extent in many mills. Less time is required for assembly in the field, greater safety is secured as live parts are better protected and shutdowns are fewer as a spare truck may be kept available to quickly replace a damaged one.

IV. Automatic Control

An interesting tendency in auxiliary mill-motor control is toward the use of time limit acceleration instead of current limit which has long been the accepted standard. In one system the time interval between the closing of successive accelerating contactors is secured by an ingenious application of the well-known principle that when a constant d-c. potential is applied to a circuit containing inductance, an appreciable time elapses before the current reaches its maximum value.

Another control system recently placed on the market secures the time element of acceleration by the delay in building up or down of a magnetic field; when the relay coil is short-circuited, a definite time is required for the flux to decrease to a point permitting the release of the relay armature. This armature is forced out by a spring of adjustable tension which, together with other features, gives a timing range of 0.2 to 2.0 seconds for the relay. Once adjusted, this timing remains constant under all operating conditions.

In one case where this control was substituted for a series-contactor control, the current peaks were reduced from nearly 800 amperes to a maximum of approximately 350 amperes. This reduction in current peaks is due to the fact that, with the series-contactor control, it is necessary to set the contactors to close at a relatively high value of current in order to take care of maximum load conditions which are encountered when a mill is first started. This adjustment usually is not changed after the mill has been limbered up, and as a result the motor and control are forced to handle all loads with the same effort as required for the maximum load. With a definite time control, the motor is forced to exert its maximum torque only when the load conditions demand it.

V. Yard Electrification

The search for the best all around system of yard transportation continues slowly because of the excessive investment charges. Installations now in operation for two years or more seem to have demonstrated conclusively that a third-rail system can be operated successfully in a steel-plant yard without excessive maintenance charges or danger to employees. The first cost is high—approximately one dollar ($1.00) per foot of trackage electrified.

The development of the Diesel Electric Locomotive for this purpose is proceeding very satisfactorily. When production permits reasonable first costs, its very attractive operating characteristics will undoubtedly bring it into general use in steel plants.

VI. Electric Heating

With the expiration of patents covering certain alloys of great value for use in resistor units, the development of annealing and heat-treating furnaces has received marked impetus. Furnaces of large capacity with temperatures of 1800-2000 deg. fahr. are being installed in considerable numbers.

Two electric furnaces for the continuous hardening, quenching and tempering of carbon-steel wire have been recently installed in wire mills. This process results in a higher quality of wire than when treated in a gas-fired furnace. A bright unoxidized surface on the wire is produced. These are the first electric furnaces to successfully do this work and have proven economically desirable as well as producing a more satisfactory product.

VII. Arc Welding

The use of arc welding as a means of repair of worn and broken parts in steel mills has shown a great increase within the past year. The savings effected by arc welding of a single worn or broken part in a number of cases more than paid for the first cost of the welding equipment. A number of steel plants are using the automatic arc-welding process for the building up of worn shafts and similar operations.

VIII. ELECTRIC FURNACES

Conditions in the development of "arc furnaces" for melting steel and iron have become fairly well standardzied, both as to installed kw. per ton, voltage between electrodes, etc. Continued investigation of the two-voltage system of operation, a high voltage for melting followed by a low voltage for refining, indicates that there is no deleterious effect on the product while there is a decided saving in the power and electrode consumption, together with the time required to make a heat.

In this field, there continues a steady, if slow, development of low frequency "induction furnaces" for making high grade steels and alloys, but the field of high frequency induction furnaces has witnessed one of the most interesting developments of recent years.

For many years it was thought that the high frequency induction furnace could not operate successfully in melting metals at frequencies lower than 5000 cycles. However, it has recently been demonstrated that frequencies approximating 500 cycles will melt metals on a commercial basis with very good efficiency. For instance, common brass has been melted starting with a hot crucible with power consumption of approximately 225 kw-hr. per short ton—and other metals in proportion.

The equipment is simple, consisting of a motor generator set taking power from standard power circuits and supplying approximately 500-kw. single-phase to the furnace. The furnace consists of a standard clay graphite crucible, as developed for steel melting, with heat insulating casing around which is placed an edge-wound copper strip coil. To the terminals of this coil is applied 900 or 1800 volts at 500 cycles, single phase; a capacitor unit being connected across the coil in order to bring the power factor up to approximately 100 per cent.

In view of this recent development, no definite data are available, but it is confidently expected that this condition will be changed in time for the next report.

Advances in Use of Electricity in Mines

By Committee on Applications to Mining Work[1]

THE work of this committee is, of necessity, limited very largely to the securing of papers from representative mining engineers.

During the year several such papers have been presented, including one by W. C. Adams of the Allen & Garcia Co., on "Coal Mine Electrification;" one by Shelton and Stoetzel on "Electric Shovels;" one by W. C. Clark of the Westinghouse Co. on "Application of Motors to Mine Locomotives;" and one by your Chairman, entitled "Electricity in Mines."

The subject of mining does not seem to particularly interest many A. I. E. E. members, and it was very difficult to draw out a good discussion on any of these papers. The reason for this, the author believes, is more or less obvious and is due, at least in part, to the fact that the mining profession in general feels that the A. I. E. E. as a body is not particularly interested in its problems. The Chairman is convinced that the only way to stimulate interest at a mining meeting and possibly break down this impression, is by holding the mining session in conjunction with some local mining society. If this is done, it seems certain that the members of the mining society will turn out and will be glad to cooperate and participate in the discussion of such points of interest as may arise.

There seems to be very little constructive work for the committee on mine applications. This field has been very well covered by other organizations; thus it would seem that the only work left for this committee is to keep constant watch on the development and assist, whenever possible, in the improvement of mine electrification.

During the year there has been no outstanding and novel development in the application of electricity to mining projects, but, on the other hand, there has been a steady and healthy growth of this application. Larger projects have been undertaken and put through to a successful finish than ever before. One notable instance is the five-mile belt conveyor underground at the Colonial Mine of the H. C. Frick Coke Co. Here we have coal transmitted on a belt conveyer from the mine face to the docks, a distance of approximately five miles, on twenty sections of conveyer at a speed of 450 to 500 ft. per minute. This conveyer has a potential capacity of some 10,000 tons per day. It has been in operation for some considerable time and can be stamped as entirely successful.

Another notable installation is that of the largest coal mine hoist in the world; namely, the 4000-h. p. Ward-Leonard coal mine hoist which operates in the Orient No. 2 Mine of the Chicago, Wilmington & Franklin Coal Co.

The Old Ben Coal Co. has purchased three 2200-h. p. coal mine hoists, two of which are in operation, the third to be installed shortly.

From a business standpoint, the bituminous mining industry finds itself today in a very unfortunate condition.

---

1. Annual Report of Committee on Applications to Mining Work.

F. L. Stone, Chairman,
R. T. Andrea, C. N. Beebe, M. C. Benedict, Graham Bright, H. W. Eales, L. C. Ilsley, G. M. Kennedy, R. L. Kingsland, A. B. Kiser, John A. Malady, D. C. McKeehan, W. F. Schwedes, W. A. Thomas, C. D. Woodward.

Presented at the A. I. E. E. Annual Convention, Saratoga Springs, N. Y. June 24, 1925.

The majority of coal operators feel that cheaper production of their product will help matters to a considerable extent. The author believes the actual savings that result from complete electrification are not fully appreciated by all operators. Reliable records show savings as high as 25 cents per ton, resulting from change-over from steam to electricity in the same mine. Further, the stand-by losses when mines are electrified are very greatly reduced, so that shut-downs and idle periods are not such serious matters from a cost standpoint with electrified mines as they are with steam-driven mines.

The electrification of coal-loading machinery is receiving a great deal of attention from the manufacturing engineers as well as from the coal mine operators. There is no other practical method of drive for these machines, and, like the majority of mine applications, improper motors have been applied on early machines with the usual result.

There is still a great deal of work to be done of an educational nature so far as the mine operator is concerned. The motors required for his work should be, almost invariably, of a special design, laid out to meet mining conditions. Standard industrial motors are very rarely applicable to this class of work, and their application usually ends in delays and dissatisfaction.

In conclusion, it is suggested that something might be accomplished by the formation of a joint committee on Application of Apparatus to Mines; this committee being made up of the chairmen of the various committees at work on this subject in other societies such as the American Institute of Mining and Metallurgical Engineers, the American Mining Congress and the United States Bureau of Mines; these gentlemen meeting with the chairman of the committee on "Application of Electricity to Mines" of the American Institute of Electrical Engineers; this latter body possibly acting as sponsor for such a committee. Such a committee could review the work already done along this line and suggest changes or give its approval.

The most outstanding work along this line has been done by the committee on Underground Transmission and the committee on Power Equipment of the American Mining Congress. These committees, working jointly, have prepared a set of rules and suggestions for the installation and care of electrical apparatus in and around mines. These rules and suggestions are, at the present time, before the American Engineering Standards Committee for its approval. A committee made up of the personnel suggested above might go over these rules and suggestions in a constructive manner, and, if their approval is received, would undoubtedly help the mining industry to some extent at least.

Rules and Personnel Problems of the Marine Field

By Committee on Applications to Marine Work[1]

It is believed that the report of the Committee on Application to Marine Work for this year may be said to be the most comprehensive of any similar reports for the past few years.

The main proposition on hand for this year was the revision of the existing Marine Rules. These rules were issued about five years ago, and at that time were more or less of a tentative draft, and had become somewhat outlawed by changes in the art. Due to the fact that the Sectional Committee of the American Engineering Standards Committee did not seem to be functioning with sufficient rapidity to insure a recognized standard within the near future, the Marine Committee voted last Fall to re-edit and publish a revised set of Marine Rules, and for the past year, practically all of the time of the Committee and Subcommittees has been devoted to this line.

In the above connection, exceptional credit must be given to last year's Chairman and the Chairmen of the other Subcommittees for their untiring efforts and cooperation to bring about the desired results.

Among a few of the details which have been under consideration, and in some cases accomplished, may be mentioned the following:

a. A member of our Committee has been appointed to represent the A. I. E. E. on the Marine Standards Committee.

b. The 1923 proceedings of the National Fire & Protective Association adopted the Marine Rules in so far as they applied to insurance.

c. The British Consul requested the Committee's advice in regard to using magnetic cranes in shipyards.

d. A member of this Committee addressed the Boston Section in March, on the subject of the Mer-

chant Marine, especially covering the point of responsibility of electrical operators, and the failure of the U. S. Steamboat Inspection Service to recognize its responsibilities.

e. In the report of the meeting of November 1924, was included an item of Publicity, giving a bibliograph of recent data which had been published in various magazines, as applying to Marine Electrical Industry.

It is believed that an extension of this service by the Institute would be a desirable undertaking, (possibly in cooperation with Mechanical Engineers) in connection with the Engineering Index. We understand that this matter is now under consideration, and the Committee most heartily endorses the proposition.

The most important work of the Marine Committee of this year is contained in the conference held on Thursday morning at the St. Louis Convention, at which session there were three articles presented: one covering the History of Electrical Application to Marine Work up to date; another, the Application of Electrical Propulsion; and a third, covering Merchant Installations and Electrical Operators, with special reference to the licensing of electrical engineers.

It is believed that a survey of these three articles may be considered as a very definite progressive report of the work of this Committee for the year, and suggestion is made that all interested might peruse these three articles to advantage.

In connection with the suggested work of next year, the recommendation would be, if possible, to develop an inspection to include electrical devices for marine use. Also, possibly, to extend the scope of the Committee to include certain branches of manufacturing as are not already included within the scope of our Marine Rules, such as Instruments, etc. Also, there will no doubt develop certain phases of the present rules that will need further revision, and the development of rules as suitably applying to electric propulsion.

Progress in Diverse Lines of Electrochemistry and Electrometallurgy

By Committee on Electrochemistry and Electrometallurgy*

TWO papers on electrochemical subjects have been presented at meetings of the Institute by members of this Committee. The first of these entitled "Electrometallurgical Applications" by J. L. McK. Yardley was presented at the Pacific Coast Convention in October 1924. This paper dealt with developments in the utilization of electrical power based upon fundamental principles of electrochemistry and the relation of the electrical engineer to the chemist and metallurgist. The second paper, by G. W. Vinal and G. N. Schramm, was entitled "Storage Battery Electrolytes." This was presented at the A. I. E. E. Midwinter Convention, February 1925. Measurements to determine the effect of a wide variety of impurities in the electrolyte were summarized and a proposed specification for using sulphuric acid in storage batteries presented for discussion.

The Committee has suggested to the Standards Committee the desirability of revising and extending the section on storage batteries in the Standards of the Institute. The section on the method of rating storage batteries is not entirely clear at the present time. Serious difficulties in the industry have recently arisen in the matter of rating the various sizes and kinds of storage batteries for use on automobiles and for radio purposes. However, the point to be considered, does not relate to the rating of particular types of batteries, but rather to the general principles for rating batteries and to clearer indication of how time and current ratings may be used. Revision of the definition of the word "charge" has been suggested as well as the possible addition of specifications for the purity of the solutions. The Standards Committee has acted favorably on these suggestions and the appointment of a working committee to include a wide range of those interested in the subject of storage batteries has been authorized. Mr. Vinal has been chosen chairman of this working committee.

A request for information on the physiological effects of electric currents, addressed to the Institute, has been referred to this Committee. In response to this inquiry a short bibliography on the subject has been prepared. This bibliography does not contain references to the therapeutical or strictly medical aspects of the subject nor to electrocardiographs. Since information on this subject does not seem to be readily available elsewhere and as it may be of interest to others, the bibliography is appended hereto.

The field of electrochemistry and electrometallurgy is so diverse, including as it does such contrasting subjects as potential measurements and electric furnaces; electro-plating and storage batteries; electrolytic rectifiers and the production of materials, that it is difficult to define its boundaries or to estimate the relative importance of achievements in the various lines of

activity. Fortunately for the electrical engineer, interested in electrochemistry and electrometallurgy, there are available several up-to-date lists of titles of publications covering the entire field. These are found in both the monthly *Bulletin* of the American Electrochemical Society and the monthly issues of *Mining and Metallurgy*. These lists are generally more up-to-date than the abstract journals.

It is inevitable that no two summaries of the progress of the art in any particular field can be alike because of the limitations of individual knowledge and the trend of personal opinions. The following resumé, for which the Chairman of the Committee is largely responsible, aims to present very briefly significant points about the recent developments within the field of electrochemistry and electrometallurgy.

The rapid growth of the automobile industry and the still more recent development of radio have resulted in a great expansion of the storage-battery industry. The vexed question of how to rate storage batteries of certain types is still being discussed. Radio batteries are marketed as having a certain number of ampere-hours capacity, but no standard method of rating them has been adopted. One of the most notable, but less conspicuous achievements, has been the production of thin plate batteries for airplane service. Plates of 0.050 inch which would have been thought impossible not long ago are now in use. Contrasting the output of these batteries with the familiar automobile battery it is found that the capacity per pound has been increased from 50 to 75 per cent in spite of the handicap imposed in making them nonspillable. The life of the plates is from 50 to 100 cycles which together with the cost, limits their use to certain kinds of service. Our knowledge of the low temperature characteristics of these batteries has been extended.

Primary batteries especially dry cells have experienced notable developments chiefly as a result of the interest in radio. The production of dry cells which runs into the hundreds of millions per year has been accompanied by a general improvement in the quality. The establishment of Standards of Performance and the Specification of Tests have been instrumental in making this advance. The quality of well established brands has been improved, and by comparing records of performance of 1918 with 1920 and 1924, it is found that there are more manufacturers today whose cells comply with the government requirements than in 1920 when the requirements were not as severe. The American Engineering Standards Committee has asked the Bureau of Standards to act as sponsor for a representative sectional committee to undertake the standardization of dry cells and batteries. This committee is now being formed.

Further development of electric furnaces involves the important question of improving the refractories. A symposium on the subject of refractories was held by the American Electrochemical Society at its Spring Meeting in Philadelphia last year. During the slump after the War, there was some question as to whether electric melting of steel and brass would continue to increase at its former rate when conditions were again normal. The rate of increase now indicates that the "saturation" point is still far from being reached. Experiments have been reported that show a saving for the electric melting of brass over coke-fired pit furnaces. Improvements in automatic electrode control devices have been made. In the low-temperature furnace work and ovens for enameling, the adverse effect has been felt of certain recently developed auto finishes.

High frequency induction furnaces are finding increased use for laboratory and experimental purposes and also for small scale production. The larger sizes are now operated on high frequency generators which have replaced the oscillatory spark gap. The smaller units may be operated by electron tubes, obviating the risk of escaping mercury vapor. It is expected that applications to large scale uses will ultimately be made.

Ring-type horizontal induction furnaces of six tons capacity and 800 kw. are now in use.

From the standpoint of the electrical engineer the fertilizer industry represents an outlet for electrical energy that is dependent upon the demand for more concentrated fertilizers. Phosphoric acid is now made in the electric furnace. The development of processes for the fixation of nitrogen has indicated a trend toward decreased power requirements per unit of nitrogen. The arc process which was first developed involved a large power consumption. The cyanamid process, next in order of time, required only one fourth as much and more recently has come the synthetic ammonia process requiring only one sixteenth the power (without electrolytic hydrogen) of the arc process. But in this last case it is evident that the electrical power requirements will depend very largely upon how successfully the electrolytic production of hydrogen can compete with more strictly chemical methods. Electrolytic hydrogen is produced directly in a high state of purity which makes it well suited to the purpose. At the September meeting of the American Electrochemical Society to be held in Chattanooga there will be a symposium on the relation of the electrochemical industry to the production of fertilizers. This is to include papers on phosphoric acid, the production of hydrogen and the fixation of nitrogen.

Production of the lighter metals by electrolysis of fused salts has been stimulated by the demand for light-weight materials of construction and by the radio industry. Aluminum and magnesium are perhaps the most important. Developments in the technique of the electrolytic production of aluminum have been made during the past year. The ability to produce aluminum of very high purity will doubtless have an effect on its uses within the field of the electrical engineer. Experiments on beryllium and calcium have also been mentioned. A symposium on fused electro-

lytes was held at the Niagara Falls meeting of the Electrochemical Society, April 23-25, 1925.

Improvements in the electrolytic production of other metals have been recorded and electrolytic tin has been added to the list of commercial products.

Three methods for the production of electrolytic iron were described at the World Power Conference. During the discussion it was stated that electrolytic iron was an assured commercial possibility, but that it would not become a serious competitor of ordinary iron for some time to come. About 28 per cent of the caustic soda produced in this country is made by the electrolytic process. New outlets for chlorine products are being sought by the newly established Chlorine Institute, Inc. which has been created by a group of manufacturers.

Electrolytic rectifiers have become a subject of renewed interest as a result of the phenomenal growth of the radio industry. Improved forms of both the aluminum and tantalum rectifiers have recently appeared. These are designed for the charging of small batteries for radio receiving sets and the latter has also been found useful by railroads for charging signal batteries. Our knowledge of output and efficiency of these rectifiers in relation to the impressed voltage and the battery voltage has been clarified and the operating characteristics materially improved.

A promising method for the study of the instantaneous values of electrode potentials has been developed by the use of a resistance coupled vacuum-tube amplifier in combination with the oscillograph. By means of this amplifier it is possible to obtain sufficient power to operate the oscillograph without polarization of the cell, and on the other hand with current flowing through the cell it is possible to distinguish between the electrode potential and the $I R$ drop.

Scientific methods are being extended in the field of electroplating. Results of research and much practical experience are gradually being welded into a comprehensive theory of electrodeposition. The structure of electrodeposited metals has been studied and new methods for the regulation of plating baths and hydrogen-ion control have been introduced. Electrolytically deposited coverings for the prevention of corrosion have recently been the object of much study. The use of zinc for this purpose is increasing. Nickel does not afford complete protection at the present time, but the technique of nickel plating is being improved. Experiments have also been made on chromium and cadium. Other preventives of corrosion include alternate layers of copper and nickel and the plating of alloy deposits such as brass, bronze and mercury-zinc.

Engineers are taking cognizance of the importance of the corrosion problem. The American Society of Testing Materials held a symposium on this subject in June 1924 and the American Electrochemical Society did likewise in October of the same year. More recently the American Chemical Society has taken the matter up and it is proposed to establish a corrosion institute. Whatever may be the outcome of conflicting opinions on the fundamental causes of corrosion, a theory for its prevention, involving both chemical and electrical agencies, will probably be ultimately agreed upon.

Use of the earth current meter during the past year has been gradually extended and there appears to be a general recognition that it affords a more accurate means for determining the rate of stray current corrosion than has been available heretofore. Its use is limited by the time and expense involved in making the excavations necessary for its use.

The recently published transactions of the first World Power Conference, London 1924 (Volume IV) contain papers on electrochemistry and electrometallurgy as follows:

The Austrian Electrochemical Industry, Paweck.

Small Waterpowers and Electrothermal and Electrochemical Loads, Bodex.

Nitrogen Fixation, Halvorsen.

A New Resistance Furnace with Reaction Zone, Holmgren.

Electrochemical Industry in Sweden, Palmaer.

Power in Electrochemical and Electrothermal Industries, Fitzgerald.

Electrical Engineering as a Leading Factor in the Development of Modern Steelworks, Geyer.

Electrolytic Iron, Hutchins.

Electrometallurgy in Italy, Giolitti.

Power in Electrometallurgy in the U. S., Mathewson.

The electrical engineer who is interested in electrochemistry as an outlet for power will find statistics of interest in several of these papers.

4. Polarization

Polarization of Living Human Body, Chanoz, *Comptes Rendus*, 147, p. 846, 1908.

Polarization of Electrodes which may be used for Electrophysiological Purposes. Gildemeister, *Zeit. Biol. Tech. Meth.*, 3, p. 28.

A Year's Progress in Lighting

By Committee on Production and Application of Light[1]

THE past year resembles the preceding one, in that the notable advances were those of better and more intensive application of available equipment and methods rather than of fundamental discoveries.

The really outstanding event of the year was a nation-wide campaign of education on home lighting. This activity was conducted by the entire electric lighting industry during the fall of 1924 and represented the most extensive cooperative movement ever undertaken by the electrical industry. Because of its noncommercial character it received widespread endorsement from school authorities, and culminated in an essay contest in which about one million high school pupils competed for valuable prizes.

It is safe to say that, as a result of this campaign, the American public has a better understanding of lighting, especially in the home, and is approaching such problems more intelligently.

1. Annual Report of Committee on Production and Application of Light.

G. H. Stickney, Chairman

W. T. Blackwell,	F. F. Fowle,	F. H. Murphy,
J. M. Bryant,	G. C. Hall,	Charles F. Scott,
W. T. Dempsey,	H. H. Higbie,	B. E. Shackelford,
H. W. Eales,	A. S. McAllister,	W. M. Skiff,
F. M. Feiker,	P. S. Millar,	C. J. Stahl.

Presented at the A. I. E. E. Annual Convention, Saratoga Springs, June 24, 1925.

In general, lighting has enjoyed a very healthful advance both in extent and quality of application. It has been a year of prosperity to the industry and of enhanced service to the people.

As pointed out in previous reports, the best numerical figures available to indicate the growth of lighting application are in the number of incandescent lamps consumed.

The large incandescent lamps represent the lighting of factories, stores, homes, streets, trains and similar places on circuits of electric service companies, electric and steam railways and other power plants. Of these large lamps, 263 million were sold in 1924, an increase of 7½ per cent over 1923.

The other major class is the miniature lamps of which about two-thirds are used on motor vehicles, one-sixth for flashlights and other small battery lamps, and one-sixth for Christmas trees and similar decorative purposes. Of this class about 188 million lamps were sold, or an increase of 8 per cent over 1923.

These figures are quite conservative, since they indicate only the number of lamps and are not weighted according to the size of lamps. Particularly in the large lamp group there is a tendency toward the use of higher power lamps. Had the measure been in terms of wattage capacity, the increase would presumably have been greater, or if in lumen capacity, still greater.

Such figures will soon be available and are desirable for certain kinds of comparison. The simple, numerical figure is, however, suitable for the present purpose.

Illuminants. Present-day illuminants are still far below the scientific ideals of efficiency, and considerable experimental investigation is underway. While favorable indications have been observed, no important practical improvements have been reported.

Frequent minor improvements have been made in incandescent lamps, but these have been mostly in the nature of refinements that do not receive prominent recognition by the users. That the improved manufacturing appliances mentioned in previous reports have brought results, is evidenced by the several reductions in lamp prices. It is also reported that the average quality of the lamps has improved during the year.

A general exposition of the advance of incandescent lamp quality since Mr. Edison's invention was given by J. W. Howell, in his address[2] (on receiving the Edison Medal) at the 1925 Midwinter Convention.

In last year's report mention was made of the tendency toward the use of the ring-shaped filament, that is, a helically coiled filament formed into an open ring. More recently there has been a tendency to warp the ring so as to give a higher horizontal component of light.

With the application of incandescent lamps to new uses, there is a constant tendency to multiply the number of special types, bases, and other features, which interfere with interchangeability, increase lamp costs, and often introduce confusion in the selection of lamps, as well as delay in securing them. Lamp Engineers are constantly studying means of simplifying and standardizing. The great advantage of standardization to light users is particularly evident to those familiar with conditions abroad where less progress has been made toward eliminating unnecessary variations.

Considerable experimental work has been done on diffusing finishes for lamp bulbs, with the view of effectively meeting the various demands of lighting practise. Some of these promise real improvement in the near future.

During the past year or two there has been an increase in accuracy of incandescent lamp manufacture, particularly in the focus types where small tolerance of light center length is important.

The automobile rear lamp has been raised from two to three candlepower and improved in efficiency. Experiments have been made with automobile headlight lamps, having two equal power filaments, to produce a suitable dipping of beam by switching from one filament to the other. Much experimental work has been carried on for the Government and others to adapt the incandescent lamp to the various requirements of night flying, and considerable improvement has been made during the year.

2. See A. I. E. E. Journal, March 1925, p. 310.

Candle Power Standard. A remarkable research extending over several years and reported in 1924, culminated in a proposal of a primary standard of candle power. All previous primary standards have been so subject to variation for one cause or another, as to be too inaccurate for standardizing purposes. In 1910, the United States Bureau of Standards cooperated with the English and French National Laboratories in establishing the international unit of candle power recorded in the construction of incandescent lamps. No other method compared with this for accuracy. The desirability of an absolute standard, which can be reproduced from specification and which will avoid any possibility of drift, is obvious. While it is too early to say absolutely that this has been accomplished, the indications are that it has. The standard device consists of a cylindrical platinum fuse with a longitudinal slit. This is supported by conductors at both ends and heated by an electric current. A certain section of the interior as viewed through the slit has been found to follow the "black body" law, and readings are taken with increasing temperature up to the point where the platinum melts, blowing the fuse. In other words, the method measures the light emitted by a black body at the melting point of platinum, a condition which has been regarded as most likely to give a suitable primary standard.

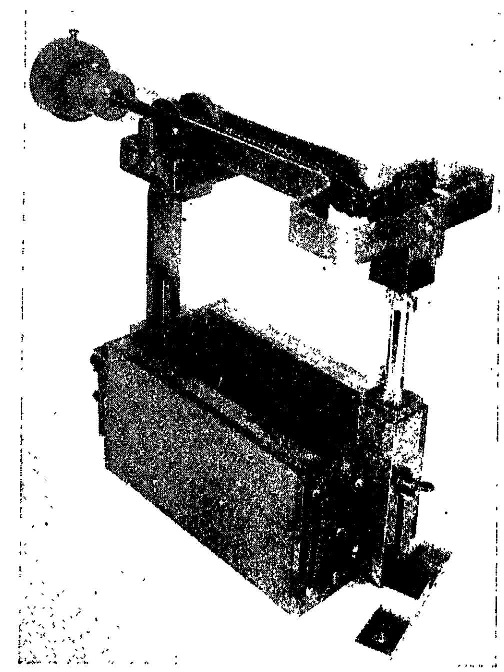

Fig. 1—New Primary Standard of Candle Power Proposed by Dr. H. E. Ives

Device for producing black body radiation at melting point of platinum showing slitted cylinder of platinum and support. (See text.)

Lighting Practise. No radically new devices have come out. The general tendencies recorded in last

year's report have continued. In commercial lighting, the shallow enclosing globe has seemed the most popular, although there has been a growing use of certain forms of indirect and semi-indirect units, especially in the highest grades of installations where accurate vision is important.

In the interest of eyesight conservation it is gratifying to note the continuing spread of appreciation of the need of good lighting in schools. This will no doubt be stimulated by the new American Engineering Standard Code of School Lighting. There is still a serious economic resistance, and it is still true that when daylight fails, the student is less adequately cared for than the office worker. Nevertheless the year has witnessed a large increase in the number of reasonably adequate installations.

Store window lighting has been a field of increased activity. The data referred to in last year's report have apparently been effective in convincing merchants of the sales value of light. Colored light and spot lights are being extensively used and are making the merchandise more interesting to look at. In the business sections, the practise of providing strong illumination in the daytime for the purpose of eliminating external reflections or rendering the displays more effective, has grown rapidly.

The advance in levels of window lighting is indicated by the fact that equipment manufacturers have found it desirable to develop and market reflectors for 300- and 500-watt lamps, whereas a year ago the reflector for 150-watt lamps was the largest in common use.

In industrial lighting the steel dome, because of its economy, coupled with moderate diffusion, is still the most common equipment, but in many processes a combination glass and steel unit, and the various forms of opal and prismatic globe equipments, are being preferred because of their greater diffusion. Illumination levels are still being raised. After a survey of the situation the electric lighting industry has concluded that the time is ripe for increased activity in the industrial field, and an extensive campaign is projected for the fall of 1925.

Home lighting is more essentially an artistic problem than an engineering problem. However, certain engineering and utilitarian features are deserving of more attention, and it is important that artistic considerations include the lighting effect as well as the design of the equipment. The trend of practise is toward better diffusion and more illumination, avoiding what has been aptly termed "glare and gloom."

The use of portable lamps is spreading rapidly, with an increasing use of those which direct considerable light to the ceiling, for redirection. Portable equipment has certain features of flexibility which permit the exercise of personal taste. It is also becoming quite common for housewives to make their own shades. While some of these are not particularly effective, they permit a rather free expression of personal taste and improvements may be expected through a better understanding of the possibilities. The best practise for general rooms usually requires a combination of fixed and portable equipment, and it is desirable that wiring should be planned to accommodate both types.

The kitchen lighting movement which was reported as very active last year has been less conspicuous, in contrast to the educational movement of 1925. Nevertheless it is probable that the number of improved installations in kitchens has continued to increase.

Electric Light Wiring. One of the problems confronting the engineers who are endeavoring to improve lighting practise is the tendency to stint in the wiring of buildings and fail to provide outlets in locations necessary to produce suitable illumination. In order to call attention to this question and encourage better provision, a so-called "Red Seal" campaign has been instituted under the direction of the Society for Electrical Development and installations complying with an accepted standard are indicated by a red seal.

FIG. 2—SIGN LIGHTING, SHOWING ONE OF THE WORLD'S LARGEST SIGNS ON BROADWAY, NEW YORK

The upper sign employs nearly 20,000 incandescent lamps.

The progress in the application of the elexit or disconnecting support for lighting units has been somewhat disappointing, in view of the inherent advantages of such a scheme. They are being found exceedingly useful in luminaire display rooms, and it is probable that such use will stimulate their application elsewhere.

Outdoor Lighting. Larger and better things are being done in sign lighting and the use of higher power lamps which was formerly confined to a few important centers, is becoming common in smaller cities and less central locations. To what an extent illuminated advertising is contributing to the illumination of metropolitan business districts can only be appreciated by visiting those sections at the very late hours when it has ceased to function. By contrast, the regular street lighting

seems surprisingly faint. One large sign installed in 1924 contained 19,000 lamp sockets.

Colored floodlighting, especially in connection with flashing effects, is finding considerable application, both for advertising signs and for buildings.

The trend is still toward the ornamental units and poles. Twin units have been used to some extent in white-way lighting, although these are usually less economical than the single higher power unit.

Recent statistics on the sale of series incandescent lamps indicate that over 60 per cent are of 1000 lumens or less. In the opinion of engineers who have made general analysis of street lighting costs this percentage is too high and better economic conditions would exist if larger lamps were being used. This is based on the principle that the cost of service increases much less rapidly than the volume of light. The tendency is in the right direction, but greater progress is desirable.

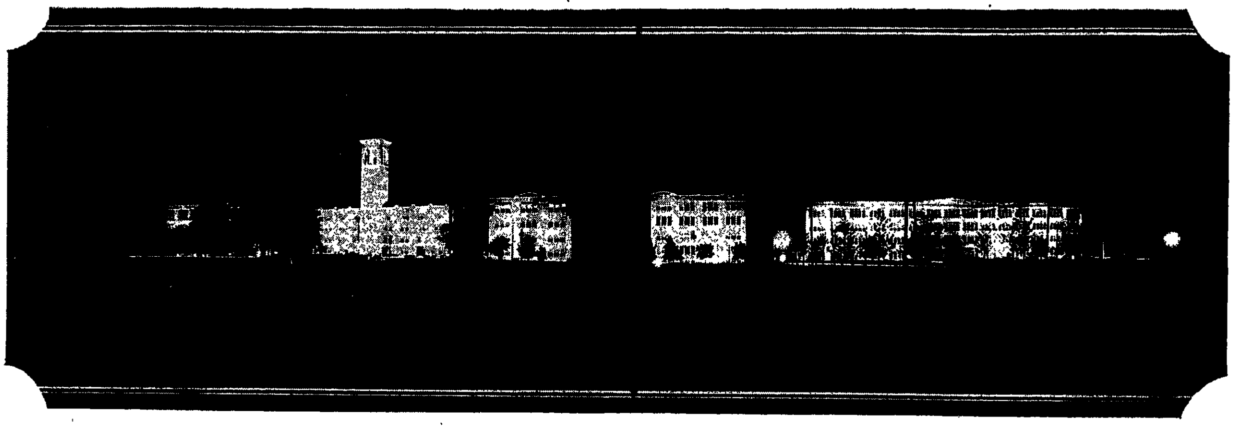

Fig. 3—Floodlighting for Publicity Purposes

A large playing card factory at Cincinnati has one of the largest of the recent installations. Eight 500-watt floodlights illumine the tower, twenty-four 1000-watt floodlights light the facades facing the camera, and eight more are projected on surfaces facing in another direction and therefore not shown.

Street Lighting. Street lighting has been quite active during the year. It is estimated that the new and replacing installations of 1924 required about fifteen per cent more equipment than those of 1923, which in itself had shown quite an advance. The vast majority of these installations utilize the gas-filled tungsten lamp.

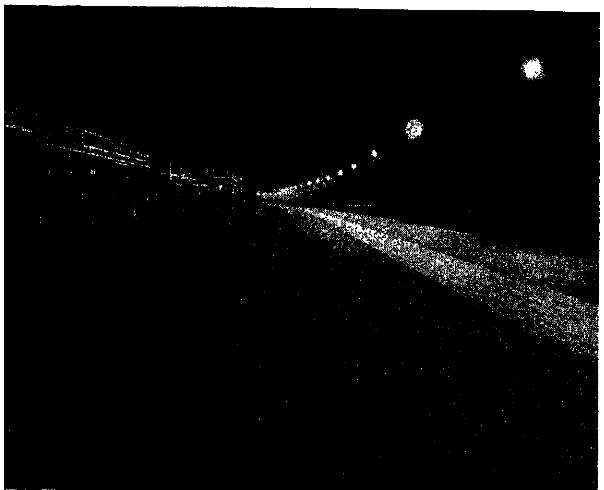

Fig. 4—The Boardwalk

Atlantic City has, in some sections, to be illuminated from one edge only. Specially devised ornamental units direct the larger portion of the light across the walk and still provide a lower illumination on the beach without shadows on the globes. Width of walk 60 ft., spacing of posts 70 ft., size of lamps 750-watt. Photo taken late at night after sign and show window lights were extinguished.

Each unit is arranged so that light from a 200-watt lamp symmetrically directed can be switched on.

There have been minor improvements in transforming and other accessory equipment, as well as a few improved designs of luminaires.

In residence and other secondary streets, the asymmetrical types of distribution seem to have proved their worth. Some discussion is still going on as to the merit of various characteristics of asymmetrical distribution, and it is probable that the next few years experience will bring out a better general understanding as to the types and degrees suited for different street lighting problems.

Asymmetrical lighting of highways, utilizing equipment designed to deliver the maximum illumination on the road surface is meeting with considerable success, and promises to provide the best solution for the problem of handling heavy night traffic on important roads.

Extensive experimental studies preliminary to establishing improved street lighting have been underway in a number of cities, notably Indianapolis, Indiana; Columbus, Ohio and St. Louis, Missouri. It is reported that the investigation in Indianapolis has led to a decision to install a new unified system through that city.

During the year, a cooperative study of urban street lighting was made by a committee appointed jointly by the New York State Conference of Mayors and other City Officials and the Empire State Gas and Electric Association. This committee has made a

constructive recommendation regarding practises to be followed and standards of lighting to be adopted for various classes of streets.

A general committee of the National Electric Light Association has been studying the problems of street lighting and is preparing a report which should be of considerable value.

Still other street lighting activities are underway, and studies by simultaneous comparison in demonstrations are being made. With the existing need and the widespread study of the various problems, it is probable that the next few years will witness a rapid advance in this field.

Traffic Signal Lighting. Closely associated with street lighting is the traffic signal lighting. This falls in two main classes.

The flashing traffic beacons which merely warn of an intersection, are placed at moderately congested points of cities, towns and interurban roads. Electric signals of this sort are being installed in considerable number.

The second group is the traffic control signals for controling the movement of traffic in congested districts. It has been found expedient to synchronize the various signals of each district, and to extend the system some distance beyond the points of traffic congestion. Not only does this sort of a system reduce accidents by speeding traffic, but it reduces the congestion, not to mention the convenience resulting to the motorist. A considerable number of such installations have been made during the past year and many others are projected.

FIG. 5—HIGHWAY LIGHTING—PLEASANTVILLE BOULEVARD, ATLANTIC CITY, ILLUMINATED WITH 2500 LUMEN (250 C. P.) LAMPS IN UNIT DESIGNED TO CONCENTRATE LIGHT ON ROADWAY

Units about 25 ft. high, spaced one for each 225 ft. of road, staggered. Central motor way, glossy surface, about 28 ft. wide, wagon way on each side about 15 ft. wide.

A notable example is that on Broadway, New York City, from Rector Street to 86th Street, a distance of six miles. This system contains a number of new and interesting features. It is arranged so as to avoid obstructing the roadway and requires only six police officers for its operations, where an earlier form would have required at least twenty-six. Moreover, these officers are on the street level and so quickly available for emergencies. A parallel system is about to be installed in Seventh Avenue.

Other Practises. Lighting practises in the operation of railroads are extending rapidly. While floodlighting of railway classification yards is not new, recent investigations have brought about a considerable extension of such lighting and a more definite crystallization of the practise. The Association of Railway Electrical Engineers is undertaking the preparation of a comprehensive manual of railroad lighting practises.

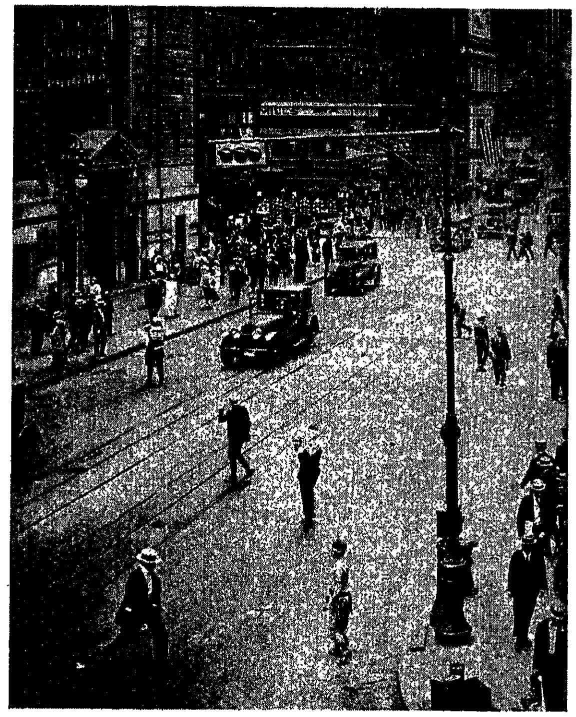

FIG. 6—TRAFFIC SIGNAL LIGHTING

New installation on Broadway, New York, showing arrangement for locating signals conspicuously over line of travel without obstructing traffic.

Electric lighting is contributing much to the facility and safety of surgical operations. Much better lighting is being provided in some of the leading operating rooms, and various small lamps are playing an important part in lighting internal organs. Although not new during the year, there appears to have been but little mention in engineering circles of an instrument for entering the stomach or lungs through the mouth. By the light of the smallest lamp made, it is possible to examine the walls of these organs, remove foreign matter, such as tacks or pins, and perform other operations in the saving of life.

In the newer applications of artificial light, such as night flying, plant growth control, the use of polarized light to study internal strains of structural forms, considerable progress has been made.

Education. Educational work has been carried on extensively. Besides a number of classes which have been operated by various organizations, notably the incandescent lamp manufacturers, an extensive course to train illuminating engineers for electric service companies was operated jointly by the Illuminating Engineering Society and the National Electric Light Association. This group of students came together in Chicago, visited South Bend, Detroit, Cleveland, Washington, New York and vicinity, Boston and Lynn. Lectures were given in Cleveland, New York and Harrison and representative illuminating engineering departments were visited and studied.

Another large lighting demonstration has been opened since the beginning of 1925 and in a number of European cities, demonstrations have been patterned after the American practise. The European activity in this field has no doubt been considerably stimulated by American engineers who have been abroad during the year, and several of whom presented important papers on lighting practise at the Geneva meeting of the International Commission on Illumination.

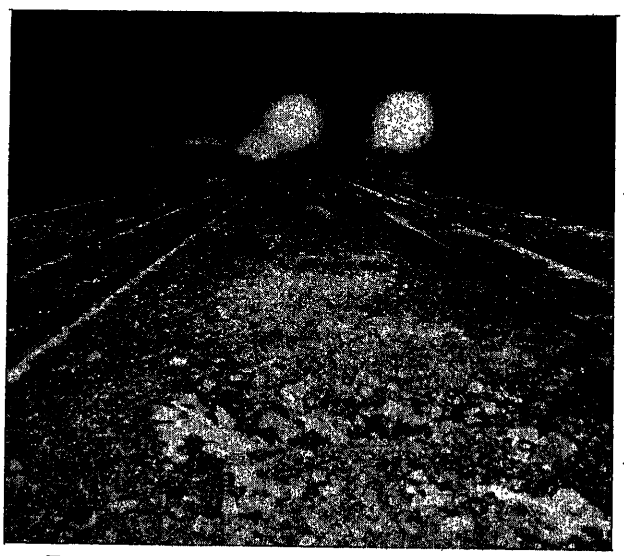

Fig. 7—Railway Classification Yard Lighting
An installation partly completed at Selkirk, N. Y. which employs nearly 100 floodlights, 1000 watts each, projecting light along the road in both directions.

At this meeting, the commission which has in the past centered its attention on standards, and highly technical phases, decided to place more emphasis on practise and applications. The 1927 meeting is scheduled to be held in the United States.

During 1924, the State of Washington adopted an industrial lighting code, making the tenth state to take such action. These ten states represent a population of about 42,000,000.

The revised School Lighting Code, initiated by the Illuminating Engineering Society, has become an American Engineering Standard under the joint sponsorship of the American Institute of Architects and the Illuminating Engineering Society.

Industrial Lighting Tests. It has been generally assumed that good illumination was warranted economically through its influence in speeding production. Data supporting this view has been accumulating for several years. The National Research Council is undertaking an extensive series of tests, which when completed should provide authoritative figures over a range of representative industries. The Council is undertaking to study the welfare aspect as well as the economic. Because of the extent of the problem as well as the thoroughness of the methods, the results are not expected to be available for at least another year.

Committee Activity

The Committee on Production and Application of Light is composed for the most part of members who are widely separated geographically.

This is suitable for the general work of the committee but precludes full attendance at meetings. As a result, after the original organization meeting each year, practically all business has been conducted by correspondence.

The organization meeting for the current year was held at A. I. E. E. headquarters, October 9, 1924, three members being in attendance. Because of this small attendance, the Chairman submitted the minutes to the entire committee for comment before considering the action final. No criticism was received.

The committee organization of last year was retained; Dr. B. E. Shackelford being detailed to solicit papers for conventions, Mr. W. M. Skiff being retained in charge of securing Illumination Items and fillers for the A. I. E. E. Journal and Mr. G. H. Stickney was asked to supervise the preparation of the Annual Report. It was decided to continue previous policies and plans.

Later in the year the question of representation on the Standards Committee came up and was handled by correspondence. Since the Chairman was already attending the meetings of that committee in another capacity, it was considered expedient that he represent this committee.

Illumination Items. Because of the relation of the Institute membership to the lighting art, this has seemed to provide the best method of presenting a larger part of the lighting material to the organization. Throughout the year, the Editor of the Journal has been kept supplied with items in advance of his requirements in ample quantity to fill all of the space which he deemed it expedient to devote to this subject.

Convention Papers. Considering the state of the art and the interests of the membership, the committee has not considered it expedient to place many papers on the convention programs. Two papers have been arranged for presentation at national conventions during the year, viz., "Street Lighting—A Municipal Problem," by Rich D. Whitney—Pacific Coast Convention, Pasadena, October, 1924, "Automotive Headlighting," by J. H. Hunt,—St. Louis Convention, April, 1925.

Preliminary arrangements are underway for securing several papers for future conventions. A paper had been arranged for the regional meeting at Cleveland, but has been held in abeyance since the withdrawal of this meeting.

Cooperation with Branches. No convenient means seems to be yet available for cooperating with Branches. The Chairman has been informally experimenting, not in the name of the Institute, with one university in the hope of arriving at a plan. A course of lectures was arranged and is now being carried out. At the termination of this course, it may be possible to draw some conclusion as to its effect. A subcommittee under the chairmanship of Professor H. H. Higbie has been studying the problem, and it is hoped that a report will be received in time to be of assistance to next year's committee.

Lighting Publicity. A system is in vogue whereby members of the committee reviewing original Illumination Items indicate other publications likely to be interested in the material, whereupon the Editor of the JOURNAL undertakes to furnish proof of article to the designated periodicals with release dates.

In conclusion, the Chairman wishes to acknowledge the cordiality which has been extended to him by the entire committee, and especially the active cooperation of those members who have assumed the specific tasks already mentioned.

Recent Advances in the Communication Art

By Committee on Communication[1]

THE name of this committee has been changed from "Telegraphy and Telephony Committee" to "Committee on Communication." This was done in accordance with a recommendation of the special committee who reviewed the technical activities of the Institute. The Communication Committee feels that this is a desirable change in name.

In this report, under appropriate headings, are briefly summarized the advances which have been made, or which have come into prominence in the communication art during the past year. Thirteen papers have been presented to the Institute under the auspices of this Committee. These papers are in general a record of advances in the art, and are mentioned under the appropriate headings in the report.

Telegraphy. The development of long telephone cables of 19 and 16-gage, capable of operating for distances of 1000 miles and more, has led to the development of telegraph systems suitable for operating through these cables. These telegraph systems, developed by the engineers of the Bell Telephone System, were described in three papers presented at the Midwinter Convention. The titles of these papers were "Metallic Polar Duplex Telegraph System for Long Small-Gage Cables," "Voice Frequency Carrier Telegraph Systems for Cables" and "Polarized Telegraph Relays."

The first paper describes a type of telegraph circuit, designed to operate over cable telephone wires at frequencies below the telephone range, and without interfering with the telephone circuits using these same wires. In this system it was necessary to reduce the telegraph operating currents to values comparable with those used in the telephone circuits in order to prevent interference with the telephone circuits by the telegraph circuits. One form of interference which has thus been avoided is called the "flutter effect" and is caused by the telegraph currents affecting the magnetic characteristics of the loading coils in the telephone circuit, so as to cause a rapid fluctuation of received current. This telegraph system is on a balanced two-wire basis in order to diminish cross-fire between telegraph currents and the effect of any currents induced in the cable.

The second paper describes a carrier type of telegraph system which makes use of a regular four-wire long distance cable circuit. No telephoning is carried on over the circuit when employed for the telegraph system, but the frequencies which are ordinarily involved in a telephone conversation are used to transmit ten telegraph messages in each direction. A separate frequency is employed for each message spaced in the frequency range from about 400 to 2000 cycles. No change is required in the telephone circuit except at its terminals.

These telegraph systems required the development of very sensitive and reliable relays which are described in the third paper noted.

Submarine Telegraphy. The Western Union Telegraph Company has put into service its new permalloy loaded submarine telegraph cable between New York and the Azores Islands. This type of cable, developed by the Western Electric Company, was described in last year's report. It represents the most radical change in the submarine cable art since its earliest days.

1. Annual Report of Committee on Communication.

O. B. Blackwell, Chairman

F. L. Baer,	Sergius P. Grace,	F. A. Raymond,
H. P. Charlesworth,	P. J. Howe,	Chester W. Rice,
L. W. Chubb,	F. H. Kroger,	J. K. Roosevelt,
C. E. Davies,	N. M. Lash,	Edgar Russel,
H. W. Drake,	Ray H. Manson,	H. A. Shepard,
R. D. Evans,	G. W. McRae,	E. B. Tuttle,
L. F. Fuller,	R. D. Parker,	F. A. Wolff,
D. H. Gage,	H. S. Phelps,	C. A. Wright,

Presented at the A. I. E. E. Annual Convention, Saratoga Springs, N. Y., June 24, 1925.

The finished cable has fully met the expectations stated in the last report, and has so well established the success of this type of cable that the Western Union has ordered a second loaded cable to be laid between New York and Penzance, England, by way of Newfoundland. A paper describing the development of this type of cable will be presented at this convention.

During the year 1924, the Western Union Telegraph Company developed a printing telegraph system for use on ocean cables. It has been in commercial operation on a transatlantic cable circuit between London and New York. In this system, signals sent from a transmitter at London are translated and printed in Roman characters at New York without manual handling at any of the intermediate repeater stations.

The initial circuit consists of an underground pair between London and Penzance, England, 312 miles; ocean cable, Penzance to Valentia, Ireland, 307 nautical miles; ocean cable, Valentia to Heart's Content, Newfoundland, 1874 nautical miles; Heart's Content to North Sydney, Nova Scotia, 335 nautical miles; overhead land-line North Sydney to New York, 1110 miles; or a total of approximately 3900 miles. Regenerative automatic repeaters which regenerate the signaling impulses as to strength, shape and time are used at Penzance, Valentia, Heart's Content and North Sydney and universal duplex repeaters are used at St. John (New Brunswick) and Boston.

The code used is of the five-unit type, the same as is used in the Western Union Multiplex system. Tape printers are used at New York for translating the signals. The printer prints in Roman characters upon a gummed strip of paper ⅜ in. wide and this strip is gummed to regular cable message receiving forms for delivery.

Telephone Signaling. The use of 16 to 20 cycles alternating current for telephone signaling was developed in the very early days of the art, and is still employed, not only for ringing subscribers, but also for signaling on many toll lines.

The introduction of composite telegraph circuits brought about the introduction of 135 cycles for signaling, in order that the signaling should be at a frequency which was not used in the telegraph signals. Considerable improvements have been made recently in 135-cycle signaling, and it is being employed on very long circuits requiring many repeaters.

More recently voice-frequency signaling systems have been developed particularly for operation over very long repeater circuits. By thus using a frequency in the voice range, any circuit over which speech can be effectively transmitted also effectively transmits signaling currents of this frequency. Since the signaling is carried out at intervals when there is no talking on the circuits, there is no interference with the speech currents. It is evidently necessary, however, that some means be provided to prevent the speech currents from operating the relays employed with this system. This is taken care of by interrupting the signaling current approximately 20 times per second, thus producing a form of current which is not produced by the voice. A relay system arranged to operate with such current will not be operated, therefore, by any voice current.

An improved signaling system for taking care of the signaling and control arrangements necessary for handling calls over the wires of a toll circuit group, is being applied in the toll plant. By the use of this system the signaling and control arrangements for as many as 30 circuits are handled over a single pair of wires, thus freeing a large number of channels for telegraph purposes.

Machine Switching. During the past year, continued progress has been made in perfecting improvements in machine-switching equipments. These improvements are the result of intensive development work and have been made with a view of facilitating manufacture, installation and operation of central offices and private branch exchanges of this type. Progress has also been made in the development of new maintenance methods and tools, and in stabilizing the maintenance methods employed. This is of importance due to the large amount of apparatus involved in automatic operation, and the dependence that must be placed on it when connections are completed by machine switching.

The theory of probability plays a very important part in the design of switching systems, and in the determination of the amount of facilities required to meet various traffic conditions. A paper on "The Theory of Probability and Some Applications to Engineering Problems" was presented at the Midwinter Convention. Only a very few papers on this important subject have ever been presented to the Institute.

On December 31, 1924, there were 993,000 stations operating on a machine switching basis in the Bell System as compared with 567,800 switching stations at the end of 1923. In New York City there were 185,300 machine switching stations in service on December 31, 1924, operated from a total of 21 central offices.

The application of machine switching to the toll plant is being studied with a view to determining where it can be employed to advantage. An installation is being made of this system on a commercial basis and if found successful it will be extended.

Coincident with the development work on machine-switching equipments, considerable progress has been made in manual switching, particularly with respect to trunking methods. These improvements have been effected largely by the increased use of automatic methods in connection with the manual handling of calls and have resulted in reducing the manual labor necessary in completing telephone connections.

Telephone Distributing Frame Wire. Improvements

in means for flame-proofing wires, developed in the Bell System's Laboratories, have resulted in the production of rubber-insulated wire showing resistance to burning fully equivalent to that obtained in flame-proofed enamel and textile insulated wires. This wire is particularly adapted for use in the distributing frames of central offices. The rubber-insulated wire, so flame-proofed, possesses advantages in electrical characteristics and cost over alternative forms.

Telephone Transmission. An extensive investigation has been carried out by the Bell Telephone engineers with regard to the characteristics of speech and of hearing. A considerable number of papers have been published on this work. This analysis of the characteristics of speech has made it possible to determine accurately the effect of different frequency ranges on the intelligibility, loudness and naturalness of the spoken word. It is interesting to note that a large proportion of the energy of the voice is in the low range of frequencies of a few hundred cycles, while the higher frequencies up to several thousand cycles are of importance in providing clear articulation. As a by-product of these researches, important scientific results are being obtained regarding the nature of hearing, and methods of aiding the deaf and the dumb.

A paper entitled "Telephone Transmission Maintenance Practises," read at the Pacific Coast Convention, described the practise employed by the telephone companies in this country to guarantee their circuits maintaining a condition for giving the best transmission results. These practises are of the greatest importance in maintaining both toll and local circuits.

A paper read at the San Francisco Convention, entitled "Guided and Radiated Energy in Wire Transmission," gives a good discussion of transmission over wire circuits, and the conditions under which part of the energy is radiated from such circuits. This is a matter of fundamental technical importance since so much of our electrical art depends on the fact that electromagnetic waves may be guided by conducting wires.

Telephone Circuits have become so long, both geographically and electrically that echoes may be set up in them. The effects produced are very similar to those with sound waves. Whenever a voice wave meets an electrical irregularity in a circuit, some part of the wave is reflected. If the time required for the speech waves to travel to the irregularity and for the reflected waves to return to the speaker or listener is sufficiently great, the effect becomes an echo. A discussion of such echo effects and arrangements devised for avoiding them where they become of importance was described in a paper before the St. Louis Convention entitled "Echo Suppressors for Long Telephone Circuits." It is in telephone circuits of such length as to require a number of repeaters, particularly in long cable circuits that the effects may become sufficiently serious to justify the echo suppressors which are described. With these suppressors, the speech currents operate relays which block the echoes without disturbing the main transmission.

Outside Plant Practises. Tests of full size poles of the various timbers used in telephone work have recently been made by the Bell System engineers, in order to redetermine their moduli of rupture. These tests are probably the most comprehensive that have ever been made on full size specimens, and it is hoped that a paper can be obtained during the coming year describing the tests and giving the results obtained.

Drop wire having the two insulated conductors placed parallel under a common braid has been standardized for use in the Bell System. This is the type of wire used generally for connecting subscribers' stations with the nearest cable terminals. The new construction, in place of the twisted pair construction formerly employed, results in reduced accumulation of ice loads, better resistance to abrasion, and in simplified insulating supports. It costs less because of reduction in material required and simplification of the manufacturing operation. Extensive trials have shown that the long twists which occur in the removal of the wire from the coils, in view of the conditions under which it is used, are sufficient to prevent cross-talk between adjacent circuits.

Radio. International radio telegraph circuits have continued to grow during the year 1924. The Radio Corporation of America has inaugurated a direct service between the United States and Sweden; and between the United States and Argentine—this being the first direct radio link between New York and South America. This Company has also established a station at Belfast, Maine, for reception of messages from Europe. The signals received are automatically relayed by radio to the Riverhead receiving station. Because of reduced static, and also the somewhat shorter distance, the signals received at Maine and thus relayed to Riverhead are generally considerably better than those received directly at Riverhead.

Considerable progress has been made during the year in the substitution in the marine field of tube transmitters generating sustained oscillations for spark transmitters. This results in increased range of communication and decreased interference, both in the marine field itself, and to broadcast listeners. The Radio Corporation has completed its program for installing tube transmitters in all of its shore stations, and has inaugurated a program for converting the ship spark transmitters in which it is interested into tube transmitters.

Marked interest is being taken by shipping companies in the use of radio direction finders aboard ships. With the increased number of new ship installations, the Lighthouse Division of the Bureau of Commerce and Labor are increasing the number of radio beacons which will be equipped with tube transmitters. Ship installations of this kind are not only of importance in

determining the position of a ship, but also enable it to determine quickly the direction of a ship in distress.

An interesting development in ship-to-ship and ship-to-shore telephony are the radio sets built by the Western Electric Company for the United States Coast Guard. These sets were designed to give voice transmission up to 50 miles, and telegraph transmission up to 100 miles. They use one-wave length only, which will lie between 100 and 200 meters. The transmitter is of the coupled oscillator type, of 50 watts output, and the receiver is of the double detection (so-called super-heterodyne) type.

A brief statement was given in last year's report of the developments in the use of short waves of 100 meters and less, and the surprising results which had been obtained with them under some conditions. A large amount of further information has been obtained as to the characteristics of these waves, and attempts have been made to explain their action from the theoretical standpoint by Larmor (*Phil. Mag.* December 1924) and by Nichols and Schelling (*Bell System Technical Journal*), April 1925). While much more remains to be done before it will be possible to predict definitely the action of such waves, they are already being put into important practical use for telegraph purposes. Four of the long transatlantic circuits are now being supplemented by short-wave systems. These systems are still largely experimental, but it is understood they give promise of having considerable value. It has not yet developed, however, whether these short waves will displace the present use of long waves, or will rather enlarge the possibilities of radio.

The interest in these short waves led to a conference in England during July last, attended by representatives of the large radio telegraph companies in Europe and America. This conference discussed ways and means of intensively studying the short wave field. The use of short waves involves interesting and important possibilities of using directive systems at both the transmitting and receiving stations.

Under the auspices of the American Engineering Standards Committee, a Sectional Committee on Radio has been organized for the purpose of formulating standards in the radio field, particularly with respect to nomenclature and methods of rating and testing apparatus. The sponsor bodies are the American Institute of Electrical Engineers and the Institute of Radio Engineers.

Last year's report mentioned the fact that weekly tests of telephone transmission from America to Europe were being carried out, and that a committee appointed by the British Post Office had recommended the installation of a 200-kw. telephone transmitter at its new Rugby station for transmission to America. These weekly tests have been continued throughout the past year and the British Post Office is proceeding with the installation of the transmitter as noted.

The production in considerable quantity of high-frequency alternating currents for radio transmission involves some very important technical problems. A paper on "Frequency Multiplication," read at the St. Louis Convention, discusses one of the means of producing such high frequency currents.

Radio Broadcasting. Radio telephone broadcasting continues with unabated public interest. From the transmitting standpoint, there has been a steady increase in the number of better grade broadcasting stations. The problem of providing a sufficient number of frequency bands in which to accommodate them has become a serious one to the authorities of the Department of Commerce, no satisfactory solution having as yet been found. This matter, as well as other aspects of the broadcasting situation, was the subject of a National Radio Conference in October last—the third to have been called by Secretary Hoover.

The developments which have been made in the art of connecting together a considerable number of broadcasting stations by long distance wire telephone circuits is strikingly indicated by the arrangements which are now made for broadcasting national events. For example, a speech by President Coolidge on November 3, was broadcast simultaneously by 28 radio broadcasting stations scattered over the entire country from the eastern to the western seaboard.

Considerable development has been made in receiving sets. Regenerative equipment in which self oscillation is prevented only by proper manipulation by the operator, is coming into disfavor and being supplanted by sets employing multi-stage radio frequency amplification, or sets of the so-called "super-heterodyne" type. Sets of these types do not interfere with each other and give good speech and music quality together with high selectivity.

The loud speakers associated with radio sets have in general presented more difficult problems in attaining high quality reproduction than have the sets themselves. Last year's report mentioned two papers which had been presented during that year to the Institute on this matter. With one of these papers was demonstrated the so-called cone-type of loud speaker developed by the Bell System engineers. This loud speaker has since been put on the market. It properly reproduces the low frequencies whose lack has been perhaps the most unfortunate characteristic of broadcast reception from a musical standpoint. At the same time it permits a better reproduction of the higher frequencies.

A paper entitled "A New Hornless Type of Loud Speaker," read at the St. Louis Convention, describes the development work on loud speakers carried out by the General Electric engineers and in particular a form of hornless loud speaker which they have developed. It is expected that this development will form the basis of a high-grade loud speaker to be put on the market.

It is very important with high-grade loud speakers that the voice frequency amplifiers associated with them, as well as the radio set, be free from distortion. A paper entitled "The Design of Distortionless Power Amplifiers," read at the Midwinter Convention, discusses the problems which arise in the design of such amplifiers and the means for overcoming them.

Inductive Relations of Power and Communication Circuits. In response to a demand for a body representative of all wire-using utilities to carefully consider the technical problems of inductive coordination, the American Committee on Inductive Coordination was organized. This committee is made up of representatives of the American Railway Association, the American Electric Railway Association, the National Electric Light Association, the Western Union Telegraph Company, the Postal Telegraph-Cable Company and the Bell System. This committee has perfected an organization, agreed upon a program, appointed subcommittees and has issued its first report.

The Joint General Committee of the N. E. L. A. and the Bell System has continued its cooperative work throughout the year. The comprehensive investigation by the Development and Research Subcommittee has been divided into eleven projects, and each project put in charge of a small Project Committee. The program includes both theoretical and experimental work in the laboratory and in the field. Subjects under investigation include; coupling coefficients between power and telephone circuits; effectiveness of coordinated transpositions; effects of unbalances in telephone circuits and means for locating and clearing them; the cumulative effects of successive exposures; protection of telephone circuits from acoustic and electric shocks; residual voltages and currents in power circuits and methods for their control, including effects of isolating and grounding the neutral by different means; noise in telephone circuits, its effects, frequency composition, methods of measurement, and survey of its magnitude and distribution; wave shapes of voltage and current in power circuits and the development of means for improvement and rating; inductive effects under joint use of poles or other conditions of close exposure; the effects of changes in the power level and sensitivity of telephone circuits; selective devices for suppressing undesirable frequencies in either or both systems; characteristics of telephone receivers and transmitters; special devices for application to either or both systems; and interference with carrier frequency channels. It will require a period of several years to complete these investigations, but it is planned that important results will be made generally available from time to time.

Fig. 1

The paper on "Telephone Circuit Unbalances—Determination of Magnitude and Location," read at the Pacific Coast Convention, covers a matter of large

importance in considerations of inductive interference.

Electrical Protection. The National Fire Protection Association, through its Committee on Signaling Systems, has undertaken a complete revision of the Regulations for Municipal Fire Alarm Systems, and for Protective Signaling Systems. The Electrical Committee of the Association is engaged in a triennial revision of the National Electric Code, including the Regulation for Wiring of Signaling Systems and Radio.

Communication in Railroad Operation. Communication plays a very important part in railway work.

FIG. 2

FIG. 3

A paper on "Communication in Railroad Operation" read at the St. Louis Convention discusses this matter from the railroad standpoint.

Solar Eclipse. The eclipse of the sun in January was of special interest to communication engineers, in that communication facilities played a very important part in the scientific observations which were made, because of the effect of the eclipse on radio transmission.

At the request of the American Astronomical Society, the telephone companies arranged circuits connecting observing parties at Buffalo, Ithaca, Poughkeepsie, East Hampton and New York, N. Y., and Middletown and New Haven, Connecticut. Telegraph signals, set by observers at five points at the instants when the eclipse became total to them, were recorded on a chronograph in conjunction with seconds beat by a very accurate electric clock.

Careful observations were made by a number of the communication companies, and by others interested in radio, as to the effect of the eclipse on radio transmission. Definite correlation between the passage of the shadow of the eclipse and radio transmission appears to have been well established in some cases.

Electrical Transmission of Pictures. There has been a large amount of activity during the year in the electrical transmission of pictures.

The report for last year gave a brief description of a system developed by the Bell Telephone System engineers for transmitting pictures over telephone lines.

Further development has so far perfected this system that the transmitted pictures present an appearance differing very little from that of the original photograph. Fig. 1 is a reproduction of a picture so transmitted, and shows the great amount of detail obtained. The picture was transmitted directly from an ordinary positive film, and about seven minutes was taken in transmission. Pictures of the inauguration of President Coolidge on March 4 were transmitted from Washington, D. C. and received simultaneously at New York, Chicago and San Francisco, and were published in the afternoon editions of the newspapers of that same day. Commercial picture service with this system has been inaugurated between the three cities of New York, Chicago and San Francisco. The system is described in a paper appearing in the *Bell Systems Technical Journal* for April, 1925.

The lines of the Western Union Telegraph Company have been used commercially by a number of newspapers for the transmission of photographs by a method devised by M. Ferree and J. Wissmar. In this system, the elements constituting the picture are sent over the line wire and handled in exactly the same manner as the signal impulses used in the transmission of ordinary telegraph messages. At the sending end a stylus moves in spirals over a specially prepared cylindrical plate. Current impulses flow through an electric circuit, of which the stylus and plate form a portion, whenever the stylus rests upon a light portion of the plate and operate a telegraph pole changer. The current reversals caused by the pole changer operation are transmitted to the receiving station or stations through the line wires and such telegraph repeating apparatus as is necessary. At the receiving station a relay opens and closes an electric circuit, in which is included a stylus which travels spirally over a chemically prepared paper. By the action of these electrical impulses upon the treated paper, marks are made so that a picture is formed corresponding to that on the sending plate. The system described has been successfully used on a circuit lay-out arranged for duplex operation, and made up of about 5300 miles of line wire connecting to fifteen cities. Fig. 2 is a reproduction of a picture transmitted in this way. About one hour is required for transmission.

The Radio Corporation of America announced during the year transmission of pictures by radio from London to New York. Fig. 3 is a reproduction of a picture so transmitted. The method employed is, in brief, as follows: At the transmitting end, the picture to be sent is wrapped around a glass cylinder which is caused to revolve. As the drum revolves, a small concentrated electric light on the inside sends a beam through successive portions of the picture to a sensitive photoelectric cell. The current variations resulting are highly amplified, and are caused to charge a condenser in such a manner that the rate of charge is determined by the amount of light piercing the transmitting film. When a given voltage is reached on the condenser, the circuit trips and gives a pulse which works a relay to start a signal. When the amount of light increases beyond a certain point, the current not only is able to charge the condenser more quickly, but is so arranged that it will hold the relay for a greater length of time. This gives rise to a peculiar characteristic of widely separated dots for one end of the light scale, of close dots for the middle ground and long-drawn-out dashes for the other end of the photographic scale.

At the receiving end a paper sheet is fastened to a drum, which rotates in synchronism with the drum at the sending end. The radio signals, highly amplified, actuate a small fountain pen suspended just above the paper, which thus records on the paper the dots and dashes received by the radio, and thus forms the picture.

The rugged character of the dot and dash signals, such as has made possible long distance communication by radio telegraphy, carry these pictures through what would otherwise be considerable interference. The question of detail is a matter of the amount of time which can be devoted to the transmission. A portrait with the amount of detail shown can be handled in about twenty minutes.

A system devised by Edouard Belin, who has long been interested in picture transmission, has been tried out during the year between St. Louis and New York, and pictures so transmitted have been published in newspapers in both of these cities.

A number of other investigators have been carrying on experiments in picture transmission, among these being C. F. Jenkins, Austin G. Cooley, M. L. D. McFarlane and H. G. Bartholomew.

Education in Communication Engineering. There has been a steady growth of interest in communication courses in the teaching of electrical engineering, although the growth is perhaps less rapid than in the years immediately following the war. The tendency seems to be toward required rather than elective courses in electrical communication, probably due to the growing realization that such courses introduce the student to certain important fundamental conceptions and ideas which he would not get from his other courses. In August, 1924, an educational conference was held in New York City, in which a group of college professors met with officials of the Bell Telephone System. The discussion of various phases of electrical communication and the methods of teaching them were of much value to all those who attended the conference.

A considerable number of educational institutions are undertaking the broadcasting of courses of lectures, music, athletic events, and other matters of interest. This promises to become an important function of some of our universities.

Power Possibilities at Muscle Shoals, Alabama

BY SAMUEL S. WYER[1]

Synopsis.—*This study was made in February and March, 1925. The author had access to the public records of the War Department but his responsibility for all statements is complete.*

Factual conveyance has been more important than euphony or euphemism. The object of the report is to present the basic facts pertaining to the whole Muscle Shoals situation in a way that the layman can make his own evaluation of,

1. What Muscle Shoals is

2. What has, and can be done at Muscle Shoals

and from these facts deduce as to what, in the public interest, on the basis of the greatest good to the greatest number, ought to be done with it.

TABLE OF CONTENTS

I. Fundamental Features

1. Public's Understanding of Term "Muscle Shoals." In the public's mind, the term "Muscle Shoals" is a definite spot and not the stretch of river described in Section 3. As used by the layman, Muscle Shoals means the water-power development now nearing completion at the Wilson Dam—named for President Wilson—and the term is so used in this study.

While the Wilson Dam is merely a small part of the proposed Tennessee River development, it is the only part now under construction and this is why the public's attention has been focused on it, rather than on the project as a whole.

2. Public's Interest in Muscle Shoals. At present Muscle Shoals is the most talked of power project in the world. No other water power has ever received so much oratorical attention, or has had expended on it so much printers' ink. The very name "Muscle Shoals" has become a symbol for power.

In the forum, in the press and in the conversation of the public, Muscle Shoals has frequently been the dominating topic of the day. From its inception as a war measure, public interest in it has grown until at times the preponderant public opinion has been that the military and economic strength of the nation was dependent upon Muscle Shoals.

3. Location of Muscle Shoals. The general geographical location of Muscle Shoals in northwestern

Alabama is shown by Fig. 1, with local details given on page 4.

1. Consulting Engineer, Columbus, Ohio.

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, June 22-26, 1925.

For a distance of about 37 miles, between the railroad bridge at Florence and Brown's Island near Decatur, Alabama, the bed of the Tennessee River is really a series of shoals, one right after the other, with a fall of 140 feet in that distance.

The shoals near Florence are known as "Muscle Shoals," as the muscle shell fish—earlier and now alternate spelling "Mussel"—were found in abundance in the bed of the shoals. The present geographical name "Muscle" has been derived from this fact. The Muscle Shoals section includes the stretch of river from Muscle Shoals up to Brown's Island.

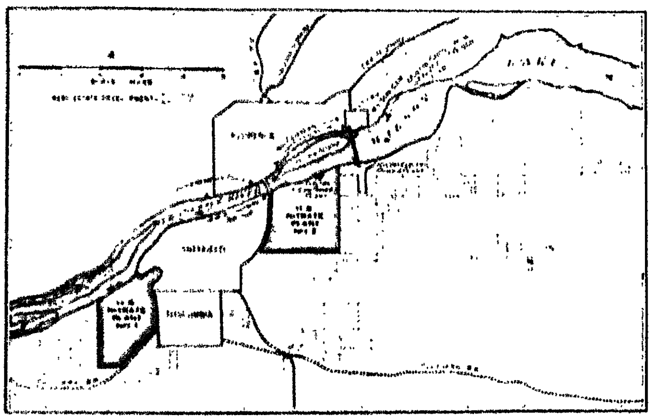

FIG. 2—MUSCLE SHOALS DISTRICT, ALABAMA, MARCH 1925

4. Current Terms Applied to Muscle Shoals. The following are commonplace expressions for and representing current ideas of Muscle Shoals:

"There is no place in the world where greater advantages are to be found for the harnessing of water power for the uses of industry, or where there is greater power awaiting development, within reach of the seaboard by water and rail transportation, than at Muscle Shoals."[1]

"If I were greedy for power over my fellow men, I should rather control Muscle Shoals than to be continuously elected President of the United States."[2]

"The completed Muscle Shoals is worth more than all the gold currency in the world."[3]

"The destiny of the American people for centuries to come lies at Muscle Shoals."[4]

"America's Gibraltar—Muscle Shoals. In peace, prosperity for the farmer; in war, preparedness for the Nation."

"Muscle Shoals, waiting through the ages for man to tame their roaring waters and harness their mighty power."

"The Niagara of the South."

"Standards of living at stake in Muscle Shoals decision."

5. Characteristics of Tennessee River Drainage Basin. The area of the drainage basin supplying the Wilson Dam at Muscle Shoals is 30,800 sq. mi. Much of this is hilly or mountainous so that the rain falls on sufficient of a slope to produce a rapid run off from the surface of ground to the stream. Daily stream-flow readings for the Tennessee River, made at the railroad bridge at Florence, about 2½ mi. below the Wilson Dam and recorded by the U. S. Geological Survey, are available since 1871[5].

The average rainfall for the entire drainage basin is 51 in., of which 13 in. occurs in the winter, 15 in. in the spring, 14 in. in the summer, and 9 in. in the autumn.

6. Why Variable Stream Flow is Natural. Rainfall is the initial source of the water in all rivers. Rainfall is not continuous but periodic and varies largely with different seasons. Therefore, unless there is natural or artificial storage to equalize the volume, the flow of a river will vary approximately with the rainfall, Variable flow is obviously the natural condition of a river.

The Tennessee has neither natural or artificial storage at present, and its variable flow characteristics are, therefore, typical, varying merely in degree with other rivers.

7. Characteristics of the Tennessee River. The banks of the Tennessee River are well cut, clearly defined and there has been little change, or tendency to change, in its course from year to year. The bottom of the river does not present any serious difficulties for dam foundations.

"The Tennessee is subject to sudden and frequent fluctuations in discharge. Its headwaters drain a mountainous region noted for heavy and prolonged rains and generally high annual precipitation. The high-water season is in the late winter and early spring and is caused by copious rainfalls, while the melting of snow, as a contributive factor, is only of minor significance.

"The maximum rates of flood flow in the Tennessee are not so high as might ordinarily be expected of a

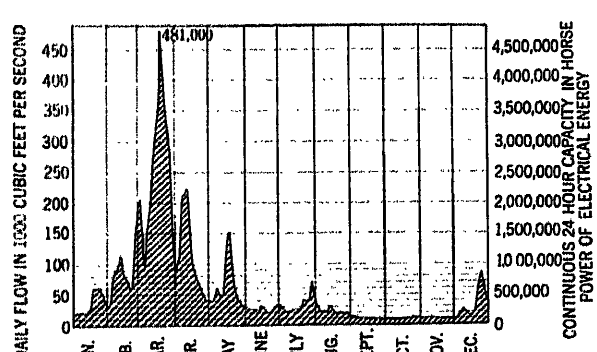

FIG. 3—VARIATION IN DAILY FLOW AND HORSE POWER OF TENNESSEE RIVER AT MUSCLE SHOALS

On the basis of 80 per cent. efficiency of the hydroelectric generators, 10 h. p. of electrical energy will be generated for each cubic foot per second flow at the Wilson Dam at Muscle Shoals. The scale at the right of figure shows h. p. capacity. (Left). Daily stream flow readings of Tennessee River at Florence, Ala., near the Wilson Dam, have been recorded by U. S. Geological Survey for 53 years. The data shown are for 1898.

river basin subject to the high rates of storm rainfall that are common there. This is attributable to three factors:

a. The peculiar configuration of the drainage basin which, near the middle, is constructed to a width of less than 40 mi.

b. The general westerly flow of the river in a direction contrary to the movement of storms.

1. Senate Document No. 83. 59th Congress, First Session.
2. Newton D. Baker.
3. Thomas A. Edison.
4. The New York Times credits this to Henry Ford.

5. Recorded in the U. S. Geological Survey Water Supply Papers Nos. 353, 383, 403, 433, 453, 473, 503.

c. The arrangement of the tributaries, which does not favor rapid collection and concentration of run off.

"On account of the mild winters, ice troubles, so common at hydroelectric plants in the northern United States and Canada, are rare and become a negligible factor in the operation of such installations in this region."[6]

8. Variation in Daily Flow of Tennessee River. This is shown in the yearly hydrograph chart, Fig. 2. In the extreme year shown—1898—the daily flow in "1000 cu. ft. per second" varied from 481 to 9, or 53 to 1.

In 1923, the daily flow varied in "1000 cu. ft. per second" from 215 to 8, or 27 to 1.

The maximum discharge of the Tennessee River recorded at Florence was 499 "1000 cu. ft. per second" and occurred on March 19, 1897.

It is important to bear in mind that these flow data are not deductions from rainfall statistics, but are actual measurements, and show the high and low flow conditions that must be coped with in water-power developments on this river.

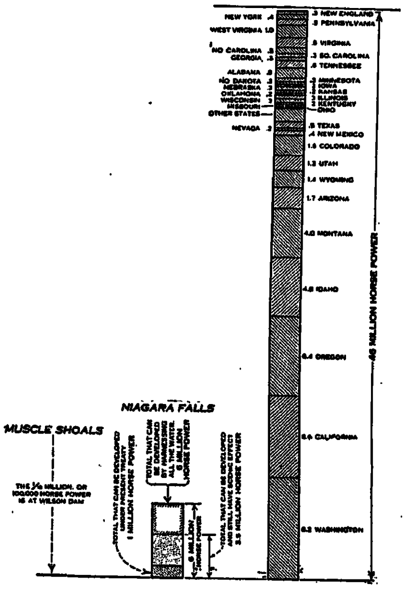

Fig. 4—Muscle Shoals Compared with Niagara Falls and Undeveloped Water Power in United States in Million H. P.

The diagram at the right, the geographic distribution of potential undeveloped water power in United States, is based on data from the U. S. Geological Survey. This total is without artificial or stream flow control and is larger than it would be feasible to develop. Probably not over 25,000,000 h. p. will be worth developing for many years. The amount of power that may be alloted to the United States in any future joint development of the Niagara and St. Lawrence Rivers is not included.

The two comparisons above are for 24-hr. capacity without artificial or stream flow control; because of scenic preservation and ice flushing conditions, not more than three and one-half million h. p. can be depended upon at Niagara Falls.

The horse power that may be developed for various conditions of river flow at the Wilson Dam at Muscle Shoals, is shown at the right on page 8.

9. Water Storage Limitations. At the Wilson Dam at Muscle Shoals, the area of the pool known as Wilson Lake is 14,500 acres, or in round numbers, 23 sq. mi. This pool gives enough ponding to meet daily fluctuations in loads but affords practically no storage.

10. Meaning of "Primary Power" and "Secondary Power." Primary power is the power that can be developed continuously for 24 hours of the day and for every day in the year. Secondary power is power that can be developed for merely a part of the time, and which may be for certain seasons of the year or for certain hours of the day only. The thing in which the ultimate consumer is interested is not primary power per se or secondary power per se, but continuous power; that is, continuity of service; and secondary power can be made continuous power only by having some other source of power to make up for the deficiency. This usually means a steam plant.

11. Primary Power of Wilson Dam at Muscle Shoals. In general, the primary power that may be depended upon at the Wilson Dam at Muscle Shoals is 100,000 h. p., continuous output. However, there will be occasional days when the primary power will drop to about 87,000 h. p. For the larger turbine capacity needed to utilize this primary power see §23.

12. Secondary Power of Wilson Dam at Muscle Shoals. In addition to the 100,000 h. p. of primary power that can be developed at the Wilson Dam, the following quantities of additional secondary power can be developed for the respective per cents of total time shown below for the two conditions of river flow shown:

Additional secondary horse power	Approximate per cent of total time available[7] Low year daily discharge basis	Mean monthy discharge basis
50,000	56 per cent	85 per cent
100,000	44 per cent	72 per cent
150,000	32 per cent	63 per cent
200,000	24 per cent	55 per cent
300,000	15 per cent	42 per cent

13. Muscle Shoals Compared with Niagara Falls.

	Muscle Shoals Wilson Dam	Niagara Falls[8]
Area drainage basin, square miles	30,800	263,400
Storage	none	1/3 area of drainage basin is water storage.
Head—that is, fall—that can be developed	95 ft.	300 ft.
Ice problem	none	Flushing the ice and maintaining scenic effect reduces the capacity from 6,000,000 h. p. to 3,500,000 h. p.
24 hour continuous capacity in horse power	100,000	3,500,000

Thus the continuous capacity that can be obtained from Muscle Shoals is 1/35 of the capacity of Niagara Falls, or it would take 35 Muscle Shoals to equal one Niagara Falls.

In using Niagara Falls as a comparative yard stick,

6. House Document No. 319, 67th Congress, Second Session.

7. House Document No. 1262, Plates 107 and 108, 64th Congress, First Session.

8. For further discussion see Smithsonian Institution Paper "Niagara Falls: Its Power Possibilities and Preservation."

it is important to bear in mind that the Niagara River is jointly owned by the United States and Canada and that the treaty limits the total development at present to 1,000,000 h. p. and there can be no further development until the treaty is amended. Furthermore, if the treaty is amended and the development is pushed to the limit—on the basis of still maintaining an adequate scenic effect—of 3,500,000 h. p., one-half of this, or 1,700,000 h. p., would belong to the United States.

14. Muscle Shoals Compared with Undeveloped Water Power in United States. While the potential undeveloped water power in the United States is, in round numbers, 46,000,000 h. p.—as shown on page 10 probably not over 25,000,000 h. p., of this 24-hour continuous capacity without artificial storage, will be worth developing for many years. Therefore, the Wilson Dam at Muscle Shoals compares with this probable undeveloped water power, available for the near future, as follows:

Total undeveloped water power in the United States worth developing	25,000,000 h. p.
Wilson Dam at Muscle Shoals	100,000 h. p.

That is, the Wilson Dam at Muscle Shoals represents 1/250 of the undeveloped water-power capacity of the United States worth developing; or it would take 250 Wilson Dams to equal the undeveloped water power now worth developing in the United States.

15. Muscle Shoals Compared with Stationary Primary Power in United States.

Using the term primary power—as defined in Section 10—with the knowledge that the aggregate horsepower capacity of all stationary steam, oil and gas engines, and steam and water turbines is in excess of 50,000,000 h. p. at the present time it is estimated that the strictly primary stationary horse power capacity in the United States is at least	40,000,000 h. p.
The primary power at the Wilson Dam at Muscle Shoals is	100,000 h. p.

That is, it would take 400 Muscle Shoals to furnish the primary stationary power that is now in use in the United States.

16. Water Power Possibilities of the Tennessee River Compared. The Wilson Dam is not the whole Muscle Shoals project, but merely a part of the proposed project; and this is but a small part of a much larger proposed development which Congress is now having studied; viz., that of the power-navigation-industrial possibilities of the entire Tennessee Basin.

The water-power possibilities of the Tennessee River compare as follows:

	Primary horse power
Undeveloped water power in the United States worth developing	25,000,000
United States share of total possible development at Niagara Falls	1,700,000
Probable total development on Tennessee River	1,000,000
Wilson Dam at Muscle Shoals	100,000

This shows that the proposed development on the Tennessee River is 1/25 of the probable power development in the United States and about 60 per cent of the United States' share of the total power that can be developed at Niagara Falls; and, further, that the present Wilson Dam development represents but one-tenth of the probable total Tennessee River development.

17. Water-Power Limitations.

1. Water power is not free. In the consideration of water power, many well meaning persons think only of the free gift of nature and entirely overlook the part that man's labor and money must necessarily play in the realization of the bounties of this gift. There seems to be an impression among some people that, since water runs down hill, water power can be developed at very little cost and with very little risk. Such an impression is, in most cases, very far from the truth. Water power is worth just what can be gotten out of it in competition with power manufactured from fuel.
2. While nature has made the water, it is no more natural or free than the nature-made coal. Both must be brought under control to be of service to man. "Much has been said about harnessing water falls. However, there has been little appreciation that someone must furnish the money for securing, maintaining and ultimately replacing the harness and hiring labor for the continuous direction of the harnessed energy."
3. Coal is relatively a small part of total power cost.
4. The cost of water-power plants per horse power of plant capacity is usually more than for steam plants, but the operating cost of a water-power plant should always be less than for a steam plant.
5. The capacity is dependent on stream fluctuation. With storage reservoirs, the maximum operating capacity is merely the average stream flow; without reservoirs, the maximum capacity that can be depended upon is merely the minimum flow. The flow of the stream may be injuriously affected by the operations of man or the agencies of nature and the available flow may be much less than anticipated.
6. While auxiliary plants can be installed to furnish power during the low water period,the increased cost would ordinarily not make this attractive in single plants.
7. Actual delivering capacity is usually much lower than the published figures.
8. Water-power development in the United States has been strewn with wrecks, due to failure to appreciate the clearly defined economic limitations under which water-power developments can take place and failure to cope with the nature-made limitations in variation in stream flow.

18. Proximity of Coal to Muscle Shoals. Extensive coal deposits are located in central Kentucky, central Tennessee and northwestern Alabama. These are, of course, advantageous from the viewpoint of furnishing fuel for any industries that would use Muscle Shoals power. These coal deposits, however, because of their proximity, make steam-power generation relatively easy and are, therefore, a determining factor in appraising Muscle Shoals power, since, in the long run, Muscle Shoals power is worth no more than power that can be generated from a steam plant.

19. Confusion of Power and Fertilizer. Much of the misunderstanding regarding Muscle Shoals arises from the confusion of the power project with nitrate production for either munitions or fertilizer. Power production must stand on its own feet and should be self-

sustaining; fertilizer production should also stand on its own feet and be self sustaining.

Fertilizer manufacture would require power. But there is no mysterious advantage whatsoever in Muscle Shoals power; power from any other source would function just as effectively. The crux is one of economic cost and not of mere geographical position.

II.—What has been Done to Date

20. History. "In 1824, J. C. Calhoun, Secretary of War, asserted that a canal around Muscle Shoals was of great national importance." The first investigation was authorized by Congress in 1828 and this was followed by others.

The first study "undertaken by the United States with a view to the possible development of the extensive potential water powers in this section of the river" was made in 1907. The whole project was finally brought to a head in the report of the Chief of Engineers, June 4, 1916,[9] describing the then-proposed dam construction, which later was named after President Wilson and officially designated the "Wilson Dam."

What is now known as the Wilson Dam was started November 9, 1918—two days before the armistice—but the work was suspended from April 15, 1921, to October 1, 1922, and the present indications are that the work will now be completed about January 1, 1926.

21. Wilson Dam. The Wilson Dam is located at the foot of Muscle Shoals, 2½ miles east of Florence, Alabama, as shown in Fig. 2.

The dam is a huge concrete structure with navigation locks at the north end, a power plant at the south end and a roadway on top. The total length of the structure is 4500 feet, and contains 1,350,000 cu. yds. of masonry, which is the largest volume of masonry in any dam in the world. The dam is 96 ft. high, 105 ft. thick at the base and rests on a hard blue limestone.

22. How the Work has been Handled. The entire project has been ably and efficiently handled by the War Department, under the general direction of the Chief of Engineers. All of the work has been done on a day labor basis and practically no contract work, except minor subcontracts, has been used on the project.

23. Hydroelectric Power Plant. This is located at the southern end of the dam, and is in fact, an integral part of the main dam construction.

The power-house building is 1250 ft. long, 160 ft. wide and 134 ft. high, built of monolithic and reinforced concrete.

Four complete hydroelectric generators, each of 30,000 h. p., are now being installed, also four at 35,000 h. p. each. The room is large enough so that 10 additional units, each of 35,000 h. p. can be installed later.

9. Published as House Document No. 1262, 64th Congress, First Session.

The total installed capacity (above auxiliary equipment used in the plant itself) contracted for now is:

	Horse power
4 units, at 30,000 h. p. each	120,000
4 " " 35,000 " "	140,000
Present capacity	260,000
Additional units proposed:	
10 units, at 35,000 h.p. each	350,000
Proposed future capacity	610,000

However, not all of the 260,000 h. p. of installed capacity is available for continuous use for the reasons given in the next paragraph.

While the stream-flow conditions will permit of a continuous output of but 100,000 h. p., the demands for electric energy are not uniformly distributed over the 24 hours and the maximum hour would ordinarily be 50 per cent more than the average hour, so that 150,000 h. p. of turbine capacity would be required to meet the probable daily peak of the primary horsepower serving capacity. One unit should be in reserve and ready to at all times take care of any breakdown in operating machines.

The additional equipment which is for secondary power can be used in general only, as arrangements are made for getting some other source of power to supplement the low stream flow periods.

24. Navigation Locks. Two navigation locks, each having a lift of 46-ft. 6-in., are a part of the north end of the Wilson Dam. The depth available in each lock is 7½ ft.

25. Highway Bridge. The extreme top of the dam structure will be used as a public highway bridge and arrangements will be made so that the Lee and Jackson Highways, now going into Florence, will connect with this bridge.

26. No. 1 Dam for Navigation. This is located near the railroad bridge at Florence, as shown on the map, Fig. 2. It is about 15 feet high and by means of a lock with a 10-ft. lift, will connect to the Wilson Dam locks by a canal about 2½ miles long on the north side of the Tennessee River. This dam will be used for navigation only.

The cost of this is entirely separate and in addition to the figures given for the Wilson Dam in the next section, it is estimated at $1,600,000.

27. Estimated Cost of the Wilson Dam. The total amount of money spent directly on the Wilson Dam up to March 1, 1925, was $38,340,822. The total cost of completing the dam and installing four 30,000-h. p. units and four 35,000-h. p. units, with all auxiliary equipment—see Sections 29 and 30—is estimated at $45,800,000.[10]

28. Wilson Dam Built with Borrowed Money. The

10. The estimated cost of the additional ten 35,000-h. p. units, or a total of 350,000 h. p., is $5,323,000.

United States Government, in order to get money to build the dam, sold bonds to a large number of private individuals. In this way, money that was earned and saved by private individuals was borrowed by the United States Government on a rental or interest basis and mobilized; that is, these individual savings were put to work collectively in building this project. In this way, the government hired capital just as it hired labor, and the rental of the money is just as much a part of the cost of the dam as the hire of the labor. Furthermore, in order to ultimately return the money borrowed from the individual owners, provision should be made within the period of the useful life of the property so that enough money will be set aside out of the income from the project to ultimately pay back the money to private owners from whom it was borrowed.

29. Omitted Cost Items. The estimate in paragraph 27 has not included all items of cost that must ultimately come out of the public treasury. In addition to the appropriations for building the dam, there is:

a. The money used for paying for the material and labor has been borrowed for a number of years and the government has been paying interest on this amount. The total interest during construction, which must come out of the public treasury, up to the completion of the dam, January 1, 1926, is, in round numbers..................	$4,000,000
b. Preliminary engineering service in the survey upon which the construction work was based, about......................	150,000
c. Services of the Army Engineers, who have directed the work, paid out of the public treasury and therefore chargeable to this work..........................	150,000
	$4,300,000

30. Cost of Wilson Dam to the Public. Taking the estimated cost of $45,800,000, plus the omitted cost items in the preceding section, $4,300,000, we get a total cost to the public of the Wilson Dam of $50,110,000

In the more than six years since the construction work on this dam was started, the United States Government has purchased construction equipment which is a part of the above dam cost. If the No. 3 Dam is built at once, a part of this equipment can be used for the additional work. If the No. 3 Dam is not built, then this equipment may be sold or transferred to another job and the Wilson Dam cost should be credited with whatever can be realized from such sale or transfer. It has been impossible to reconcile the widely divergent views as to the credit that could be allowed for this equipment. For the purposes of comparison, an allowance of $1,000,000 is made as a credit to the Wilson Dam cost, thus making the net cost in round numbers to the public on the Wilson Dam, $49,000,000.

31. Wilson Dam Cost Compared with Steam Plant Cost.

Taking the total cost given in the preceding section for the Wilson Dam as $49,000,000, and with the frank recognition that this gives but 100,000 h. p. of primary power, we at once get an investment cost per horse power of plant capacity of............	$490.00
The per horse power cost per actual primary horse power output of a high grade steam plant, with $^1/_5$ of the capacity in reserve at all times to guard against breakdown to insure continuity of service, would be........	100.00

The additional secondary power that can be generated at Muscle Shoals will, of course, be of service but it can be of service only as it is combined with other plants, which will keep the combined capital investment above a single steam plant.

32. Navigation's Share of Wilson Dam Cost. The water-power development of the Wilson Dam at Muscle Shoals is not sufficiently attractive to subsidize navigation. The comparative cost figures given in the preceding section indicate the financial handicap for this water power project, so far as investment is concerned.

It has been suggested that 25 per cent of the total cost could be charged to navigation, but it must be remembered that this would be merely a bookkeeping transfer and would, in no way, change the blunt fact that the public must ultimately foot the entire bill, for, under our present navigation policy, the contribution would come out of the public treasury and not from the people who benefit directly by the navigation advantages.

33. Real Estate Speculation. There naturally has been an abnormal real estate boom in the Muscle Shoals district. Detailed records of 109 subdivisions totalling 48,381 lots and aggregating 6750 acres or 10.7 sq. mi. area, were examined. This is merely part of the development and some of the allotments are indicated on Fig. 2.

Alluring but deceptive advertising matter has been persistently and widely circulated; lots have been sold to widely scattered buyers. Many of these allotments are in corn fields or pasture land, and practically all are without improvements other than a few graded dirt streets and cheaply constructed sidewalks. Twelve miles distant from the Wilson Dam is not an uncommon location for these additions that are advertised as being right at Muscle Shoals.

34. Origin of Public Misconceptions about Muscle Shoals. We have a wide gap between current popular beliefs regarding Muscle Shoals and the fundamental facts because:

1. The narcotic and hypnotic effect of superlative terms, like those cited in Section 4, used repeatedly, has produced a distorted perspective.
2. As a nation, we have been more interested in debating than in fact-finding, fact-recording, and fact-facing. There has been all too little appreciation that while slogans may change beliefs and mental attitudes, they never can alter facts. Imagination plays an important role in our national life. To many, symbols are the same as realities and the symbol rather than the reality aspect has been stressed at Muscle Shoals.

3. The current newspaper expression of "white coal" for water power is creating an erroneous idea as to the value of water power and the public has jumped to the unwarranted conclusion that when you have a water power, you are getting something for nothing. Deflation of many of our water power ideas is desirable.

4. There is nothing magical about water power and it is worth just whatever can be obtained from it in competition with coal,—and no more.

5. Even though the Muscle Shoals dam is the largest concrete monolith and the largest dam in the world, mere size of structure—that is, volume of masonry—does not make power. Water power requires water fall and continuity of flow and has been much over-estimated at Muscle Shoals.

6. Optimism run wild in real estate development has not only disseminated many erroneous statements but has secured the financial interest of a large number of individuals scattered all over the United States in the unwarranted real estate developments which have tended to still further mislead the public as to the possibilities that might be realized at Muscle Shoals.

III—What can be Done at Muscle Shoals

35. Possible Future Dams. The map, Fig 1 shows the locations of possibly twelve future dams that may be built in the Tennessee River drainage basin. "Examinations made of the rocks which will be used show that excellent foundations can be obtained throughout this region."[11] The aggregate primary horse power that can be developed at the twelve future dam sites shown, is 751,000. In addition, the Cove Creek Dam would make a storage reservoir from which some regulation of stream flow can be secured and this would increase the primary horse power capacity at the present Wilson Dam and Hale's Bar Dam.

The estimated cost of these twelve dams is $125,000,000. The land that would have to be condemned aggregates 109,000 acres; and the above estimated cost has allowed $30,000,000 for land acquisition. Obviously, any tendency on the part of the present land owners to hold up prices could easily so increase the cost as to make future projects from this aspect alone undesirable from a business viewpoint.

36. Tennessee River Power Possibilities. The 100,000 primary h. p. capacity of the present Wilson Dam at Muscle Shoals plus the 751,000 primary horse power of the proposed 12 dams, referred to in the preceding section, plus the increase in primary horse power capacity that regulated stream flow would produce in the present Wilson and Hale's Bar Dams, would give a primary horse power capacity of the Tennessee River, in round numbers, of 1,000,000 horse power.

37. Navigation Aspects. Building the additional dams would give satisfactory navigation conditions for this part of the river, however, there still would be a stretch between the Riverton Dam going north to the mouth of the Tennessee River at Paducah that needs improvement.

38. Muscle Shoals a Mere Incident in the Tennessee River. From the preceding, especially in paragraph 35, it is obvious that Muscle Shoals is a mere incident in the Tennessee River development program and it must be evaluated from this point of view.

39. United States Government's Position at Completion of Wilson Dam. Toward the end of this year, when the Wilson Dam will be completed, the United States Government will be in the position of having about $49,000,000 invested in a water power project that can be depended upon for 100,000 primary horse power, but will be without transmission lines or a market. That is, the Muscle Shoals power project will be "all dressed up and no place to go."

The secondary power at Muscle Shoals can be made available only as it can be combined by transmission lines with other power sources.

40. United States Government Steam Plant. An excellent steam plant was built at Nitrate Plant No. 2 in 1918. It contains a 60,000-kw. steam turbine in three elements, of 80,000 h. p. capacity.[12] It is in good physical shape and could be used for supplementing the secondary power of the Wilson Dam.

41. Common Sense on Fertilizer Situation.[13] Fertilizer will be made by fixing the nitrogen of the air or any other process whenever it is good business to do so; that is, when the process can be carried on at a fair profit. No sane man would go into an enterprise unless it could be carried on at a profit. In other words, the same motive that prompts the farmer to expend labor and capital in raising a crop (which is merely getting a living wage or return for labor and capital) will insure the manufacturer of fertilizer. It is no more wicked for a fertilizer manufacturer to make a fair profit than for a farmer to make a fair profit. Without profit there is no incentive; without incentive, there can be no progress.

The fixation of nitrogen is a long way from fertilizer. To compare the cost of segregated nitrogen at Muscle Shoals before its proper combination with other ingredients to make usable fertilizer, is not unlike comparing the cost of raw wool with the cost after it becomes a suit.

42. U. S. Nitrate Plant No. 1. This was an experimental synthetic ammonia plant. It never operated, and, as it now stands, is not of interest for commercial production. It probably would be cheaper to construct a new plant than to redesign and rebuild Plant No. 1 to permit of its competing with plants based upon the latest developments. This represents an investment of about $12,000,000.

43. U. S. Nitrate Plant No. 2. This is constructed to operate on the cyanamid process, which won its place because it requires less than one-fourth the power necessary for the earlier, but now out of date, arc process and because the raw materials—coal, limestone,

11. Wilbur A. Nelson, State Geologist, Nashville, Tennessee.

12. One horse power is equal to 0.746 kw., or one kilowatt is equal to 1.34 h. p.

13. For further discussion see Part 3 "The Air-Nitrogen Processes"—U. S. Department of Commerce, Trade Information Bulletin No. 240.

and nitrogen—are obtainable in many places. The synthetic ammonia process is rapidly rendering the cyanamid process commercially obsolete as a method for fixing atmospheric nitrogen for fertilizer purposes. It uses less than one-third of the power required for the cyanamid process and this power need not be electric energy. Progress in the synthetic ammonia process makes the cost of pure hydrogen, and not power, the controlling economic factor. This plant, including the Waco Quarry, represents an investment of about $67,000,000.

44. Future Market for Muscle Shoals Power. Electric power has completely revolutionized industrial living and social conditions in parts of the South. In Alabama, east Tennessee, Georgia, and the Carolinas, hydro power is largely employed in various industrial and textile activities. Western Tennessee and practically all of Mississippi have already been touched and are waiting for this development program.

The absence of income or inheritance taxes in Alabama and other taxation inducements, make this state an exceptionally favorable one for the investment of capital for carrying on industrial activities.

Abundant reserves of non-migratory, reliable, English speaking, intelligent, white labor, accustomed to simple living and living close to food supplies with small fuel needs for house heating and lack of labor concentration with attendant housing problems, give the South an advantageous mill labor situation for converting its raw cotton into the finished product right in the South, providing dependable and continuous electric power service is available.

The shortened transportation of the raw cotton, by finishing the product in the South, is, of course, also advantageous.

The southern negro, living here in his natural and normal habitat, employed extensively for common labor, because of his tractability, is rarely susceptible to the disturbing influence common where the foreign element dominates the labor field, and is a distinct labor asset for the heavier tasks.

The South is growing rapidly and there has been a marked exodus of the cotton industry from the New England states to the South. The number of wage earners, the annual million pounds of cotton manufactured, number of active spindles, and primary horse power employed in cotton industry is increasing much faster in the southern states than in the north.

The per cent of cotton produced, that is, converted into the manufactured product is for:

Mississippi..................	5 per cent
Louisiana....................	13 per cent
Tennessee....................	31 per cent
Alabama......................	44 per cent
Georgia......................	111 per cent
North Carolina..............	141 per cent
South Carolina..............	174 per cent

That is, the last three states are fabricating more cotton than they are producing and are, therefore, importing from other producing states, due primarily to the advantageous labor and electric power conditions.

Within the limits of the Tennessee River Basin and where power will be required for development, at least 50 mineral substances of economic value are found.

"Special emphasis should be placed on the large phosphate deposits of middle Tennessee; the extensive coal fields of northern Alabama and eastern Tennessee; the fine ball clays of western Tennessee, which are used in making electrical insulators and other high-grade articles; the great marble copper mines at Ducktown; the unlimited deposits of limestone of the purest quality, suitable for making high grade lime and other similar uses; to the iron ores of Alabama and Tennessee and the bauxite deposits of eastern Tennessee and northern Georgia."[14]

Securing lower labor and lower production costs is, of course, of vital interest to the public at large. There has been all too little appreciation of the fact that every man's wage is a part of some other man's cost of living.

"It therefore appears that a broad and well-founded judgment would dictate that the Muscle Shoals development should be interconnected for exchange of power with the existing power systems of the Southern States, and that this interconnection and exchange should be arranged for without delay, so that future construction, both at Muscle Shoals and elsewhere, can be directed for the production of plants which will supplement each other for economy of construction and operation."[15]

In conclusion, within easy transmitting distance from Muscle Shoals, there is an adequate, existing, electric-power market that can promptly absorb all of the electric power that can be developed. This market can be economically reached and effectively served only as Muscle Shoals is made part of an integrated, interconnected transmission system, so that advantageously located steam plants and storage reservoirs can be used for supplementing the otherwise practically valueless secondary power at Muscle Shoals.

Hydroelectric Development of the Saguenay River

The Duke-Price Power Company, Ltd., at Isle Maligne, Quebec, Canada

BY W. S. LEE[1]

Fellow, A. I. E. E.

Synopsis.—*The building of the Isle Maligne Station in a remote section with extreme difficulties due to weather and floods, called for very careful planning and coordination of the various parts of the work. The steps in the construction of this plant are shown perhaps at rather extreme length, but this is done largely to bring out the value and importance of designing with the idea of cooperating and coordinating with the contractor or the construction forces. The design and layout of the construction plant were given as much attention on this work as the design of the powerhouse. The writer maintains and endeavors to impress upon designing and construction engineers of any large project, this very important cooperative feature. Had this not been done at the Isle Maligne Station, the great amount of work could never have been executed in the same length of time.*

THE largest single installation in water-power development ever undertaken is at Isle Maligne on the Saguenay River, Province of Quebec, Canada, where a total power-house installation of 540,000 h. p. is being made, of which 360,000 h. p. is completely, and 180,000 h. p. partially installed.

The Saguenay River is one of the great tributaries of the St. Lawrence River and flows out of Lake St. John by two channels, the Grand Discharge and the Little Discharge. These two channels unite at a point nine miles below the Lake outlet, and thirteen miles further downstream the Saguenay River reaches tidewater.

Lake St. John is located about 100 miles north of the City of Quebec. Its normal water level is 310 ft. above mean sea-level and the drainage area of the Lake is estimated to be 30,000 sq. mi. Since 1913, the Quebec Development Company, Ltd., has been maintaining a gaging station on Lake St. John and the zero point of the gage corresponds to the mean low-water level in January. By a grant of the Government, the Power Company is permitted to utilize the storage capacity of Lake St. John between ordinary low water and ordinary high water, which is estimated to be 187.1 billion cu. ft. in a depth of water of 17.5 ft., based on the survey of the Quebec Streams Commission. The superficial areas of Lake St. John for various gage readings are as follows:

TABLE GIVING AREAS OF LAKE ST. JOHN FOR DIFFERENT ELEVATIONS OF ITS WATER-SURFACE

Gage Reading Ft.	Area of Lake Sq. Mi.
0	328
5	380
10	394
15	403
17.5	408

The daily discharges of Lake St. John, observed during the year 1922 before the water power development was commenced, are shown on curve, Fig. 1. It will be noticed that the curve is pretty regular, due to the natural storage effect of Lake St. John. The bulk of the water from Lake St. John passes through the Grand Discharge and in winter time the Little Discharge is practically dry.

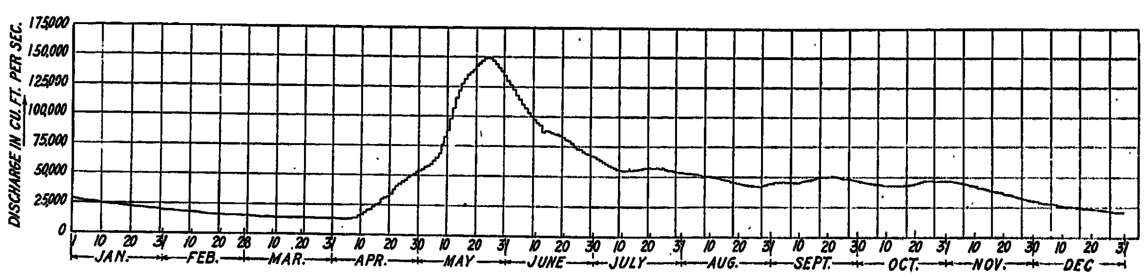

FIG. 1—DAILY DISCHARGE CURVE OF SAGUENAY RIVER 1922

Isle Maligne, the last of the many islands in the Grand Discharge is about 1¼ miles long and divides the stream-bed into two rocky gorges. Its foot is two miles above the junction of the Grand Discharge with the Little Discharge and at the first-named point the mean low-water level of the river is 105 ft. below the ordinary low-water level of Lake St. John and 122.5 ft. below the level of the fully impounded Lake.

1. Southern Power Co., Charlotte, N. C.

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, June 22-26, 1925.

After exhaustive studies, it was decided to locate the power house in the left channel of the Grand Discharge at the downstream end of Isle Maligne and to close up the right channel at the upstream end of the Isle Maligne by a spillway, the difference in normal water elevations between these two points being 45 ft. At this spillway site, called No. 4 on the general map, Fig. 2, the river is deeply cut in rock and it was necessary to provide additional spillways on Isle Maligne, which is barely covered with soil above its granitic formation. Finally an earth dam was required in the ravine near Spillway No. 4, on Alma Island between the Grand Discharge and

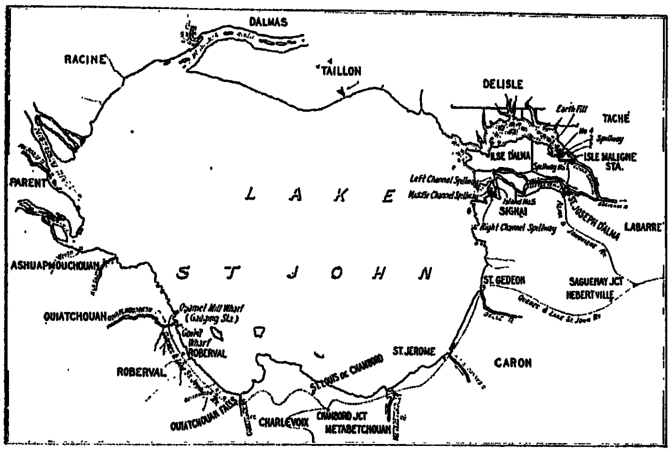

FIG. 2—GENERAL PLAN OF DEVELOPMENT

the Little Discharge, so as to extend Lake St. John to the intake structure of the power house. As previously mentioned, the Little Discharge is practically dry in winter time and its head consists of three small, rocky channels, calling for a comparatively small quantity of masonry for the confinement at this point of the impounded Lake St. John.

It will be noticed that this layout permits the drawing of the water into the turbines directly from the natural storage of Lake St. John, from an average depth of about 20 ft. under its surface, and no trouble is anticipated by ice which is from two to three feet thick on Lake St. John in the winter time. Furthermore, the ice will melt directly and the Lake is usually drawn down at the end of the winter season, thus making the water available for use through the turbines at a very opportune time.

RAILWAY TO POWER SITE

Authority to begin with the construction of this undertaking was given in December 1922 and the schedule called for the completion of the entire development by January 1926. At that time, Isle Maligne, where the principal amount of the construction was to be done, was practically inaccessible and severe winters of long duration were to be faced. The nearest railway station was Hebertville, on the Canadian National Railway Line, about eleven miles south of the power site, and the nearest settlement was St. Joseph d'Alma on the Little Discharge, which was connected with Hebertville by a fairly good highway, but with heavy grades, extending to, and crossing, the Grand Discharge on a covered wooden bridge one mile below Isle Maligne. Beside getting in the employes and doing some sledge haulage of materials and supplies for the preliminary work of the first winter, the highway was not considered of much use. A railway provided a short haul, with reasonable grades, unbroken shipments, load capacity, volume of traffic and means of handling the snow, none of which were available by any practicable road. Moreover, a railway was an integral parcel of a complete power development, giving a shipping outlet to any further industrial development, such as the planned paper mills at St. Joseph d'Alma, and, extended by service tracks to the spillways and other parts of the work, it completed a positive construction function. Therefore construction for an eleven-mile railway line from Hebertville Station to Isle Maligne, as shown on the map, Fig. 2, was begun immediately. This line crosses the Bedard River, a low- and high-water channel of the Little Discharge, above St. Joseph d'Alma and the right channel of the Grand Discharge at the foot of Isle Maligne. The track is ballasted and laid with 70-lb. rail and all bridges are steel on concrete piers, the longest being that to Isle Maligne. As shown on Fig. 3, this latter bridge consists of two 90-ft. long and one 220-ft. long truss spans for double track service. Because the rapid and deep current in the river was practically doubled in volume by the diversion of flow from the left channel, by a cofferdam at the head of

FIG. 3—VIEW OF BRIDGE ACROSS RIGHT CHANNEL OF GRAND DISCHARGE AT FOOT OF ISLE MALIGNE, LOOKING DOWNSTREAM

Isle Maligne, (described elsewhere in this article), and did not permit the use of falsework, the large span was erected by the cantilever method from the 90-ft. approach span. The railroad was completed to the terminal, at the Grand Discharge opposite Isle Maligne, the middle of August 1923, and transportation, across the bridge to Isle Maligne, was started the end of October 1923.

CONSTRUCTION CAMP

The next important step was to provide means of housing and feeding sixteen hundred workmen and to furnish homes for the company's employes and their

families. The plateau above the railroad terminal on Alma Island opposite Isle Maligne and overlooking the construction operations in the south, was the most favorable location for a construction camp, inasmuch as it was close to the works and provided natural drainage. It is called Isle Maligne and has been made an official postal station. Fig. 4 is a general plan of the camp, and Fig. 5 is a partial view showing the type of buildings

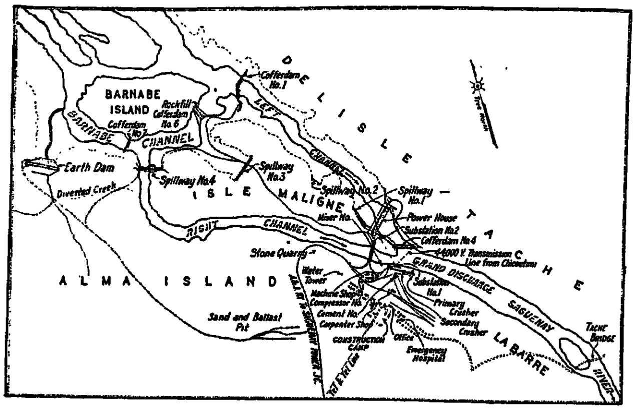

FIG. 4

constructed. All buildings have sewerage and water supply, are electrically lighted and furnished with stoves.

Particular attention has been given to the water supply. Water from the river is pumped to a 20,000-gal. tank on a hill above the camp, and thence distributed over the camp and works. The distribution was rather expensive because of the cold climate. All

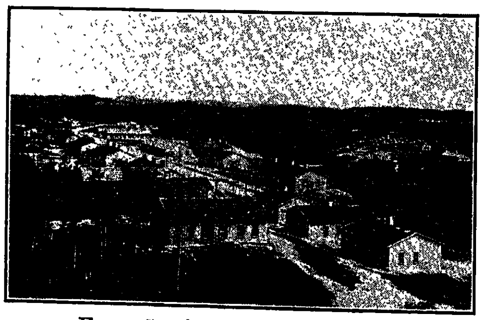

FIG. 5—CONSTRUCTION CAMP

pipes had to be placed at least six feet under ground to prevent freezing and much of the trenching was in rock. Chlorination was also employed. While the large volume of river flow made the danger from pollution rather remote, it was felt necessary to guard against typhoid as fully as possible and a chlorination plant was installed.

The camp was made self-contained, since the community is isolated, particularly in wintertime; a store, bank, post office and hospital were provided in addition to the usual dining halls, also bunk houses and cottages and one of the common rooms provide means for a school. There is also a resident physician.

A chart showing the number of laborers employed each day during the year 1924 is given in Fig. 6.

Construction Plant

Having the location and type of permanent structures fixed, and the volume of work to be done determined, progress schedules were prepared, giving the time allowed for the completion of each structure, keeping always in mind the fact that climate and stream flow set the time when certain construction operations could be begun and must be finished.

As the illustrations indicate, the main construction items are concrete masonry and excavation, largely in

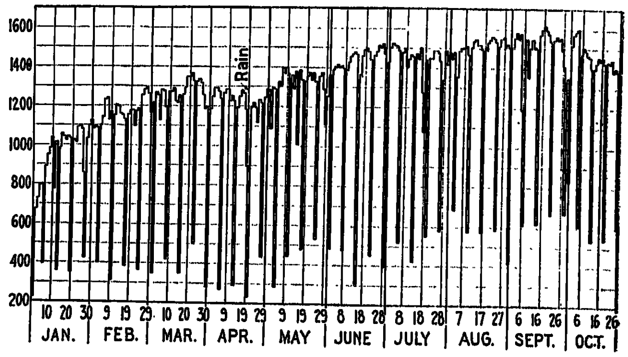

FIG. 6

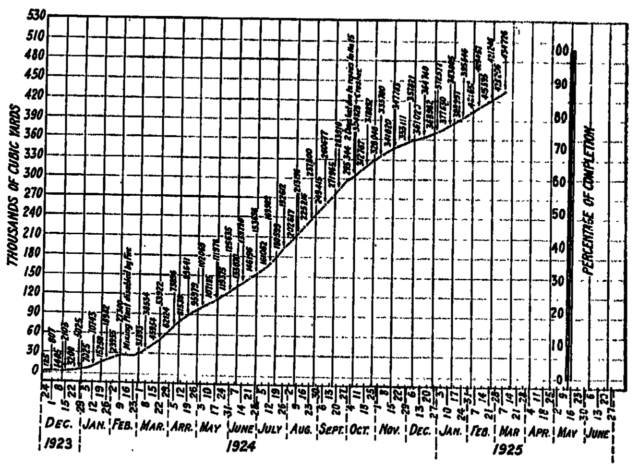

FIG. 7

rock, besides the steelwork for the turbines and powerhouse.

The estimated masonry quantities in the Grand Discharge are as follows:

	Cu. Yds.
Powerhouse Bulkhead & Substructure	288,000
Powerhouse Bulkhead Extension	40,500
Splashwall & Retaining Walls	10,000
Spillway No. 1	51,500
Spillway No. 2	3,000
Spillway No. 3	29,000
Spillway No. 4	80,000
Total	502,000

The estimated quantity of masonry in the Little Discharge is 20,000 cu. yd.

A weekly progress chart, showing the amounts of masonry placed in all the structures combined, to end of February 1925, is shown on Fig. 7.

The estimated quantities of excavation are as follows:

Tail-race	165,000 cu. yd.
Masonry Foundations	155,000 " "
Total	320,000 " "

Connecting with the railroad terminal on Alma Island, a track system was laid out to all structures and con-

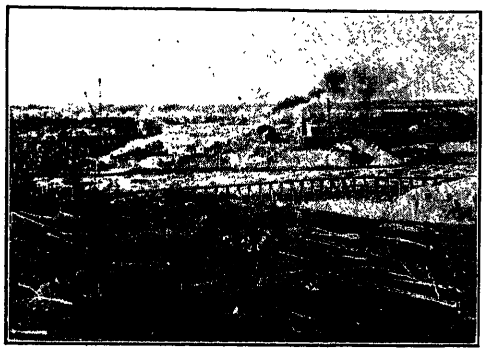

Fig. 8—Crusher and Mixer Plant

way No. 1 are 1000 ft. away, Spillway No. 2, 2500 ft., Spillway No. 3, 4000 ft. and Spillway No. 4, which is approached at both ends, is two miles away, on Isle Maligne and 2.7 miles on Alma Island. In the Little Discharge for the construction of the isolated spillways containing a comparatively small quantity of masonry, an individual mixer plant was provided.

As shown in Fig. 9, with a typical elevation of the crusher and mixer plant, the equipment consists of the following:

A. Crusher Plant:

One 66 by 84 in. manganese steel fitted jaw-crusher, driven by one 400-h. p. motor, 360 rev. per min.

One No. 15 manganese steel fitted gyratory crusher, driven by one 200-h. p. motor, 860 rev. per min.

Four No. 6 manganese steel fitted gyratory-crushers, driven by two 150-h. p. motors, 860 rev. per min.

Two 60 in. by 12 ft. 0 in. long scalping screens driven by one 50-h. p., 860-rev. per min., motor.

Two 72 in. by 24 ft. 0 in. long finishing screens driven by one 75-h. p., 860-rev. per min. motor, each.

One 42 in. belt conveyor, 174 ft. long, driven by one 75-h. p., 860-rev. per min. motor.

One 42 in. belt conveyor, 274 ft. long, driven by one 100-h. p., 860-rev. per min. motor.

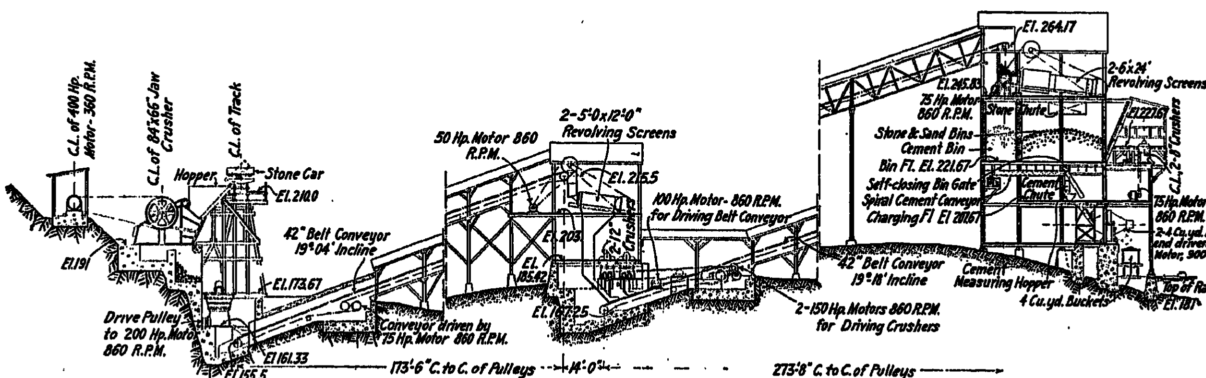

Fig. 9

struction plant units, practically eliminating job haulage by any other means. The maximum grade is three per cent, allowing for compensation in the curves and 70-lb. rails were used for the 15 miles of service tracks.

Since the bulk of masonry was to be placed near the foot of Isle Maligne, the crusher and mixer plant was placed on the Alma shore near the double track bridge across the right channel of the Grand Discharge. There, the topographical conditions were favorable for the layout of a gravity crushing plant; a large sand pit and quarry, supplementing the stone supply from the tail-race excavation, were also close by along the railroad to Hebertville, and cement could be quickly brought in. A panoramic view of the crusher and mixer plant is shown on Fig. 8 and its location and the layout of the service track system is indicated on the map, Fig. 4. Considering the mixing plant as the center, it will be noticed that the power house and spill-

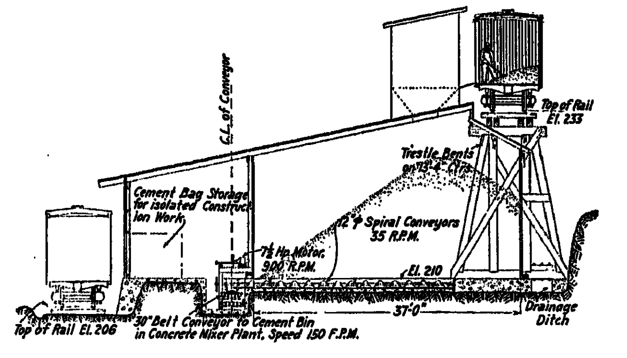

Fig. 10

One set transmission machinery for driving the four No. 6 crushers with two motors.

One set transmission machinery for driving the 203-foot long belt conveyor.

One set transmission machinery for driving the 293-foot long belt conveyor.

One set transmission machinery for driving scalping screens.

One set transmission machinery for driving finishing screens.

All motors are of the slip-ring type, 40-deg. rating, 2200-volt, 60-cycle, three-phase, each equipped with drum starter, with resistance for two-minute starting duty. Each motor (with the exception of the 400-h. p. motor which has a rope sheave for driving the jaw-crusher), is provided with sliding base rails and pulley. All these motors have also dust proof bearings and covers for the slip rings.

The scalping screens are perforated with two-in. round holes, and the finishing screens have dust jackets perforated with ½-in. diameter holes.

The maximum capacity of the crusher plant is 400 tons of two-inch ring-stone per hour.

B. Mixer Plant:

Two stone bins, of 510 cu. yd. capacity each.

One sand bin, of 540 cu. yd. capacity.

Two 4-yd. Smith tilting mixers on steel skids, with gated batch hoppers on steel frames, each driven by a 75 h. p., 2200-volt, 900-rev. per min. induction motor.

One 30-in. wide cement belt conveyer driven by one 10-h. p., 220-volt, 900-rev. per. min. induction motor.

Two 100-h. p. boilers for heating mixing water.

One 90-h. p. boiler for heating sand.

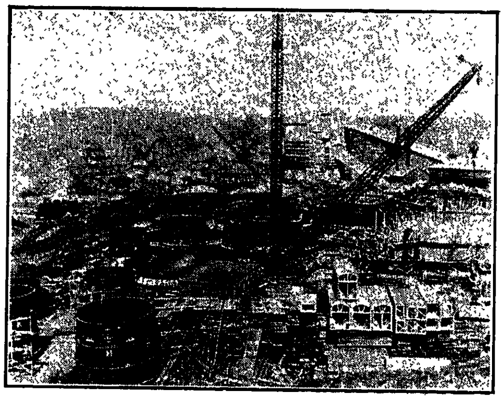

Fig. 11—Shop Manufacture of Draft Tube Forms

The cement house, a typical cross-section of which is shown on Fig. 10, is laid out for the handling of cement in bulk, with a storage capacity corresponding to 75,000 bags. A screw conveyer, running in a groove at the bottom of each cement bin, feeds the belt conveyer to the mixer plant. Only a small quantity of cement is shipped and stored in bags, available for isolated work.

The maximum output of the concrete mixer plant was, on September 26, 1924, amounting to 676 batches of 4 cu. yds. concrete.

Excavating Plant

For the earlier operations in connection with the cofferdam construction at the head of Isle Maligne and the service track construction, an 8 by 8 in. gasoline engine-driven portable compressor of 210 cu. ft. per min. displacement and a stationary steam-driven compressor of 340 cu. ft. per min. displacement supplied from one 100-h. p. boiler, were used.

The main air-compressor plant is located on Alma Island, 300 ft. south of the bridge to Isle Maligne. It consists of two 350-h. p. 2200-volt, 200-rev. per min., three-phase, 60-cycle synchronous motors, direct-connected to cross-compound compressors of the clearance-control type. Each compressor has cylinders of 25- and 15¾-in. diameter, with 18-in. stroke, and a capacity of 2033 cu. ft. of free air per minute.

The rock-drill equipment includes high speed drills on tripods and jack hammers. The drill steels are sharpened by three "Leyner" sharpeners after the drills are heated in oil furnaces.

A separate compressor plant, of 350 cu. ft. per min. free air capacity, is provided for riveting. In the plate-steel work of each scroll case for the twelve turbines, there are contained 12,000 rivets, and a uniform pressure is required which cannot be continuously maintained in the service pipes of the main compressor plant.

For bulk excavation and loading of the blasted rock in the tail-race, steam shovels are employed. Three shovels are of the railway type and two smaller size shovels are fitted with caterpillar traction.

For soft excavation, wherever practicable, a hydraulic monitor is used, consisting of a four-stage, 520-ft.-head centrifugal pump, direct-connected to a 400- h. p. induction motor, having an eight-in. delivery pipe and 2½-in. nozzle.

Work Shop and Saw Mill

The machine shop, near the compressor plant, is fitted with planers, drills, lathe, shears, bolt and pipe machines and forges. It is used for maintenance of rolling stock, general repair work and the manufacture of smaller articles; it is, however, large enough for the construction of flat cars, frogs and switches, of which a number were built.

The carpenter shop, located further away from the congested track system near the crusher and mixer plant, is equipped with band, swing and rip saws, planing and jointing machines. It is principally engaged in making the multitude of forms required for the construction of the concrete masonry structures. A view of a completely assembled draft-tube form for one of the twelve turbines is shown in Fig. 11.

A saw mill is in operation during the winter months when the snow permits of logs being hauled to the site from local sources. However, all structural timber is brought in by rail and is mostly British Columbia fir. About 10,000,000 ft. b. m. timber were used on the job to the end of 1924.

Electric Power Supply

With the exception of steam shovels, locomotive cranes and railway locomotives, all construction and shop equipment is motor operated and the aggregate motor equipment is 5000 h. p.

Price Bros. and Co., Ltd. which are connected with the Saguenay Power development, have a hydroelectric plant at Chicoutimi from which they furnish the electric power. Early in 1923 a 40-mile, 44000-volt, three-

phase, transmission line was built from the Chicoutimi plant to Isle Maligne and at the works, the current is stepped down to 2300 volts for major motors and to 440 volts and 220 volts, respectively, for the minor motors and lighting circuits distributed about the camp and works, as illustrated by Fig. 4. A study of this map and Tables I and II, will furnish the essential details of power distribution and equipment.

Altogether, about fifty odd motors are required and all but two or three are of the a-c. induction type. The largest motors are 400 h. p., for the jaw-crusher and sluicing pump, 350 h. p. for the air compressors and 200-h. p. for the No. 15 crusher. The derrick motors are all 100 h. p. The advantages of electric power, for the construction plant of the Isle Maligne development, are a continuous supply from a central source, ease of distribution with the smallest loss and reduction of attendance to machines.

Equipment for Delivering Concrete

For the delivery of the concrete from the mixer plant, full-batch buckets, consisting of four cu. yd. bottom-dumping buckets, are used; also two-cu. yd. buckets for structures of smaller volume.

The concrete is handled on flat cars of 80,000- to 100,000-lb. capacity, which take four four-cu. yd. or six two-cu. yd. buckets. Certain work such as portions of the power-house substructure were built by depositing the concrete by means of chutes. For this purpose, special four-cu. yd. wooden boxes provided with steel gates were built and four of them placed on a flat car, as shown in Fig. 12. By suitable operation of the concrete train, a box is brought opposite a chute and the gate then opened for discharging the concrete directly through the chute to its final place.

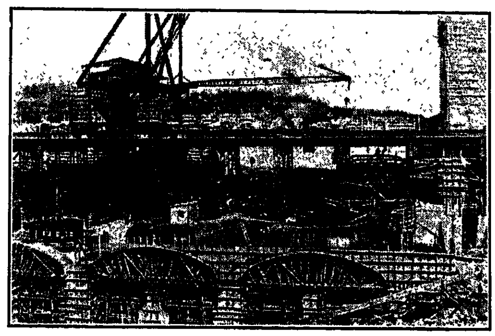

Fig. 12—Train of Four-Yard Buckets under Traveler Crane in Process of Depositing Concrete to Chutes

Hoisting Equipment

With the exception of two small wooden stiff-leg derricks, all derricks are built of steel and their capacity is in proportion to the power required for handling the four-cu. yd. bottom-dump concrete buckets. There are distributed over the various parts of the works nine steel stiff-leg derricks and six steel guy derricks. Of special interest are the five traveler cranes built for the construction of the power-house bulkhead and substructure and for subsequent use in connection with the construction of Spillway No. 4. As shown on the view, Fig. 13, each traveler crane consists of two stiff-leg derricks with individual hoisting engines mounted on top of a portal of steel construction. This portal has a length of 36 feet, a span of 43.5 ft. between centers of runways and a clearance of 19 feet above the three railway tracks, arranged within the traveler span permitting trains and locomotive cranes to pass under it. These two derricks handle a load of 10 tons per boom at a radius of 80 ft. and of 20 tons per boom at a radius of 40 ft.

The twenty-five hoisting engines for the various derricks are of the double-drum type for ¾-in. and ⅝-in. diameter rope and have interchangeable parts. Each

hoist is fitted with a 100-h. p. motor at 900 rev. per min. with suitable drum controller and resistance for three-phase, 60-cycle, 440-volt current. Based on 75 per cent of the motor horse power, the rating of the hoist is 9000 lb. at a speed of 275 ft. per min. on a single line.

The two steam locomotive cranes used on the works have a lifting capacity of 25 tons at 15-ft. radius and of 5 tons at 50-ft. radius.

Rolling Stock

As stated before, the railroad from Hebertville to Alma Island opposite Isle Maligne is 11 miles long and in addition there are 15 miles of service tracks in use on the works, all of standard gage.

The sixteen construction locomotives in operation on these tracks are 33- and 40-ton saddle tanks with 14,400-lb. and 17,400-lb. traction power, respectively. For hauling the concrete and other construction materials, twenty-two flat cars of 80,000- to 100,000-lb. capacity are used. For excavation and earth-fill work, there are available thirty-six 20-cu. yd. air-dump cars and twenty 6-cu. yd. hand-dump cars.

Designing Features of Structures

Preliminary examinations made at the sites finally selected for the power-house bulkhead and substructure, for Spillways No. 1 to No. 4, inclusive in the Grand Discharge, and for the spillways in the Little Discharge, indicated that excellent rock foundations, consisting of hard granite, were available.

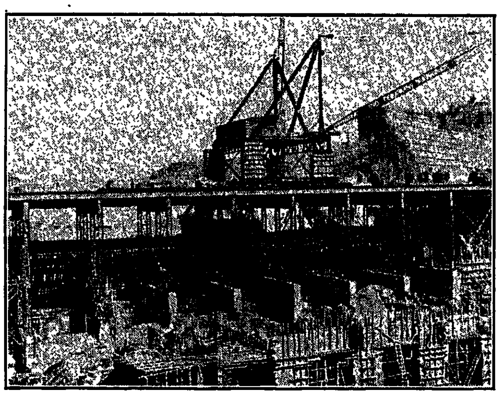

Fig. 13—View of Traveler Crane used in Construction of Concrete Work for Powerhouse

Spillways

Since 1913, daily stream-flow records of the Grand Discharge and of the Little Discharge of the Saguenay River (as well as the daily stages of Lake St. John), were taken by the Power Company.

By Government grant the ordinary high-water level of Lake St. John was fixed at el. 257.5 which is 17.5 ft. above the zero point of the gage at Roberval on Lake St. John, and, to have the full benefit of the available storage capacity, it was decided to install movable weirs or regulating gates on top of the concrete masonry spillways wherever it could be economically done. As shown in Figs. 14 and 16, the regulating gates are built of steel and are of the Stoney type, with suspended roller trains. All the gates are 40 ft. wide in the clear between piers and their top is at el. 257.5 when in closed position. The number and height of gates in each spillway and the corresponding discharge capacities with all the gates raised are given in Table III.

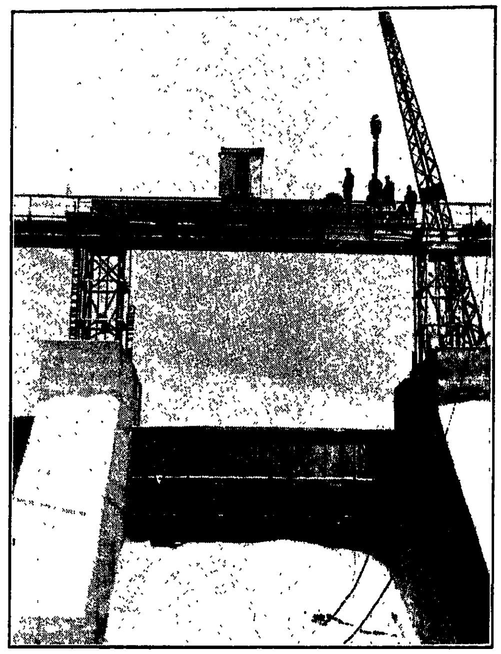

Fig. 14—Flood Gate Installed in Spillway No. 3

TABLE III
DISCHARGE CAPACITIES OF 40-FT. WIDE FLOODGATE OPENINGS IN SPILLWAYS OF GRAND DISCHARGE AND LITTLE DISCHARGE CONSIDERING WATER ELEVATION 257.5

Left "	2	17 ft. 6 in.	21,100	52,800
		Total Discharge of	Lake St. John.	469,100

Extending for a distance of about three-quarters of a mile from the outlet of Lake St. John, the Narrows of the Grand Discharge will be enlarged, thus increasing the available water areas both below the low-water level, when the present Lake discharge is not sufficient for operating all the turbines, and below the high-water level, to eliminate the gorging condition at this point.

It is not deemed practical to make any excavations in the turbulent waters of the Narrows of the Grand Discharge before the spillways are completed and the water backed up against the rapids and falls in the river. According to the construction program, this excavation work will be only partially done before the Isle Maligne Station begins operation.

Serious consideration was given to the possible effect of ice pressure. As known, the tendency of the ice is to expand at rising temperatures and where this expansion cannot freely act, it will exert pressure against the structures, causing obstruction. The maximum thickness of ice on Lake St. John is from two to three feet; however, its layers are formed under all kinds of weather

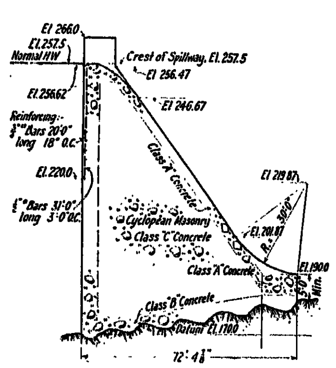

FIG. 15

conditions, which explains the fact that the unit crushing strength of the ice decreases with the increase in thickness of the ice. Furthermore, the heat transmitted to the ice, due to the rise in temperature of the atmosphere, gradually loses its intensity in the bottom layers, so that only the top layers of ice will expand and exert pressure if obstructed.

For the structures which are likely to be subjected to ice pressure from Lake St. John, an allowance of 20,000 lb. per lin. ft. of structure is made in the design. Referring to Fig. 15, showing a typical cross-section of Spillway No. 1 with masonry crest at el. 257.5, it will be noticed that steel reinforcement is provided on the upstream face to take care of the ice pressure.

A typical cross-section of Spillway No. 4, showing the arrangement of the regulating gate is given in Fig. 16. The masonry in the spillway structures is mass concrete with large stones ranging up to five tons, embedded in same to secure a good bond between the successive layers of concrete.

No silt pressure against the up-stream face of the spillways is considered, since the water carries no silt in suspension. An allowance for possible uplift at the base of the spillway is made, assuming that full water pressure, acting at the heel, decreases to zero at the toe in a parabolic function.

With the exception of spillway No. 2 and the spillway in the middle channel of the Little Discharge, neither of which have regulating gates, each spillway is provided with a crane runway, supported by steel towers, anchored to the 10-ft. thick piers between the gates. On top of each runway, there is a traveling hoist of the screw-type, designed for raising and lowering each gate at a speed of two ft. per min. under the most adverse conditions. For handling stop logs, for which vertical grooves are provided at the up-stream end of the piers, the traveling hoist is equipped with an auxiliary hoist, having a capacity of 10 tons at each end; it can be operated by the main hoisting motor and is designed for a vertical lifting speed of 10 ft. per min.

All five traveling hoists have interchangeable parts and the motors of the marine type, 550-volt, three-phase, 60-cycle are fully enclosed. The main hoist motors have a capacity of 30 h. p., each, which is based on the power required for handling the 27-ft. 6-in. gates; the motors for the traverse have a capacity of 10 h. p., each. Each screw stem of 6-in. outside diameter, is operated by a manganese-bronze operating nut, to which the power is transmitted by steel gears. The cast-iron case enclosing each hoisting mechanism contains a nest of cushion springs sufficiently strong to create gradually the necessary overload in the hoisting motor and to trip the overload-release switch in case the gate should meet an obstruction while being lowered; this device will prevent the screw stems from buckling. Four rail grippers are provided for each hoist, holding

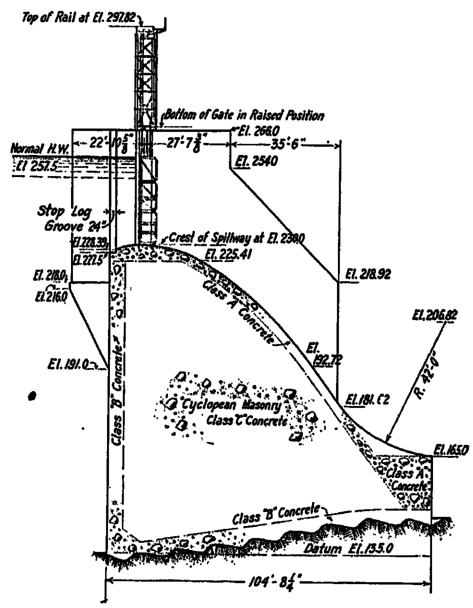

FIG. 16

the hoist to the rails while a gate is in operation. The gate to be operated is connected by steel pins to the end of the two hoisting-screw stems. On top of the piers there are stops, consisting of heavy cast-iron brackets with heavy forged steel pawls, which are strong enough to support the weight of the heaviest gate when it is in raised position and disconnected from the screw stems of the traveling hoist.

Power-House

Considering the 720-ft. over-all length of the power-house and the 163.5-ft. width of the power-house bulkhead and substructure at the base, it was deemed necessary to provide for expansion and contraction of the structure due to temperature changes. Referring to Fig. 17, which is a typical cross-section of the power-house, an expansion joint is shown between the power-house substructure and the forebay structure, beginning at el. 137.0 or 1.4 feet below the mean tail-water level and ending at the generator floor level. This joint, provided along the entire building, separates the massy bulkhead structure from the cut-up substructure containing the turbines. The plate-steel intake pipes embedded in the bulkhead masonry are connected to the respective turbine spiral casings by

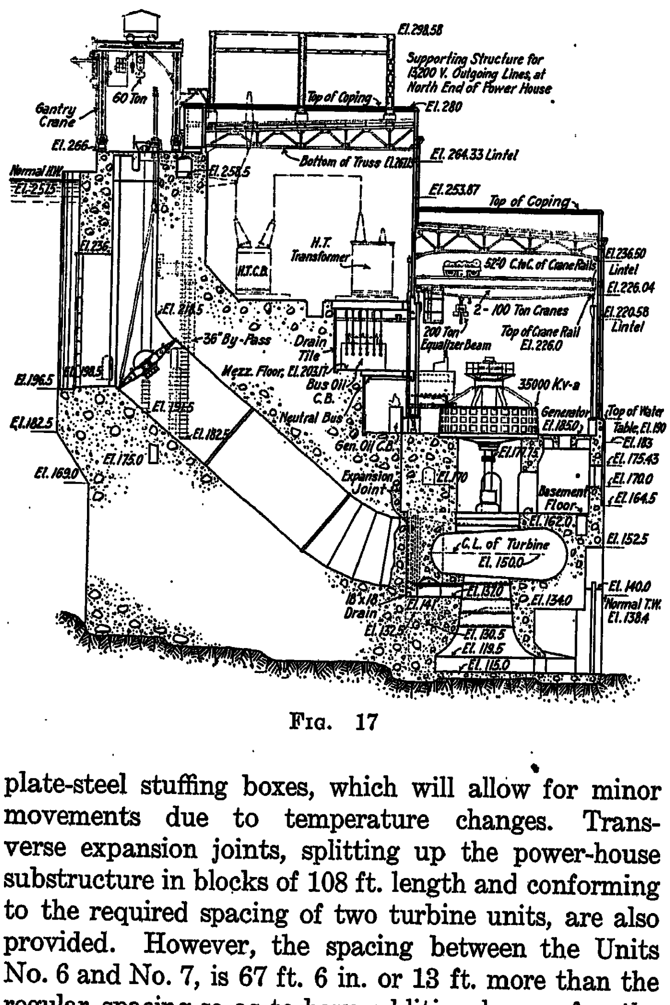

Fig. 17

plate-steel stuffing boxes, which will allow for minor movements due to temperature changes. Transverse expansion joints, splitting up the power-house substructure in blocks of 108 ft. length and conforming to the required spacing of two turbine units, are also provided. However, the spacing between the Units No. 6 and No. 7, is 67 ft. 6 in. or 13 ft. more than the regular spacing so as to have additional room for the accommodation of the electric bench-board.

The rack structure at the up-stream face of the power-house bulkhead is built of reinforced concrete and structural steel. The top of the rack bars is at el. 236.0 or 4 ft. below the ordinary low-water level of Lake St. John. The spacing of the 6 by 3/8-in. rack bars is 4 1/2 in., center to center.

The intake to each of the twelve turbine flumes consists of two 16 by 22 ft. openings formed in the concrete masonry. Each opening contains a rectangular gate of the butterfly-valve type, having in the center a cast-steel girder of 2 ft.-8 in. depth and of 2 ft.-6 in. width, with bronze-bushed trunnions of 18 in. outside diameter and 24 in. length at each end. The wings of cast iron are firmly attached to the girder by machine bolts and shrink rods. A built-up cast-iron wall frame securely anchored to the masonry is provided with machine-finished surfaces at its lower half at which point the surfaces of the gate and wall frame come in direct contact. The upper half of the wall frame has machine finished bevelled faces conforming to similar surfaces of the gate. The slot between the upper half of the gate and the wall frame is sealed by a set of brass flaps attached to the upstream side of the wall frame. Each gate is operated by an individual, completely enclosed hoist located on top of the power-house bulkhead as outlined on Fig. 17. The design of the gate is such that the connecting rod, consisting of a 9 in. extra heavy steel pipe, is in tension under all operating conditions. To prevent buckling of the connecting rod when the gate is reaching its lowest position the upper pin connection of the rod is machine-slotted for the pin in the cross-head to allow a 4 in. overtravel on the downward stroke. There is also a nest of heavy coil springs in the gear housing of the hoist which will act as a cushion for the operating stand in the range of over-travel on the downward stroke and gradually create the necessary overload, causing a tripping of the overload release switch. An allowance of 24 in. for overtravel on the upward stroke is made by proportioning the length of the screw stem and cross-head guide. A gate-position indicator is provided on top of the hoist, also a limit switch arrangement of moisture and spray-proof construction.

Direct-current, 230-volt, electric power is supplied for the operation of the hoists. Each headgate motor is completely enclosed, and has a starting torque of 275 ft.-lb. and a running torque of 140 ft.-lb., based on six minutes' service with a temperature rise not exceeding 55 deg. cent. Under the most severe operating conditions, the gate may be completely closed or opened in five minutes. A weather-proof push-button control station is provided for each hoisting mechanism on top of the bulkhead, and a non-weather proof control station on the power-house benchboard for distant closing of each gate. The emergency push-button control on the switchboard is for use in accidents only as the intake gates can be readily closed when the generator is operating under full load.

Each of the twelve turbine flumes formed in the concrete masonry of the power-house bulkhead gradually converged into a 22-ft. diameter opening which is the beginning of the plate-steel intake pipe forming an extension of the turbine spiral casing embedded in the power-house substructure.

Due to the fact that the turbine draft tubes are of the White hydro-cone design, calling for large openings in the lower part of the power-house substructure, considerable steel reinforcement was required in this portion of the structure to take care of the superimposed loading.

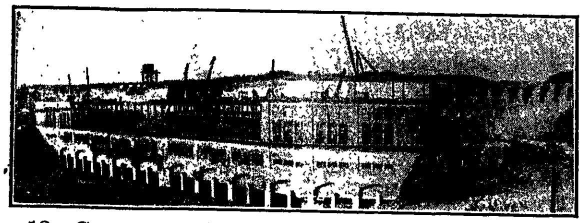

FIG. 18—GENERAL VIEW OF INCOMPLETE POWERHOUSE, LOOKING UPSTREAM

The power-house superstructure, shown in Fig. 18, is built of hollow tile and face brick of buff color which encase the structural steel frame supporting the roof

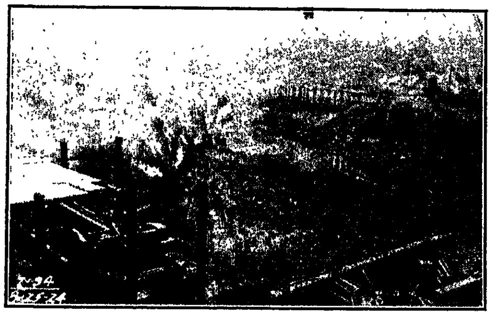

FIG. 19—EXCAVATION WORK IN TAILRACE

trusses and the steel runways for the two 100-ton capacity electric cranes in the generator room. The hollow tile face in the interior of the power-house is covered with plaster and finished with a coat of paint.

the tail-race is estimated to be 50,400 cu. ft. per sec; for eight units it is 33,600 cu. ft. per sec. Measured at the bottom the width of the tail-race immediately below the downstream face of the powerhouse is 657.5 ft; the depth below normal watersurface is 23 ft. The total length of the tail-race to the foot of Isle Maligne where it joins the Grand Discharge is 800 feet, of which the downstream portion of 240-ft. length has a bottom width of 300 ft. The maximum velocity of water in the tail-race is estimated to be 8.1 ft. per sec. with all 12 turbines operating at full load.

Practically all of the tail-race excavation consisted of hard rock, as may be seen on the illustration, Fig. 19.

EARTH DAM

The only structure to withstand water pressure, which is not built of masonry, is the earth dam across the ravine near Spillway No. 4 on Alma Island. Preliminary examinations and test borings made at the site disclosed the fact that below the 10 ft. thick overburden of muskeg there is a layer of impervious clay of about 15 ft. thickness before rock formation is struck. It was, therefore, decided to wash out the layer of muskeg by means of a hydraulic monitor and to build a semihydraulic fill with a clay core in the center and slopes as indicated on the cross-section, Fig. 20.

The earth dam has a length of 650 ft. measured on top. The upstream slope is covered with riprap for protection against the action of waves and ice.

STATION INSTALLATION

The power-house design calls for the installation of 12 vertical-shaft, single-runner, Francis-type turbines, having plate-steel spiral casings and operating at a speed of 112.5 rev. per min. Eight turbine units are now completely installed and all the parts which go into the concrete for the four additional units are in place.

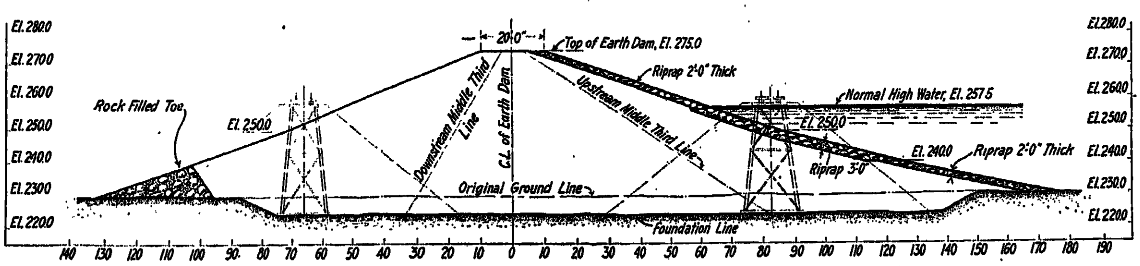

FIG. 20

The generator floor and the 5-ft. high inside face of the concrete water table are covered with glazed tile. The large window sashes are built of steel and are securely attached to the steel columns supporting the roof trusses. The roof consists of reinforced gypsum slabs resting on steel purlins and the top of the slabs has a finish of tar and gravel.

TAIL-RACE

When all twelve turbines are operating at full load and under 110 ft. effective head, the total discharge into

The range in head on these turbines is between 100 ft. and 120 ft. and within these limits the rating of each unit is as follows:

Head in feet	100	105	110	115	120
Horse power at best efficiency	35,000	37,500	40,000	42,500	45,000
Maximum horse power	40,000	42,500	45,000	47,500	50,000

An individual governor system operating under an oil pressure up to 220 lb. per sq. in. is provided for each turbine, and the piping is so arranged that the governors

may be operated separately or as an interconnected system in units of four, each. The governor fly-balls are directly connected to the turbine shaft below the rotor. The governor stands, gear-type oil pumps, pressure tanks and receiving tanks are located in the spacious power-house basement or, better expressed, in the turbine room. An emergency-stop device is installed for each turbine, enabling the operator at the benchboard to shut the turbine gates and stop any machine without the assistance of an operator in the turbine room.

The closing time for the governor for the full stroke of the servo-motors is three seconds.

The eight generators directly connected to the turbines now completely installed have a continuous full load rating of 30,000-kv-a. or 24,000-kw. at 80 per cent powerfactor, 13,200-volt, three-phase, 60-cycles, 112.5-rev. per min. They are guaranteed for a temperature rise, not to exceed 55 deg. cent.; the required exciter capacity is 185 kw. Each generator will carry 35,000 kv-a., continuously at normal voltage and 80 per cent power factor, with a temperature rise, not exceeding

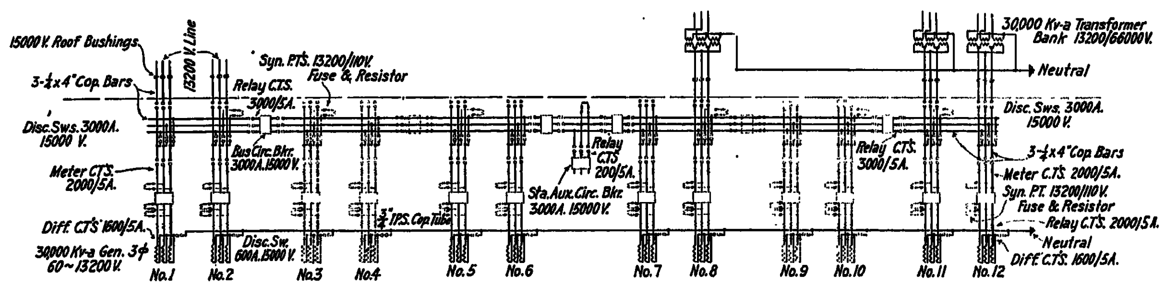

FIG. 21

70 deg. cent. by thermometer, and with a required exciter capacity of 210 kw. It will also carry 24,000 kw. continuously at 15,180 volt and 80 per cent power factor. The guarantees are based on the cooling air having a temperature of 40 deg. cent. or lower. Each generator is equipped with an upper and lower guide bearing. The thrust bearing on top of the generator is of the Kingsbury type and its housing is provided with water cooling coils.

The individual exciters placed above the thrust bearings have a full load rating of 185 kw. at 250 volts and 112.5 rev. per min. and are guaranteed for a temperature rise not to exceed 40 deg. cent. Followed by 225 kw. load for 24 hours, the temperature rise is not to exceed 50 deg. cent.

The oiling system of each generator unit is self contained and automatic in operation. The thrust bearing is immersed in an oil reservoir containing water-cooling coils located on top of the upper bearing bracket. A gear pump, mounted in a smaller oil reservoir located below the lower bearing bracket, is driven by a gear on the generator shaft and forces the oil to the upper thrust bearing reservoir. Proper pipes also conduct the necessary oil to the two guide bearings and the overflow oil from each bearing is carried back to the lower reservoir for recirculation.

Large brakes are provided for four of the eight arms of the lower generator bearing bracket. If operated by air pressure, the brakes will stop the generator with the turbine gates closed and if operated by oil pressure from the governor system, the brakes may be used as jacks to lift the rotor. Cast-iron stools are provided for mounting on the bracket arms to support the rotor when lifted.

The generator armature is star-connected and the six leads are brought out from the upstream side of the generator. By means of a 15,000-volt disconnecting switch, the neutral tie is connected to the neutral bus consisting of a ¾ in. copper tube suspended by porcelain insulators to the mezzanine floor along the upstream side of the power-house and it is then grounded outside of the station.

A diagram showing the connection of the main generator leads with the low-tension bus system is shown on Fig. 21. It will be noticed that the connections from the generators No. 3, 4, 9 and 10, which are left blank, are indicated by dotted lines. The generator leads and the transfer busses are built up of three ¼ by 4 in. copper bars and the spacing between conductors is 18 in. Normally each generator feeds its own transmission line and the duty of the low-tension bus system is to transfer power from another generator in case of emergency and to provide the means for delivering power to the transformers for the station auxiliaries.

The triple-pole, single-throw generator and bus oil circuit breakers are identical in construction and of the same capacity. The rating of each circuit breaker is 3000 amperes at 15,000 volts and the guaranteed interrupting capacity is 65,000 r. m. s. amperes at 13,200 volts. The cell structure for the breaker is of reinforced concrete and each pole is mounted on a casting provided with wheels to enable rapid roll-out for inspection. An electrically-operated motor mechanism is provided for each breaker and arrangement is made for emergency manual operation. Direct-current power at 230 volts, for the operation of the mechanism, is furnished from a 25-kw. motor-generator set.

The benchboard is located on an extension of the mezzanine floor into the generator room between units No. 6 and 7. It is of the continuous closed type and

has a length of 40 ft. The auxiliary vertical board containing recording ammeters, volt-meters, watthour meters and relays is 16 ft. 4 in. long and 7 ft. 6 in. high.

The control circuits are for 230 volts and the lighting circuits for 115 volts. They are placed in 1½ in. diameter pipe conduits embedded in the generator and mezzanine floors and the estimated aggregate length of conduits in the power-house, including a number of flexible conduits, is 108,500 ft.

For station use, there are installed two banks of transformers which are located in the center of the high-tension room and each bank consists of three 200-kv-a. single-phase transformers, stepping down the

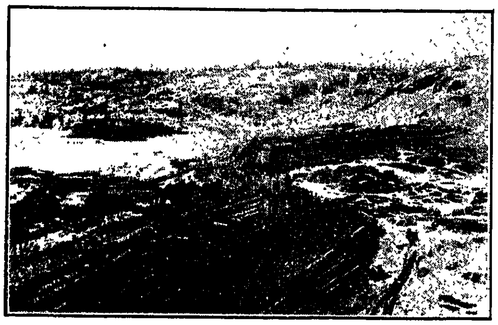

Fig. 22—Cofferdam No. 1 under Construction

voltage from 13,200 to 550 volts. The two 100-ton capacity power-house cranes, the 100-ton capacity crane for lifting and transferring apparatus from the generator room to the high-tension room, the 60-ton capacity gantry crane on top of the power-house bulkhead and the sixteen headgate hoist motors now installed, are using 230-volt direct current. The power for operating these motors is furnished by a 200-kw. motor-generator set. The three air compressors supplying compressed air for the governor system and the two air compressors for general station use are driven by alternating-current motors at 220 volts; power is furnished through three 25-kv-a. single-phase 550- to 220-volt step-down transformers. For station lighting the current is stepped down in three 25-kv-a., 550/110-volt single-phase transformers.

All these motors, including the 550-volt induction motors driving two 1200-gal. per min., 65-ft. head, centrifugal pumps furnishing cooling water for the high-tension power transformers, the 25-kw. motor generator set and all station lighting circuits, are supplied by the first bank of transformers. At present, the other bank of transformers is delivering power at 550 volts to one 150-h. p. induction motor, driving a centrifugal pump of 1200-gal. per min. capacity against a head of 400 ft., forming part of the general water supply system for the entire Isle Maligne development; provision is made for the installation of two additional pumps of the same capacity for future use.

Method of Construction

With the exception of some isolated bridge piers which were built by contract, the entire construction work for the Isle Maligne development was done by force account. The work was prosecuted uninterruptedly and while the winters were long and severe, with temperatures reaching 45 deg. below zero fahr., the snow on the ground permitting haulage on sledges; the formation of ice on the river where the current was not too swift made it easier to build cofferdams. Beginning with November, the Saguenay River gradually falls until extreme low-water is reached around the end of March; advantage of this season was taken to build the main cofferdams and temporary rock fill dams. The procedure was to build up the cribs on the ice, then to cut out the surface to be occupied by each crib and to drop and sink the crib into position. The extreme high-water stage of the Saguenay River is reached around the end of May, flood conditions lasting until the end of June. It was, therefore, necessary to build high cofferdams so as to have no delay in the construction work during the late spring and to have the full benefit of the early summer season with long hours of daylight.

Power-House Construction

The power-house construction and the tail-race excavation involved the largest volume of work to be done. The first step taken was to immediately construct the cofferdams across the left channel of the Grand Discharge at both the head and foot of Isle Maligne, so as to be able to unwater the power-house foundations and the tail-race area. The upstream cofferdam, marked No. 1 on Fig. 4, was commenced in January 1923 after a construction force had been organized. With the exception of a 200-ft. long section

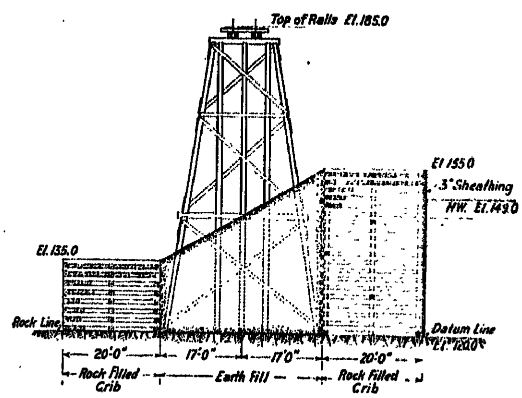

Fig. 23

across a highwater channel on the Isle Maligne shore, which was closed in the following July as the water subsided, it was completed in two months. This cofferdam is of the usual crib construction, rock filled, with two layers of 1½ in. sheathing on the up-stream face; however, its length is, 1143 ft. and its maximum height 42 ft. Fig. 22 is a view showing the cofferdam under construction:

The cofferdam at the foot of Isle Maligne, marked No. 4 on Fig. 4, was built to shut off the backwater of the Grand Discharge from the tail-race excavation and to give a footing for a timber trestle, forming part of the

construction railroad system for the transportation of excavated rock from the tail-race to the crusher plant. The length of cofferdam No. 4 is 627 ft. and a typical cross-section of same is shown on Fig. 23.

With the power-house foundations unwatered, a steel trestle of 715 ft. 6 in. length, carrying three lines of standard track and a runway of 43 ft. 6 in. gage to accommodate four traveler cranes was built. This trestle, a view of which is shown in Fig. 24, covered the entire length of the power-house and the top of rail for the three tracks was at el. 188.0, which is 50 ft. above

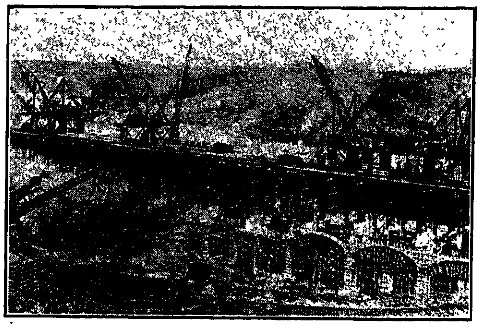

Fig. 24—Construction Trestle for Powerhouse

the normal tail-water level; it was completed during the end of December 1923, two months later traffic was started over the bridge connecting with the railroad system on Alma Island.

The steps followed in the construction of the power-house bulkhead and substructure, the relative location

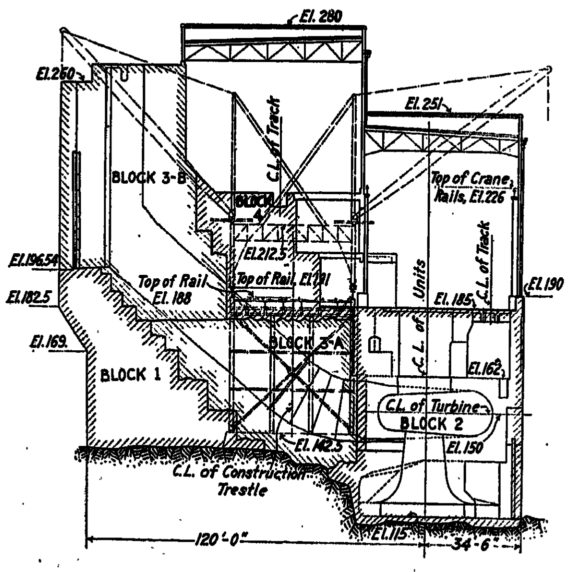

Fig. 25

of the steel trestle and an outline of the traveler crane are indicated on the section, Fig. 25. It will be noticed that the masonry is subdivided into five blocks. According to the schedule, Block No. 1 and the power-house bulkhead extension to el. 197.5, containing altogether 89,000 cu. yd., were built first so as to eliminate any possible danger from extreme high-water which cofferdam No. 1 could not safely hold back. This work was completed the middle of April 1924, six weeks before the river reached its highest stage, records being taken by the Quebec Development Company. At that time the peak of the high-water was within one ft. of over-

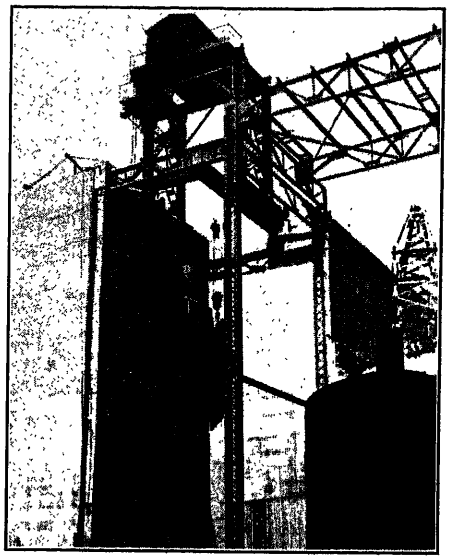

Fig. 26—Gantry Crane Lifting Headgate Weighing 54 Tons

topping the cofferdam. Block No. 2, forming the power-house substructure proper and containing 60,711 cu. yd. was completed end of November 1924; Block No. 3-b of 61,474 cu. yd. end of December 1924. In Block No. 3-a containing 53,961 cu. yd., the 28 steel bents of the construction trestle were embedded and this

Fig. 27—Uncompleted Spillway No. 1 and Its Relative Location to Right Channel of Grand Discharge

work was completed middle of October 1924. Block No. 4 of 39,527 cu. yd., the last portion of power-house masonry, was completed in March 1925.

The power-house design called for a gantry crane running on top of the bulkhead and capable of lifting any of the 24 headgates provided for the penstock intakes. This crane has a capacity of 60 tons when the main hoist is operated and of five tons with the auxiliary hoist running; in addition two bracket hoists of five tons capacity, each, are provided for lowering and raising stop logs in front of the rack structure. Immediately after completion of Block 3-b, the gantry crane was

erected, being used for unloading and lifting each headgate on top of the bulkhead and transferring and lowering same to its respective position. Each 16-ft. by 22-ft. headgate weighs 108,000 lb. and railroad clearances permitted the gates to be shipped assembled in special flat cars. A view showing a headgate being lifted by the gantry crane above the special railroad car is shown on Fig. 26.

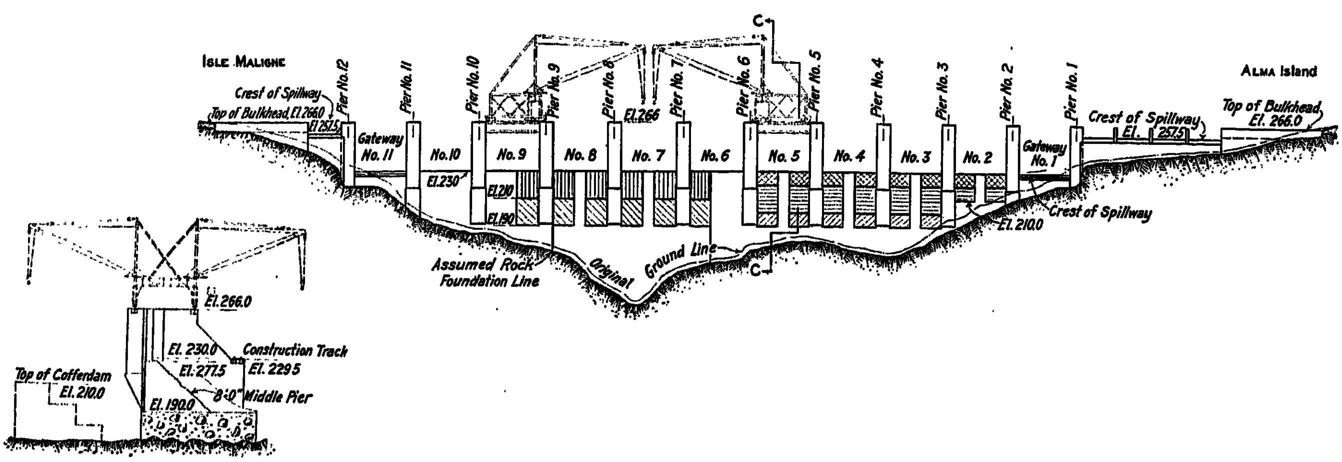

Fig. 31

Spillway Construction

The major part of Spillway No. 1, which is located on Isle Maligne and forms an extension of the power-house bulkhead at right angles to same, was built simultaneously with the power-house masonry. According to the program the right channel of the Grand Discharge at the head of Isle Maligne was closed up (as described later), on February 15, 1925; and the cofferdam No. 1 blown out so as to return the riverflow to the Left Channel and to discharge water through two of the turbines operating temporarily under a head of 70 ft. The gaps left in the masonry of Spillway No. 1 provided additional discharge capacity so that the normal flow of the Grand Discharge could be controlled during the critical construction period when the deep foundations for Spillway No. 4 were being unwatered and the masonry built up. Fig. 27 shows a view of the uncompleted Spillway No. 1 and its relative location to the Right Channel of the Grand Discharge.

Spillways No. 2 and 3 are located in natural depressions of Isle Maligne above the present highwater line, but below the final raised water level, and no special difficulties were encountered in the construction of these structures. Spillway No. 3 was completed in January 1925 and a view of same is shown on Fig. 28.

The final control of the Saguenay River and the raising of the water to the level of the Lake St. John was accomplished by the construction of Spillway No. 4 and this work called for the most careful planning, so as to complete the structure at the scheduled date. Due to the great depth and the swift current it was not found practical to build a cofferdam across the right channel of the Grand Discharge immediately above the site of Spillway No. 4 to hold back the entire stream. It was, therefore, decided to go further upstream and use the channel between Barnabe Island and Isle Maligne, where much more favorable conditions for the location of a temporary dam were encountered. This layout called, however, for the location of another cofferdam of 475 ft. length across the so-called Barnabe Channel between Barnabe and Alma Islands; but this channel was practically dry during the construction period and offered no difficulties. The temporary dam between Barnabe Island and Isle Maligne is marked No. 6 on the

general plan, Fig. 4, and it is of rock fill construction as shown on Fig. 29. This arrangement made it possible to divert the river flow into the left channel of the Grand Discharge after the cofferdam No. 1 at the head of Isle Maligne was blown out, and to discharge the water through the turbines operating under a reduced

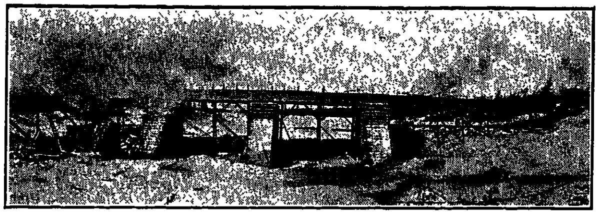

FIG. 32—SPILLWAY ACROSS RIGHT CHANNEL OF LITTLE DISCHARGE UNDER CONSTRUCTION

head of 70 ft. and through the temporary gaps left in Spillway No. 1, which accomplished the unwatering of the deep portion of the riverbed at the site of Spillway No. 4 for the construction of the masonry.

During the time that these two temporary dams were being built, concrete masonry was laid from both ends of the spillway site and steel runways placed on top of each of the completed masonry sections for the accommodation of two traveler cranes which were previously used in the construction of the power-house masonry. As shown in the illustration, Fig. 30, these two traveler cranes cover the entire deep river-bed area, which was unwatered. The method of building up the masonry for Spillway No. 4 and making the final closure is indicated on the profile, Fig. 31.

The spillways in the three channels of the Little Discharge at the outlet of Lake St. John were constructed during the winter season of 1924-1925 when only the small flow through the right channel was interfering with the work. A view showing the spillway across the right channel of the Little Discharge under construction is shown on Fig 32.

CONSTRUCTION OF EARTH DAM

The construction of the earth dam across the ravine near Spillway No. 4 on Alma Island was commenced in May, 1924. The foundation was cleared of all vegetable matter and the muskeg over-burden in the low part of the ravine removed by use of a hydraulic Monitor.

Suitable borrow pits for both the gravel dikes forming the outer thirds and the clay core of the fill were found within a short haul of the dam. The fill material was excavated with a 2 yd. steam shovel and loaded into 6 yd. dump cars made up in trains and transported by

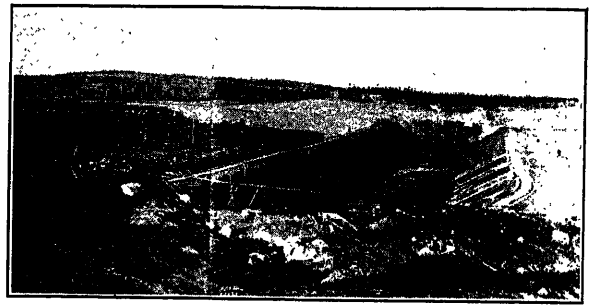

FIG. 33—EARTH DAM ACROSS RAVINE NEAR SPILLWAY NO. 4, UNDER CONSTRUCTION

locomotives to the upstream and downstream construction trestles as indicated on the typical section through the earth-fill, Fig. 20. The material was then dumped into wooden chutes placed at intervals and washed down into the pool between the two dikes by means of a hose pipe with the nozzle attached to a push car moved along the train track, as shown on the view, Fig. 33.

Work on the fill progressed until middle of December 1924, at which time the dam was 82 per cent complete and during freezing weather, occurring previous to this date, the areas of the fill on which no work was done were covered with tarpaulins and a series of steam pipes run underneath the cover.

Two-Phase, Five-Wire Distribution

Its Engineering and Economic Elements

BY P. H. CHASE[1]

Member, A. I. E. E.

***Synopsis:**—In view of the present trend toward three-phase secondary distribution involving, in some cases, a change from a two-phase system, an analysis of the engineering and economic elements of a two-phase system may be of value. The two-phase five-wire secondary system is examined in the light of fundamental requirements, such as service continuity, safety, standard voltages, flexibility, low cost, etc., and compared particularly with the three-phase, four-wire star system. Many of the advantages of the two-phase, five-wire system result from the diametrical connection of the two phases, from the inherent balance thereby obtained, and from the greater power carried per wire. An important advantage of the two-phase, five-wire system lies in the fact that single-phase, two-wire and three-wire loads and two-phase loads can be supplied at standard voltages from combination lighting and power secondaries and that new loads can be flexibly supplied through all stages of load growth. There are marked advantages from a construction and operating point of view in having ordinarily only two transformers in banks which supply two-phase secondaries from either two-phase or three-phase primaries. The two-phase, five-wire system has certain advantages as to metering and a comparison of the first cost and the annual cost of two-phase and three-phase motor installations, with wiring, shows small differences. The inherent cost differential between two- and three-phase secondaries with several types of primary systems is shown to be of such a small magnitude that the cost of change over from one type of system to another may over shadow the theoretical savings. Accordingly, with a relatively small inherent cost differential between the existent system and one having certain more or less proved advantages and disadvantages, the central station engineer must produce extremely strong arguments leading out of his local situation in order to justify a change from the existing system.*

* * * * *

ENGINEERING AND ECONOMIC ELEMENTS OF TWO-PHASE, FIVE-WIRE DISTRIBUTION

SINCE the inception of alternating current distribution, initially single-phase, there have been developed various schemes of polyphase distribution, the oldest of these being two-phase. For more than the past decade the change-over of distribution systems from two-phase to three-phase has been considerable. Usually the justification for the change-over of any distribution system lies in the particular combination of conditions which appertain to the territory and system in question. It may be unsafe to derive conclusions for any particular locality from those reached in another locality or from generalized or purely theoretical grounds.

The subject of the best type of distribution system has received intensive study by many electric companies and, in view of the present general trend to three-phase, it is felt that many of the features of a recent analysis of a system which still has two-phase distribution for its secondary and 2300-volt primary systems, will be of particular interest at this time.

For reasons which will be stated later, this paper gives consideration to secondary distribution suitable for the supply from the same mains of both light and power, with only such references to primary distribution as appear necessary for completeness. Distribution transformers, however, are treated as a part of the secondary system.

FUNDAMENTAL REQUIREMENTS

As a basis for further discussion, the fundamental requirements which must be met by any secondary distribution system, in order to meet the requirements of the customer with safety and economy, are outlined.

CUSTOMERS' AND UTILIZATION REQUIREMENTS

1. *Service Continuity.* A high degree of service continuity is required for all classes of service. This is afforded by various feeder, main and service combinations with their requisite protective equipment to afford the desired service insurance.

2. *Safety.* For a secondary distribution system, the requirement for safety is met according to present accepted ideas by a service voltage of approximately 115 from any wire to ground. Existing wiring standards and appliances allow this voltage to be handled safely for a wide diversity of applications.

3. *Standard Voltage.* The voltage for lamps has been standardized at 115 volts, with 120 volts as an allowable higher figure. The voltage for motors for combined light and power systems has been standardized at 110 and 220. Any system of distribution should conform to these basic voltage standards, established through years of experience and investigation.

4. *Voltage Regulation and Balance.* The inherent voltage regulation and balance of the secondary distribution system must be such that, with the usual voltage regulating equipment at the substation, the variations of service voltage, on all phases, and under all load conditions, will be kept within a value which will not impair illumination from lamps nor service from motors and appliances.

5. *Customers' Equipment and Wiring.* The type of distribution system should be such that the customers' equipment may be of standard, readily secured types and the wiring simple, efficient, and inexpensive.

1. Asst. Engr. Trans. and Distr., Philadelphia Electric Co., Philadelphia, Pa.

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, June 22-26, 1925.

Distribution System Requirements

1. Simplicity and Standardization. Separate or combination light and power service should be readily available from a single set of mains in order to take the maximum advantage of diversity between power and lighting loads. The distribution system should make use of standard equipment.

2. Load Balance. . The secondary distribution system should be readily adapted for service both to single-phase and to polyphase loads without material load unbalance between the phases.

3. Voltage Balance. The voltages of the different phases should remain balanced with respect to each other and to ground.

4. Adaptability to Physical Conditions. The distribution system should be equally adaptable to aerial or underground construction, to urban, suburban, and rural conditions, and to residential, commercial, and manufacturing districts.

5. Growth Adaptability. The secondary distribution system should be adaptable to all stages of load growth and load density, by means of additions and reinforcement, and with the minimum amount of reconstruction work at any stage. When the initial single-phase lighting load in residential areas eventually develops demands for polyphase service, the distribution system should be sufficiently flexible to render such service without extensive changes.

6. Investment. There should be the minimum investment in mains, services, transformers, meters, etc. The annual charges on the investment are usually the largest portion of the total annual cost of the secondary distribution system.

7. Power Losses. The secondary distribution system should have low power losses. This requirement is usually met when the requirements for voltage regulation are properly met.

8. Operating and Maintenance Costs. These costs should be low. They usually will be a fairly constant percentage of the investment.

Combined Light and Power Secondaries

The treatment of the subject throughout is based on the requirement of a system suitable for the supply of power and lighting, either single-phase or polyphase, from the same mains. A study of the economic advantages of combination mains, under assumed average conditions, points toward savings of the order of twenty per cent in the total annual cost (fixed charges and losses) of transformers, mains and services, as compared with separate transformers, mains and services for lighting and power. It is recognized that there are and will be many instances, particularly on aerial systems, where the use of separate lighting and power mains is necessary to prevent fluctuating power loads or the frequent starting of motors from impairing lighting service, and that on many systems the mileage of separate lighting and power mains greatly outweighs the mileage of combined mains.

The Two-Phase, Five-Wire Secondary System

The two-phase, five-wire secondary system is shown schematically in Fig. 1. The system is strictly a four-phase, five-wire *diametrical* system, with 115 volts to neutral. This *diametrical* connection is responsible for many advantages of the two-phase system, owing to the relative independence of the phases. If there is any virtue in the *number* of phases, surely such a four-phase system should compare favorably with the three-phase!

The two-phase, five-wire system has the following outstanding features:

1. Standard 115 volts for lamps and appliances.
2. Standard 115 or 230 volts for motors.
3. Voltage to ground balanced.
4. Load balanced.
5. Two transformers per bank.
6. Transformers or standard ratio and voltage.

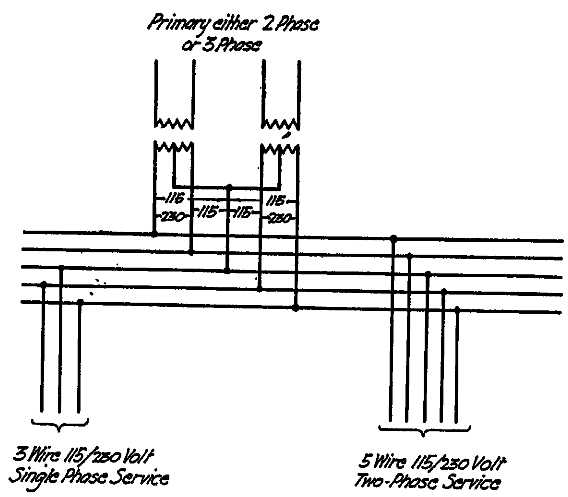

Fig. 1—Schematic Diagram of Connections for Two-Phase, Five-Wire Secondary Mains

Power per Wire

Considering the secondary distribution problem from a fundamental point of view, it will be realized that the condition which largely influences the economic advantages of one system over another is the *amount of power carried per wire.* Table I shows the amount of power per wire for various systems, all with 115-volt lamp voltage (E), assuming the same current (I), per

TABLE I
POWER PER WIRE

System	No. of Wires	Power Carried	Power Carried Per Wire
5-wire 2 ϕ 115-230 Volt...	5	4 $E\,I.$	4/5 $E\,I.$ = 0.80 $E\,I.$
4-wire 3 ϕ 115-199 Volt...	4	3 $E\,I.$	3/4 $E\,I.$ = 0.75 $E\,I.$
3-wire 1 ϕ 115-230 Volt...	3	2 $E\,I.$	2/3 $E\,I.$ = 0.667 $E\,I.$
2-wire 1 ϕ 115 Volt.......	2	1 $E\,I.$	1/2 $E\,I.$ = 0.50 $E\,I.$*

*Voltage regulation requirements will often operate to reduce this value as a comparative measure of power per wire.

wire and the same size wire. This comparison is based on equal voltage drop and therefore represents equivalent conditions for the distribution systems set forth.

The two-phase, five-wire system carries 6.6 per cent greater power per wire because, with 20 per cent more copper, it carries 33 ⅓ per cent more power than the three-phase, four-wire system having the same lamp voltage.

Inherent Advantages

Consider the inherent advantages of the two-phase, five-wire system. It has a fifth or neutral wire common to two *independent* 115-230-volt phases. A current in the neutral is caused only by a load unbalance on one side of a phase and this is ironed out in the transformers.

The neutral of the three-phase, four-wire star system, and also the transformers, will carry the resultant current due to any line—neutral load unbalance, and thus transfer the unbalance to the primary mains.

In a secondary distribution system, which ordinarily supplied both single-phase and polyphase loads of various types, there is inevitably unbalance between line and neutral loads and the effect of this upon the voltage balance of the system is inherently greater with the three-phase, four-wire star system than with the two-phase, five-wire system.

In the aerial plant, standard cross arms and racks can be utilized practically as efficiently by the two-phase, five-wire system as by the three-phase, four-wire system. Four wires utilize practically as much space as five wires and the four wires will have to be larger for the same amount of power carried under the same conditions.

In the underground plant the two-phase, five-wire system can make use of single conductor, two-conductor, three-conductor, or four-conductor cable as local duct, heating, loading, and service conditions warrant. Under many conditions, where it is economically preferable to install mains on two sides of a street, the two-phase, five-wire system affords a very flexible method of rendering service to loads largely single-phase on each side of such a street while still maintaining balanced load on the mains and phases.

With heavy load densities, the two-phase, five-wire system may readily be accommodated with one phase in each of two ducts. There is a consequent improvement in the transmission of heat from the cables and a decrease of the hazard to service from one phase in the event of a fault on the other phase. The three-phase, four-wire star system requires a voltage unbalancing arrangement of the cables if two ducts are used, unless all three phase conductors are in each duct.

Although local conditions will materially affect the handling of any underground system, it is felt that the two-phase, five-wire system has at least every advantage that the three-phase, four-wire has in best utilization of pole and duct space.

Comparison with Three-Phase, Four-Wire Star System

On the other hand, the three-phase, four-wire secondary system forces the distribution engineer into a choice of one of the following dilemmas:

1. A decrease in the motor service voltage to 199 volts nominal, with 115-volt lamp voltage. This may require the development of a new line of motors, or the de-rating or under-loading of the present line of 220-volt motors.
2. An increase in the lamp voltage to 133, thus bringing the motor service voltage to 230. This requires the introduction of a new line of lamps and appliances and a new line of distribution transformers, or the marked over-excitation of the present standard ratio transformers to give 133 volts, secondary. Also changes to present standards for substation equipment might be necessary.
3. A compromise raising the lamp voltage to around 125, and decreasing the motor voltage to around 216. This presents complications with lighting, appliance, and motor loads, as the compromise voltages are often high for lamps and appliances and materially, if not seriously, below the 230-volt standard for motor service.
4. The use of auto-transformers for stepping up the main voltage of 115-199 to 230 volts for motors. Under conditions where the lighting and power loads on a secondary main system are approximately equal, it would then be necessary to transform one-half of the load from 115-199 volts up to 133-230 volts by means of auto-transformers. Assuming an average connected load per power customer of 12.5 kv-a. in power, a fair average figure for an underground city area, it is estimated that the necessary auto-transformers (excluding installation costs) would cost more than twenty-five per cent of the entire investment in secondary mains, conduits, and manholes.

The service which on the two-phase, five-wire system would be three-wire, 115-230 volts, single-phase, on the three-phase, four-wire system must be either (a) two-wire, 115-volt, single-phase, or (b) three-wire, 115-199 volt, open "Y", or (c) three-phase, four-wire. Each of these solutions results in higher losses, poorer voltage regulation, unbalanced voltage, higher investment, singly or in combination.

The two-phase, five-wire system requires none of these compromises or sacrifices.

In this comparison, consideration has not been given to the various other three-phase secondary systems which do not have some of the disadvantages of the three-phase "Y"—connected system. They have other combinations of disadvantages which are summarized in "Alternating-Current, Low-Voltage Networks," Serial Report of the N. E. L. A., Publication No. 25-1.

Transformer Installations

For the purpose of this paper, the transformer installation for supplying the secondary mains from the

primary distribution system is considered as a part of the secondary system. In considering the transformer installation, it is fully as important that attention be directed to the construction and cost elements of the supporting structure for the transformers if on a pole, or to the manhole or vault if the transformers are subway type.

For the two-phase, five-wire, 115-230 volt secondary distribution system, the connections will be as shown in Figs. 2A and 2B for a two-phase primary and in Fig. 2C for a three-phase primary. In all of these combinations, for a given size bank, only two transformers, or a multiple of two, are required. For the three-phase, four-wire system, three transformers, or a multiple of three, are required. The use of polyphase transformer units is practicable for either two- or three-phase, but certain service and operating advantages are generally felt to be lost as compared with standard single-phase units.

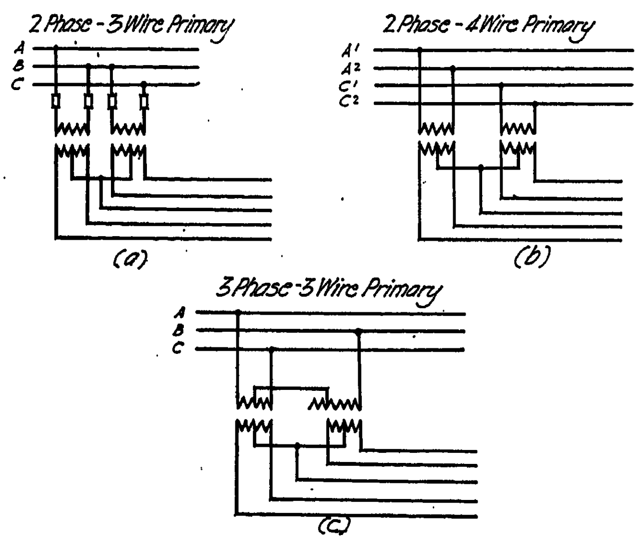

Fig. 2—Transformer Connections for Supplying Two-Phase, Five-Wire Secondary Mains from Two-Phase or Three-Phase Primary Circuits

There are marked advantages of having ordinarily two transformers per bank, with the two-phase system. On the aerial system, two units can be hung or arranged much more readily on a pole, with minimum decrease of working and climbing space for linemen. The mechanical advantages of a balanced transformer arrangement are apparent from Fig. 3. In the underground system, the use of two transformers is generally more economical of manhole space than the use of three transformers.

With two-phase primaries, standard transformers may be used in connection with the five-wire, two-phase secondary system. In the case of three-phase primaries, standard transformers with Scott taps are readily available at a slight increase in cost per unit.

The Scott connection and the combination of three-phase primaries with two-phase secondaries has sometimes been referred to as a hybrid scheme. Let us reserve judgment on this matter and base our conclusions upon common-sense engineering which must recognize construction, operating, and cost facts in addition to purely theoretical considerations.

In the modern Scott-connected transformer bank, there is a voltage unbalance of the order of one and one-half per cent, and a phase displacement of the order of one and one-half degree at eighty per cent power factor and much less at higher power factors. It can be readily shown that the per cent voltage unbalance caused

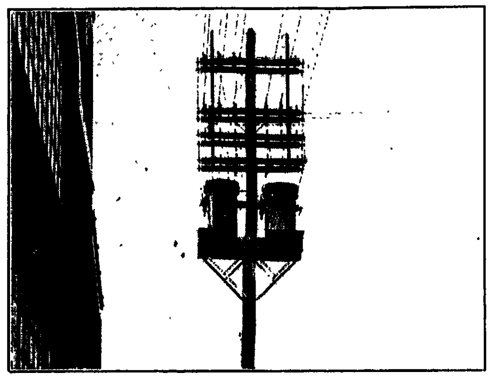

Fig. 3—Typical Construction—Two-Phase Transformer Bank

by 100 amperes per wire in approximately 500 feet of three-phase, 115-199 volt, four-wire No. 00 secondaries on a cross arm with standard 14½-inch spacing, is about the same as in a Scott-connected transformer bank having approximately five per cent impedance. There is no such inherent unbalance in two-phase, five-wire secondaries, when properly grouped, as the phases are separate and diametrically connected. The existence of current in the neutral will affect the voltage balance

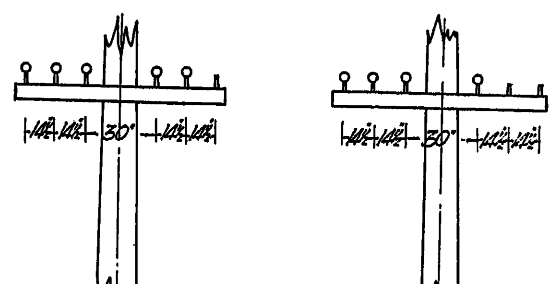

Fig. 4—Typical Arrangements of Secondary Mains on Cross Arms

of the three-phase system more seriously than that of the two-phase system.

See Fig. 4 for typical arrangements of wires on a cross arm.

For an economic statement of the cost differentials between aerial transformer banks of the standard type connected (1) two-phase to two-phase, (2) three-phase to two-phase, and (3) three-phase to three-phase, refer to Table II, which shows the comparative invest-

TABLE II
COMPARATIVE COST OF AERIAL TRANSFORMER INSTALLATIONS

Distribution System	Two-Phase—Two-Phase 2300-115/230 Volt	Three-Phase—Two-Phase 2300/3984-115/230 Volt	Three-Phase—Three-Phase 2300/3984-115/199 Volt

Total annual cost per kv-a.†	3.10	3.74	3.62

*Transformers are the type rated at 2300/4600-115/230 volts with taps for 3984 and 3444 volts and will give full rated output when Scott-connected.
†Total annual cost includes fixed charges on investment and cost of losses evaluated on increment cost basis.

ments and annual cost (fixed charges and cost of losses) estimated on a comparative basis.

It will be noted that the costs for the two-phase to two-phase banks are distinctly less than for the other connections, and that the three-phase to two-phase and the three-phase to three-phase costs run very close.

The three-phase to two-phase transformer costs are based on a relatively costly unit with taps suitable for either a 4000-or 4600-volt primary, while the three-phase to three-phase transformer costs are based on the standard 2300-volt unit. The three-phase to two-phase scheme therefore would allow a primary voltage of 4600 with consequent appreciable primary feeder savings as compared with 4000 volts.

It is therefore apparent that the two-phase, five-wire secondary system may be readily supplied economically from either two-phase or three-phase primaries.

Growth Adaptability

The two-phase, five-wire system, a combination of two single-phase, three-wire systems, possesses a high degree of flexibility and adaptability to all stages of load growth in a distribution system. Generally a district initially is supplied from single-phase, three-wire, 115-230-volt mains. As the district develops demands for polyphase supply to motors, this stage of development is readily met, especially with a two-phase primary system, by extensions of existing adjacent three-wire, single-phase secondaries supplied from different primary phases, thus affording a five-wire, two-phase service with the minimum additional investment in transformer installations and secondary mains, as diagrammatically shown in Fig. 5. If the primaries are three-phase, and as the amount of motor load grows, the transformers will be erected in banks of two, and part of the secondary mains will become five-wire. A three-wire service from mains originally three-wire, when the mains are increased to five-wire, requires no change in the motor or to the customer's wiring. There is, accordingly, a large degree of growth flexibility with the two-phase system. This is also a result of the inherent high capacity per wire, of particular value with continuing growth of load where theoretical considerations often are completely outweighed by the necessity of reasonably providing for development.

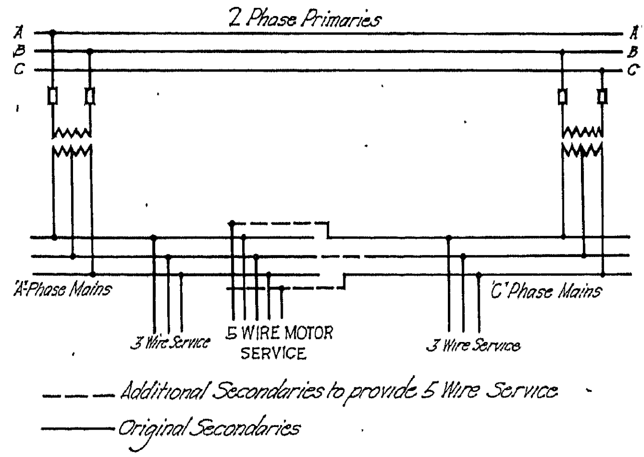

Fig. 5—Typical Method of Development for Two-Phase, Five-Wire System

With the three-phase, four-wire system, it is apparent that if a district is permitted to originally develop on a single-phase, three-wire basis, when it becomes necessary to provide for polyphase loads, the erection of two additional transformers will be necessary and also the conversion of the three-wire, single-phase secondary mains to four-wire, three-phase, unless such expedients as open "Y", three-wire mains are resorted to.

In such a transition it will be necessary to care for every three-wire, 115/230-volt, single-phase customers' service in one of the following ways:

1. Change to four-wire, three-phase. This requires running an additional wire, replacement of the single-phase meter by a polyphase meter, and changing the customers' wiring for a four-wire service.

2. Change to two-wire, 115-volt, single-phase. This may require larger service wires, and a change to a two-wire meter. In many situations, as with electric range loads, such a change would greatly increase the voltage

drop or necessitate a separate service to maintain the proper voltage on lamps.

3. Change to three-wire, three-phase 115/199-volt open-"Y." This will require a second meter or replacement of three-wire meters by polyphase metering. The service voltage will be unbalanced by the current in the neutral and the losses will be much higher in the service wires and the main neutral.

If the mains are made four-wire initially, there is the initial extra investment in transformers and mains, and the unavoidable choice must be made between the above three types of services, each with its disadvantages as compared with the three-wire, 115/230-volt service. The importance of this situation is apparent from the relatively large proportion of services which are single-phase on most systems.

Although many situations of the above nature are being solved by the use of separate mains for light and power, the substantial savings in combined mains, it is felt, compel consideration of any secondary system from the point of view of its suitability to the ultimate supply of practically all types of small and medium size loads from the same mains. To this end stricter requirements in motor starting currents and improved methods of distribution should be considered.

Relation of Primary Distribution

Although this paper deals particularly with secondary distribution, there are a number of related points in connection with primary distribution which should be borne in mind.

Primary distribution is affected by a large number of variable elements, including:

1. The size and spacing of substations.
2. Length and capacity of feeders.
3. Density and character of load, both primary and secondary.
4. Type of system, radial, parallel, loop, network feed, aerial, underground, etc.
5. Configuration of streets.
6. Tree conditions.
7. Governmental restrictions relating to voltage, aerial construction, tree trimming, etc.
8. Contractual restrictions such as those relating to voltage, type of construction, etc., in joint pole use.

Again, as in the case of secondary distribution, the influence of local conditions upon the type of system is very great, and it is often difficult to make comparisons between systems in different localities.

It is desired in connection with primary distribution to call attention to one factor which in recent years has become of increasing importance in this involved problem. Pressure of increasing-load demands by the public and the desire for greater economies by central station engineers in the use of copper and the saving of losses, have of late greatly accelerated the increase from 2300 to 4000 volts, to 6600 and 11,000 volts, and to 13,200 and 22,000 volts. The economies have resulted, not particularly from any change in the number of phases as such, but from *the higher voltage*. This voltage increase has progressed in a way undreamed of twenty, or even ten, years ago.

Improvements in insulators, protective devices, and all materials used in the distribution plant have resulted in gratifying operating experience and have practically wiped out the older, natural distrust of voltages higher than 4000 volts. The great economic savings of these high voltages therefore have been taken advantage of, in recent years, by many companies.

The situation in some instances is that of a superposition of a primary distribution system with voltages such as 11,000 and 13,200, over the present 2300-or 4000-volt primaries. There is either direct transformation to the secondary mains or utilization of the present 2300- or 4000-volt primaries, merely as an intermediate short-haul facility.

Thus, this tendency in primary distribution, where prompted by local conditions, appears to be toward what may be called super-distribution circuits, often at generated voltage, with consequent lower substation costs from the omission of transformers and with lower losses, instead of toward a moderate change of voltage such as from 2300 to 4000 volts.

The strength of this idea lies in the probability that a moderate increase in the primary voltage, so often resulting in marked theoretical economies in primary copper investment and losses, may require expensive reconstruction of substations, distribution plant, and, often more serious, costly change-over of primary customers' installations. The additional investment, power losses, operating and maintenance costs of the duplicate plant during a long transition period require very careful consideration in order to avoid a long postponement of actual net savings from the change. Further, during the change-over, the load conditions may have so changed that the primary system has become inadequate to meet the new conditions and another increase in voltage may be required. A glance backward over the history of power distribution should constitute a warning as to the possible futility of taking too early what may later stand out as only a make-shift economic step. These statements apply with equal force to secondary distribution.

Metering, Motors, and Customers' Installations

In the two-phase, five-wire system, single-phase service loops generally are two-wire for loads up to a prescribed figure and three-wire for loads in excess. For the former range of loads, which are representative of small residential consumers, the metering is identical, whether from a two-phase or a three-phase system. For the latter range of loads, the metering costs involve a comparison between a three-wire, single-phase meter for the two-phase system and polyphase metering or raising the limit for two-wire services for the three-phase system. The cost of a three-wire, single-phase

meter installation is slightly lower than the cost of a two-wire, single-phase meter installation of the same kilovolt-ampere capacity and is very much less than any type of polyphase metering now in use.

For metering polyphase power load, there is practically no difference in the meter costs for two-phase or three-phase.

A study of metering costs for a typical system including all types of metering indicates that the total investment in metering equipment would be about fifteen per cent greater for the three-phase system than for the two-phase system.

The cost of two-phase motors of the usual voltage and speed ratings is identical with that of three-phase motors. In some cases there is a slight additional cost for the starting compensators for two-phase motors. The two-phase motor at rated full load has an efficiency slightly less than the three-phase motor, for the usual voltage and speed ratings, which is of the order of one per cent for sizes up to about 25 h. p. and less for larger sizes. This difference is due partly to the slightly less efficient coil design for two-phase and partly to the fact that most manufacturers design parts which are interchangeable for two-phase and three-phase motors but which are not always quite the most efficient design for two-phase motors. The torque characteristics of the two-phase motor are as good as, if not better than, the three-phase motor, according to manufacturer's rating sheets. The effect of reduced voltage under some of the three-phase, four-wire schemes is to materially decrease the pull-out torque of the standard 220-volt motor.

The two-phase, five-wire system uses standard motors of standard 220-volt rating while the three-phase, four-wire system with 115/199-volt mains requires the development of a new line of 199-volt motors or the material de-rating of the present line of motors,(unless auto-transformers are resorted to), thus resulting in a distinctly unfavorable situation.

It has been claimed that the two-phase, five-wire system, which for motor service requires four wires as against three wires for the three-phase system, requires more expensive wiring. Comparative estimates prepared for motor sizes from 10 to 50 h. p., both three-phase, three-wire, and two-phase, four-wire, show differences of the order of one per cent, in some cases in favor of the two-phase and in some cases in favor of the three-phase.

These figures are based on 220-volt motors for both two-phase and three-phase. If the cost of the necessary auto-transformers were included with the three-phase motor or allowance made for the additional cost of a 199-volt motor with its wiring, to be supplied from 115/199-volt mains, the comparison would be favorable to the two-phase system.

A typical example will serve to illustrate the small magnitude of the difference of the losses in a two-phase motor with its wiring, and a three-phase motor with its wiring. Assuming a 10-h. p. motor first three-phase, 199-volt, and second, two-phase 220-volt, the difference in the value of losses for a period of operation of 2000 hours per year at an average of 75 per cent full load, at two cents per kw-hr., amounts to less than $2.75 per year in favor of the three-phase motor. This is less than one per cent of the value of the power input to the motor and is of such a small order of magnitude as compared with the usual variables of installation costs, over-sized motors, operating hours, length of wiring, etc., that it should not be considered important in the choice between a three-phase and a two-phase system.

Thus, if the three-phase motor is supplied through an auto-transformer from 115/199-volt mains or the motor is a 199-volt, the carrying charges on the extra investment in motor and wiring, or in auto-transformers, and the additional losses would throw the saving in favor of two-phase.

With a three-phase motor service voltage of 199 volts, the voltage drop in the wiring in many cases will result in a materially lower voltage at the motor terminals. Using the same per cent in this case as is nominally allowed between a 230-volt service and a 220-volt motor, the rated motor voltage should be 191 volts.

For lighting loads there are difficulties with the three-phase, four-wire system which do not exist with the two-phase, five-wire system. The main feeds to panel boards must be either four-wire, 115/199-volt, with a more expensive four-wire panel board, or they must be three-wire, open "Y", with the losses in the wiring approximately 50 per cent higher than with three-wire, single-phase feeds. There will also be a voltage unbalance due to the assymetrical phase relations of the current in the wires, its magnitude depending upon the power factor, and an increased voltage drop. Single-phase, three-wire feeds from a two-phase, five-wire system do not have these disadvantages.

General Economic Features of Two-Phase, Five-Wire Distribution

It has been seen from the foregoing discussion that the character of service from the two-phase, five-wire secondary system, so far as it meets the various distribution, engineering, and customers' requirements, has no serious disadvantages as compared with the three-phase system, and in many respects has outstanding advantages.

Therefore, under such conditions, it will be of interest to compare the overall economies of the two systems, in order to determine the probable magnitude of the cost differential and the importance of this factor as compared with costs of change-over and other factors not readily measured in dollars.

For this measurement of their relative inherent economic standing, an analysis of several combinations of underground primary and secondary distribution systems with two- and three-phase secondaries, was made

TABLE III

TOTAL ANNUAL COST OF NETWORK SYSTEMS

Excluding Operation and Maintenance

No.	Primary	Secondary	Substation	Feeders	Transformers	Mains	Total
		Range of Primary Voltages: 2300–4600 Volts					
1	2-ph. 3-wire 2300/3252-volt	4-ph. 5-wire 115/230-volt	$216,050	$92,900	$118,200	$108,760	$535,910
2	3-ph. 4-wire 2300/3984-volt	3-ph. 4-wire 133/230-volt	211,700	67,120	122,800	97,680	499,300
3	3-ph. 4-wire 2300/3984-volt	3-ph. 4-wire 115/199-volt	211,700	67,120	122,800	101,820	503,440
4	3-ph. 3-wire 300/3984-volt	4-ph. 5-wire 115/230-volt	211,700	67,120	125,300	108,760	512,880
5	4-ph. 5-wire 2300/4600-volt	4-ph. 5-wire 115/230-volt	218,900	93,580	119,600	108,760	540,840
		13,200-Volt Primary					
1	3-ph. 3-wire 13,200-volt	3-ph. 4-wire 133/230-volt	122,900	44,100	147,900	97,680	412,580
2	3-ph. 3-wire 13,200-volt	3-ph. 4-wire 115/199-volt	122,900	44,100	147,900	101,820	416,720
3	3-ph. 3-wire 13,200-volt	4-ph. 5-wire 115/230-volt	122,900	44,100	153,800	108,760	420,560

on a comparative basis, as applied to a definite load and area. Each type of system was given the full benefit of its most economical design. Tables III and IV summarize the results of this investigation. Table III shows the total annual cost of an underground network plant, including in the total annual cost the fixed charges on the investment and the value of the energy losses in the various parts. Table IV shows the investment in the various parts of the plant for the systems considered.

The cost of the mains for the different types of secondary systems does not vary widely, being of the order of magnitude of 10 per cent for the total annual main cost and for the investment in mains. For the transformers and mains together, the cost variation is even smaller in either the 2300-to 4600-volt primary range or with 13,200-volt primary. It will also be noted that the investment in mains is only about 20 per cent of the total plant investment in substations, feeders, transformers, and secondary mains. The tables also indicate that the part of the problem demanding further engineering attention is that pertaining to the primary, where higher voltages than 4600 show marked possible economies.

These analyses, although on a comparable basis, cannot evaluate in dollars many of the advantages of the

TABLE IV

INVESTMENT FOR NETWORK SYSTEMS

No.	Primary	Secondary	Substation	Feeders	Transformers	Mains	Total
		Range of Primary Voltages: 2300-4600 Volts					
1	2-ph. 3-wire 2300/3252-volt	4-ph. 5-wire 115/230-volt	$1,695,000	$792,000	$773,000	$938,300	$4,198,300
2	3-ph. 4-wire 2300/3984-volt	3-ph. 4-wire 133/230-volt	1,665,900	584,000	790,000	851,700	3,891,600
3	3-ph. 4-wire 2300/3984-volt	3-ph. 4-wire 115/199-volt	1,665,900	584,000	790,000	880,700	3,920,600
4	3-ph. 3-wire 2300/3984-volt	4-ph. 5-wire 115/230-volt	1,665,900	584,000	830,000	938,300	4,018,200

		13,200-Volt Primary					
1	3-ph. 3-wire 13,200-volt	3-ph. 4-wire 133/230-volt	1,023,000	402,000	954,200	851,700	3,230,900
2	3-ph. 3-wire 13,200-volt	3-ph. 4-wire 115/199-volt	1,023,000	402,000	954,200	880,700	3,259,900
3	3-ph. 3-wire 13,200-volt	4-ph. 5-wire 115/230-volt	1,023,000	402,000	1,019,000	938,300	3,382,300

two-phase, five-wire secondary system, which it is felt fairly match or outweigh the advantages of the three-phase, four-wire system for a densely loaded underground district.

Other figures which have been prepared lead to the same conclusions for the aerial system.

In the change-over of a d-c. network system to alternating current, it may be possible in the choice of the best a-c. system to consider the particular district as a separate problem, because the d-c. equipment will require replacement in any event. However, existing a-c. areas, both aerial and underground, which eventually will form part of the network area, and the need for standardization on one universal type of system will have a necessarily large, if not a predominating, influence on the decision.

Conclusion

With an existing a-c. system of any type, now rendering adequate service satisfactory to the consumers, and economical and adaptable to growth, the cost of change-over to any other system becomes a very important factor. In addition to those costs of a fairly determinable nature, there are others less susceptible of accurate prediction, such as the extra cost of operating two types of systems during the change-over and the effect of a longer or shorter change-over period.

Accordingly, with a relatively small inherent cost differential between the existing system and one having certain more or less proved advantages and some known disadvantages, the central station engineer must have extremely strong arguments leading out of his local situation in order to justfy a change from the existing system.

In conclusion, I desire to express my appreciation of the assistance and suggestions rendered by a number of my associates.

Discussion

A. H. Kehoe: If one first reads the conclusions of this paper (which are carefully drawn), he is apt to take a more generous view of the statements which appear earlier in the text. For instance, the emphasis on cost of making system changes is well placed.

Concerning the subject of a combined light and power system, we believe it can be demonstrated that starting *de novo*, the advantages and disadvantages of two- and three-phase will be so nearly balanced that any difference in cost is well within the accuracy of the original assumptions. In practical applications, however, there are three factors which should always receive consideration:

First, the sources of power and transmission, if these exist, are three-phase, and the country in general is, and will doubtless remain, on a three-phase basis for general polyphase utilization. This necessitates the use of special polyphase devices where two-phase, five-wire distribution is adopted.

Second, the three-phase, four-wire system requires an odd voltage according to present standards, for either one or both of the single-phase or polyphase loads.

In addition to the above the adaptation of existing equipment for combined light and power distribution should be accomplished with minimum cost.

In the two locations where two-phase, five-wire light and power distribution systems are contemplated at the present time, there is little doubt that due to the existence of a two-phase system it is much cheaper to retain the two-phase than it is to change over to a three-phase, four-wire supply. These two locations are the exceptions however, and the same elements of cost have the opposite effect on the typical systems of the country which, of course, are three-phase. The systems adopting two-phase, five-wire will perpetuate non-standard polyphase equipment while the three-phase, four-wire systems will force certain rating compromises but should be able to utilize standard equipment, both existing and new. Just what this later effect will be, depends upon what voltages are selected. The author has everywhere in his paper ignored 120/208-volt, three-phase, four-wire which seems to me to affect seriously some of his deductions. This voltage appears to be the only compromise which can be adopted that will allow all existing standard equipment to be utilized successfully.

I have noted such a large number of exceptions in the detailed text of the paper that it would be impossible to comment upon all of them. I shall therefore deal with but four or five matters which seem to be of most importance.

Carrying the matter of "power per wire" to its absurd conclusion, the system proposed by the author is but 80 per cent efficient. However, we all must appreciate the tremendous advantage of the simple three-wire, d-c. system. It is the obvious necessity of generating and transmitting polyphase as well as having some polyphase utilization, that makes it necessary to even consider the complications of going to four-wire or five-wire systems to obtain balanced loading on a single system. It may be well, however, to bring out the fact that neutral wires have to be sufficient to carry the unbalance which depends upon the utilization equipment and not the type of system.

Under "inherent advantages" on the third page, the question of accommodating phases in separate ducts introduces the element of polyphase motors acting as phase converters while running single-phase. This condition at times of secondary short circuits is one of the problems with which there has not been sufficient operating experience to obtain a positive solution. It seems certain, however, that separate polyphase secondary cables in separate ducts will not improve the hazard which already exists in the matter.

On the fourth page, mention is made of polyphase transformer units. I wish to emphasize this, as in the writer's opinion we have scarcely begun the economic use of polyphase units that will come automatically as soon as the light and power systems are established in a reasonable number of places.

With reference to the Scott connection as a hybrid scheme, some of us who do not agree with the author believe we are basing our conclusion upon common-sense engineering. Regarding the unbalance due to Scott transformation, it should be realized that this occurs at the source of the supply while the voltage unbalance, set up in the case of secondaries, occurs at the end points of the line. It is doubtful whether any quantity of secondary light and power mains would be installed in the country with spacing as indicated on the fourth page. Our telephone friends might be interested.

In discussing primary voltages higher than 4000 volts, the author speaks of the older natural distrust as if the distribution conditions of the last ten years were not justified. We believe that it has just been demonstrated by a different design of system that it is possible to distribute at the generator voltage and any distrust which has existed in the past was a very proper one for the systems then in use.

R. A. Paine: In the first part of the paper a discussion is given of the fundamental requirements which any distribution

system must meet. The field has been covered in a very complete manner but there appear to be several points on which there is disagreement as to just how nearly certain types of distribution systems meet all of the requirements. A comparison has been made in the paper principally between two types of secondary distribution systems, *i. e.*, (1) two-phase, five-wire system, and (2) three-phase, four-wire system.

Throughout the paper the voltage of the three-phase, four-wire system has been stressed as being 115/199 volts. This apparently has been done for a purpose. Since the two-phase, five-wire system considered was 115/230 volts, the voltage to ground for the three-phase system for sake of convenience was also selected as 115 volts. We believe the comparison should be made either on the basis of a two-phase system voltage of 120/240 with a corresponding three-phase voltage of 120/208, or on the basis of a two-phase system voltage of 115/230 and a three-phase system voltage of 120/208.

The comparison should be made in accordance with one of the above stated methods because in all cases where a distribution voltage of 115/230 exists, it is entirely possible by proper notification to customers, after authority has been received from the public service commission, to raise the voltage to 120/240. If a particular company does not desire to raise its voltage to the above standard, the benefits to be derived from so doing, such as decreased losses on account of the higher voltage, etc., should not be withheld in making a comparative economic study of the two systems.

Accepting this as fact,—namely, that with a three-phase, four-wire system the distribution voltage would be 120/208 volts if operation similar to present practise is followed out,—it should be possible to maintain practically this voltage at the customer's service. Hence, if the motor wiring is at all suitable, voltage at the motor should be well above 200 volts, three-phase. When standard 220-volt motors are used, and assuming the motor terminal voltage to be 205 volts, the efficiency at full load is not materially less than when the motor is operated at 220 volts. The efficiencies at fractional loads will be somewhat higher when the motor is operated below 220 volts. The pull-out torque will be reduced to roughly 86.6 per cent of the pull-out torque at 220 volts. Assuming the pull-out torque value to be 250 per cent of normal full-load torque, and that the motor is operated at rated voltage, the new figure will be approximately 217 per cent which should prove ample.

There should be no trouble in operating three-phase motors at 120/208 volts, since the heating of the motors should not be materially increased and because the majority of motors operate at somewhat less than their rating. Further advantage may also be taken due to the fact that the motors are rated on a 40-deg., ambient temperature basis and the usual ambient temperatures encountered are somewhat lower than this figure.

A study of the performance curves of present-day motors indicates that motors rated at 220 volts are apparently designed for a voltage between 200 and 210. Unless the design of motors is changed, cases where 220-volt motors will not operate entirely satisfactorily at 205 volts will be very rare.

The "Outstanding Features" of a two-phase, five-wire distribution system which have been outlined in the paper are, with two exceptions, equally applicable to a three-phase, four-wire system. Of these exceptions, one (namely, use of 208 volts three-phase as the motor voltage for the three-phase system as against 230 volts for motor voltage of the two-phase system) is not a serious disadvantage, if it can be called a disadvantage at all. This is on account of the reasons given above. The second exception (namely, the use of three transformers per bank for the three-phase system instead of two transformers per bank for the two-phase system) is, of course, somewhat of a handicap in the case of the three-phase system. Usually, however, there is considerable flexibility possible in the manner in which loads are cared for in the three-phase system so that this disadvantage can probably be compensated for.

Voltage unbalances which take place or are inherent in a three-phase, four-wire system are in all cases extremely small and practically no difficulty is encountered from an operating standpoint in satisfactorily compensating for them.

This suggestion is made in the paper that a common set of secondary mains be used for supplying both power and lighting loads. This practise is quite commonly followed by several companies at the present time. From the economical point of view, it is very desirable and works out very nicely in practise except in cases where extremely severe conditions are imposed upon the circuits by some types of power load which necessitate separate sets of mains for the power and lighting loads. Stress has been placed upon the saving in the capacity of mains due to diversity between lighting loads and power loads. Any saving due to diversity of load in this part of the system will be exceedingly small as a rule. While the value of diversity is exceedingly great it is felt that the actual diversity existing in the part of the system being discussed in this paper is generally greatly over-estimated. The character of the service which must be rendered has a far greater effect upon the design of the secondary mains than does diversity. Any advantage which might exist in certain special cases may be realized equally well for either the two-phase or three-phase distribution system.

An advantage is claimed for the two-phase, five-wire system, particularly in underground districts, in that multiple-conductor cable can be more readily utilized than with the three-phase system. While this might be an advantage in some cases it would be obtained at the expense of lower quality of service due to the fact that any trouble in the cable would affect a larger number of customers than if single conductor cable were used. The three-phase, four-wire system has a very distinct advantage over the two-phase, five-wire system in underground districts in that for the same power to be transmitted, four single-conductor cables of somewhat larger size can be installed instead of five single-conductor cables with considerable economy in investment and duct space occupied.

In the case where secondary circuits are extended into new territory, a three-wire, open-Y, 120/208-volt installation may initially be made. This arrangement is the equivalent of installing a three-wire, 115/230-volt, secondary line in the two-phase system. If later, polyphase service is required, it is necessary only to run an additional wire or cable, while with the two-phase system to render polyphase service two additional wires must be installed.

Referring to Table No. 4, it is seen that the total annual cost of the three-phase, four-wire primary, three-phase, four-wire secondary system is approximately 7 per cent less than the two-phase systems shown as Nos. 1 and 2 in the same table. This amounts to upwards of $30,000 annually. Capitalizing this saving at 12½ per cent the above figures correspond to an investment saving of about a quarter of a million dollars.

With regard to all of the points at issue, it may be confidently stated that the three-phase, four-wire distribution system with voltages 120/208 is quite able to hold its own with the two-phase, five-wire system with voltages 115/230 and has the decided advantage of using recognized standard apparatus, including three-phase motors. It is very likely that future developments and refinements will benefit the three-phase system to a greater extent than they would benefit the two-phase system since developments are usually made for the benefit of the majority.

In discussing a common system of a-c. secondary mains for both lights and motors, the author suggests stricter requirements in motor-starting currents. If lower starting currents than now exist are a requisite for any particular type of distribution system, all factors entering into the problem should be carefully evalu-

ated as, in general, the larger the permissible starting current, the lower the cost of the motors. In Brooklyn the use of a combined lighting and power secondary is practically universal and has been for a great many years. We have made our motor-starting current requirements very broad and have found that we have encouraged the use of electricity as a power source, by lowering the customer's initial investment. Any motor installation conforming with the 1923 N. E. L. A. Motor Rules is accepted. In addition, we shall accept motor installations having starting currents in excess of these rules, provided no objectional voltage fluctuations are experienced by other customers connected to the same secondary, as the customer having the large starting current. We believe that all forward looking engineers should plan and design their distribution systems so that any motor installation meeting the requirements of the 1923 N. E. L. A. Rules is an acceptable installation. When distribution systems are brought up to this standard we may be able to lower still further the initial costs of motor installations by broadening the present motor rules.

H. R. Woodrow: Mr. Chase's paper attacks the problem from the standpoint of the existing system and for a new layout he is in agreement that the two-phase system is more costly than the three-phase.

In attacking a remodeling problem for a rapidly growing system, I should like first to see how we should develop the system without limitations of existing equipment and then determine how the new layout can be worked into the existing plant or the existing plant worked into the new system, for in a 10- to 12-year period the existing equipment is only one-third of new additions required.

The statement is made in the paper, "If there is any virtue in the number of phases surely it should compare favorably with the three-phase." It would seem to me that this should represent an indirect function in place of a direct one, as the best system, if it gives the same economy, would be a single-wire system.

Referring to the second page, the number of wires per customer would, in many cases, more nearly represent the cost than the power carried per wire, as in the majority of cases the limitation is determined by the minimum size of wire which is practical from the mechanical strength standpoint. The four-phase, five-wire system has 33⅓ per cent more current-carrying wires per service than the three-phase, four-wire system.

Referring to the tabulation under "Feeders" and the comparison of the three-phase, 2300/3900-volt system with four-phase, the four-phase distribution is 40 per cent more expensive than the three-phase. In the "Mains" the annual cost of the four-phase, five-wire system is represented as 7 per cent greater than the three-phase, four-wire system and the transformers under the 2300-volt heading show an increase in cost of the four-phase, five-wire system as 4 per cent. In other words, the tabulation shows an advantage of from 5 to 10 per cent in annual cost for the three-phase, four-wire system in comparison to the four-phase, five-wire, which is in agreement with the general studies we have made.

The only conclusion to which I can come from the study of the new system is that the central station is required to spend from 4 to 10 per cent more for the four-phase, five-wire system than the three-phase, four-wire without increased economy, and that the customer is required to spend more money to take the service and have increased losses in his system. This condition would naturally produce a rapidly increasing demand for three-phase equipment with a reducing demand for two-phase, and therefore the complications of the two-phase system would become more and more involved each year.

Although these factors favoring the three-phase, four-wire system may not in some cases justify the expense of changing over an existing plant, I do think these factors should be very carefully weighed before definitely perpetuating an inferior system.

P. H. Adams: I think Mr. Woodrow overlooked the fact that Mr. Chase's five-wire circuit is made up of two two-phase, three-wire circuits, using a common neutral. In his comparison of costs, he forgot the fact that each customer is connected as a two-phase, three-wire customer.

I agree with Mr. Woodrow in his criticism of the five-wire, two-phase system as a continuation of something that is inherently bad, and that we should tackle the problem of changing from two-phase, 2400 volts to a higher voltage by considering the existing system as something that will be comparatively small as contrasted with the system five or ten years hence.

We had the same problem in New Jersey, and while our system is a four-wire, two-phase instead of a three-wire, two-phase, as the one with which Mr. Chase has dealt, when we made our change we chose the 4150-volt, three-phase, four-wire system. I think we were right in making this decision, as our system is growing rapidly and in five years we expect to have a system at least four or five times as large as that which existed when we started the change.

L. T. Robinson: I think there is another side to this question of distribution systems that should not be overlooked; that is, that systems and convenience in the arrangement of systems is not everything; you should do as much as you can to make it possible to employ standard apparatus and have conditions under which the apparatus must be used as uniform as possible.

The question of lamp voltages, transformer ratios, the torque and heating of motors, their starting current and efficiency are all involved. While the idea that standard apparatus may be used on both the four-wire, three-phase, and five-wire, quarter-phase systems runs through the presentation and discussion, you must recognize the fact that to the difficulties always present due to the regulation of systems for voltage and frequency, there will be added the conditions of having to meet variable base voltages.

Possibly the apparatus can be successfully made to cover the base-voltage range required as well as the variations found in practise, but it will be more difficult for the designers, and I feel, to some extent,—I can't say off-hand to what extent—it is going to make the apparatus more bulky and more expensive.

H. Richter: Throughout the paper there are references indicating that the author intended his arguments to apply particularly to areas that now have two-phase distribution, where a combined light and power secondary system is contemplated and it is necessary to solve the involved problem of choosing the type of system best suited to those particular areas. I wish to emphasize the importance of confining the meaning of the paper to such two-phase systems and of not considering it to apply to systems that are now three-phase or to entirely new distribution layouts which may be started in the future.

In my estimation the paper refers almost exclusively to underground and overhead secondary network systems and not to purely radial systems. The idea of extensively using the combined light and power secondary system has been entertained seriously only since the advent of what might be called the latest type of underground a-c. low-voltage network; that is, where a number of primary feeders supply in common an interconnected secondary network. Isolated cases where the combined scheme has been tried out on typical radial systems are known, but the majority of companies have kept away from it because, unless an excessive expenditure is made, there is likely to be winking of lights when motors are started and burnout of polyphase motors due to insufficient voltage. It should therefore be recognized that the paper applies only to network systems. The inclusion of overhead secondary systems in the analysis is sound, I believe, for the surprisingly rapid spread of the network idea indicates that in the future, ten to twenty years from now, practically all

of the underground systems of the cities will not only be networked, but a good portion of the overhead systems will also have networks, possibly in a simpler form and using simpler apparatus.

The comparison has been confirmed to the 115/199-volt three-phase system. I should like to forestall consideration of the 110/190-volt and 125/216-volt, three-phase systems in the discussion. Satisfactory operation of polyphase apparatus on 190 volts would entail so great an expenditure, both in taking care of existing installations and development of new apparatus, that 110/190 volts is practically out of the running. 125/216 volts is also more or less out of the picture, partly because 125 volts is not even a recognized exception as a lamp standard, and partly due to the excessive burden that would be thrown on the industry as a whole by the necessity of developing new lines for the many types of apparatus now standardized at 115 volts or considered satisfactory for operation on 120 volts. The comparison of two-phase with three-phase should therefore be confined to 115/199, or possibly 120/208 volts for the three-phase systems.

Wherever low-voltage networks are being installed or planned, the companies are figuring on employing three-phase for the primaries, either at potentials in the class below 5000 volts or at some such higher voltage as 13,200. Even the two companies that have indicated a leaning towards two-phase secondary distribution have expressed the intention of employing 13,200-volt, three-phase feeders for future growth. Consequently, we must keep in mind, as of five or ten years from now, only the comparison of the Scott connection with its attendant disadvantages, for transformer banks serving two-phase as against the straight step-down for three-phase distribution.

While it is true that in the past there has been a general tendency to avoid such high primary voltages as 13,200 for miscellaneous distribution in cities, it is also a fact that this is no longer the case. The change in sentiment has been brought about almost entirely by the ability to employ a simple system of distribution in which all primary protective and sectionalizing devices are eliminated, and the only protective apparatus on the distribution system is a low-voltage device of proved performance.

These remarks have been made in an endeavor to clarify the discussion and in that way, if possible, simplify the comparison of the various network propositions. As Mr. Robinson has said, this is quite necessary for it is extremely important from the standpoint of the manufacturers, customers and, indirectly, the operating companies, that the latter get together without further delay and standardize as far as possible on such a combined light and power scheme as can be used to the greatest advantage on the majority of systems introducing the least possible extra expense in the manufacture and stocking of different types of apparatus.

Even though the including of items for operation and maintenance gaged over a period of ten years would probably have increased the difference in favor of the three-phase secondary system, Tables III and IV do not show a large economic advantage for three-phase. Further, it is apparent that despite a weighing of all evidence of engineering and operating nature a balance shows in favor of three-phase, and also, this balance is not large. It is therefore admissible that if the standpoint of the operating company only is considered and the analysis is confined to the usual period of ten years to come, the net advantage of three-phase over two-phase may not be great enough to outweigh the obvious benefits of having a uniform system of secondary distribution throughout a city. In connection with that which follows it should be borne in mind that the greater part of these benefits accrue from the attitude of the public in general.

Likewise, where a large number of two-phase motors now exist in an area that it is proposed to network, it is evident that the expense of changing them over to three-phase, or in all cases providing auto-transformers for a three-phase to two-phase transformation, could probably not be counterbalanced even in ten years by the small economic advantage of the three-phase.

However, it is conceivable that in this particular problem, an unusually broad point of view should be applied. The paper touches on the conditions that are tending to make two-phase obsolete. Exact data in this regard are difficult to obtain. There are but two large distribution systems and a few smaller ones still two-phase. The ratio of present investment in two-phase systems to that in all systems in the country may be gaged approximately by the fact that in 1923 only 6 per cent of all the polyphase motors sold by one prominent manufacturer were two-phase. It does not require a stretch of the imagination to foresee that within the next ten or twenty years this percentage is likely to decrease to even half its present value as the tendency for smaller companies operating two-phase to change to three-phase continues and as new systems in rapidly growing parts of the country start up, using the present standard of three-phase. With that reduced percentage of two-phase business it is natural to expect that prices and deliveries of two-phase apparatus will be adversely affected. Thereupon, customers in two-phase areas will set up a demand for three-phase service and this will have to be complied with by the operating companies. At the current rate of load increase, in ten years there will be about four times as many motors on the two-phase systems as at present and in twenty years about sixteen times as many. The expense of change-over to three-phase at that time will be correspondingly greater than at present. Even though measures may be taken to postpone the change-over, these will of necessity have only a temporary effect. The greater the delay the worse will be the situation when the change to three-phase finally takes place.

Coming now to systems where three-phase already exists, enough has been said to prove that it is almost out of the question to expect them to go to two-phase, five-wire secondaries. To review a few of the reasons, there is the great expense of changing three-phase motors to two-phase, replacing three-phase transformer banks by Scott-connected banks, and pulling in a fifth secondary service as well as sometimes in many places riser wire. Where ducts and service pipes are too small for the fifth wire, reconstruction would be necessary.

Finally, there are the companies that will install networks in what might be termed virgin territory. The paper shows certain definite though small advantages for three-phase, four-wire over two-phase, five-wire, such as in annual charges and first cost. In the majority of cities the cost of operation and maintenance of the two-phase system would be greater, due to the added maintenance of the fifth wire and five-wire protective equipment. There are also the extra losses due to the Scott transformation to two-phase. Three-phase motors and utilization devices are standard, while two-phase apparatus is becoming obsolete. In some makes of motors there is quite an appreciable difference in performance in favor of three-phase, assuming operation at rated voltage. Even though the advantages for each of these factors may not individually be great, when added together they point unmistakably to the wisdom of making networks in all new distribution layouts three-phase.

P. H. Chase: In some of the discussions on my paper there has been a tendency to confuse what is common practise with that which is good, and what is not common practise with that which is bad. Though two-phase, secondary distribution is not so common as three-phase, proper use of the fundamental distribution requirements as yard sticks certainly cannot lead to the opinion expressed by two of the critics that the two-phase system is bad or inferior.

It is interesting to note that advocates of "Three-Phase" are by no means unanimous in their choice of which is best of the various types of three-phase systems. One type requires what one supporter diplomatically calls "certain rating compromises", but these may result in widespread changes to equipment, to

standard lamp voltages, or to motor ratings. Another type does not afford load balance or balanced voltages to ground. Expensive expedients, such as auto-transformers and the like, are offered to overcome these drawbacks in order to adhere to three-phase and continue to render standard voltages to customers.

Most of the operating companies will continue to have the greatest part of their *secondary* load neither two-phase nor three-phase, but two-wire and three-wire, single-phase. In addition, the number of customers supplied with single-phase as compared with those supplied with polyphase service will be greater than the proportion of the actual single-phase and polyphase loads. Any system which penalizes single-phase customers is laboring under a handicap.

The flexibility and adaptability of the two-phase, five-wire system in handling a combination of two-wire single-phase, three-wire single-phase, and two-phase loads, with superior regulation and load and voltage balance, has not been successfully challenged. These valuable advantages have been demonstrated by long experience but are difficult of expression in dollars.

The small percentage of two-phase motors does not tell the story. From early days there has been a general tendency to operate motors on separate secondaries (and often separate primaries) from lighting. Consequently, the motor voltage and number of phases could be determined by considerations relating to and affecting the motor alone. Lighting was two-wire and three-wire, single-phase, because of the utilization devices, simpler metering, and lower service costs, which conditions still obtain. The trend of generation and of transmission toward three-phase naturally directed motor development and primary and secondary polyphase distribution along three-phase lines. Accordingly, three-phase motors predominate but lighting has remained single-phase.

Of recent years, the advent of a-c. secondary networks and the advantages of combined light and power secondaries have brought to the front a requirement which was originally unimportant,—that is, the flexible supply from the same secondary polyphase mains of all types of load, at established standard voltages. The three-phase system cannot meet this without expensive changes or doubtful compromises and such expedients as three-wire, open-Y, or four-wire services and polyphase metering for residence lighting. The two-phase, five-wire system now meets this need without change for both radial and network systems.

Standard two-phase motors are neither obsolete nor penalized in price, as reference to motor price-books will show. The adoption of a *new* line of 199-volt, three-phase motors would be a greater deviation from the principle of standardization than the retention of the already established line of two-phase motors.

Three-phase primary distribution can readily be utilized for supplying two-phase secondaries by the Scott connection of transformers which has been proved by years of operation and does not involve a deviation from standard voltages. The Scott connection deserves no more attention or criticism than many of the common modifications to "standard" transformers which are asked for and furnished almost as a matter of course.

We must keep this matter of standardization in mind. Standardization refers particularly to voltage, frequency, capacity, speeds, and types of equipment. On the two-phase, secondary, five-wire system, apparatus, equipment and devices are used that are standard as to voltage, frequency, capacity, and kind.

From the standpoint of the operating man, the matter reduces down to whether he is giving adequate service at reasonable cost, by adhering to his existing secondary system, and whether—although there may be a slight theoretical differential in cost, if he were starting new—he is justified in paying the high cost of change-over from the existing system. It is universally admitted that the cost of change-over is extremely high because of the cost of change-over of customers' installations. If the theoretical saving, over a long period of years—say ten—does not pay for the cost of change-over, how can a change be justified?

I referred particularly to 115 volts as the lamp voltage. The same relative situation applies to both two-phase and three-phase taking 120 volts instead of 115 volts. Even with 120/208 volts, three-phase, I believe most operating engineers would feel apprehensive about giving 208 volts to motor customers where they are used to receiving 225 to 235 volts for 220-volt motors.

Regarding "power per wire," this comparison indicates the efficiency in using the capacity of the installed wires including the neutral, which as a matter of practise is comparable in size to the other conductors. One critic states that the two-phase, five-wire system is only 80 per cent efficient. This is true as regards the utilization of the installed copper and on the same basis the three-phase, four-wire system is only 75 per cent efficient.

As to the matter of voltage unbalance on three-phase secondary mains, with a wire spacing of 14½ in., I might say the unbalance is not much decreased even with a spacing of 4½ in. such as on a bracket. That can be easily checked by calculation. Whether voltage unbalance is caused at the source or along the mains makes no difference in the effect.

As I think the paper brought out, I favor the higher primary voltages. However, it is true that there has been in the past some distrust, at any rate on the part of the public and some engineers, of the higher primary voltages for distribution.

Comparing systems on the basis of starting off new would be interesting, but hardly justifiable. But the words of the old adage still hold true:—"No matter where you are going, you must start from where you are." That is the point from which my paper started.

In the matter of relative costs of distribution systems and the relative savings in the light of growth, Tables No. III and IV were based, for the particular area under investigation, on a doubling of the present dense load. Whether doubling or quadrupling of load is assumed, there must be taken into account one factor which seems very important—the increasing loads supplied to customers at primary voltage. As larger buildings are erected and the load grows, it does not necessarily follow, particularly in a congested area, that delivery of all the increased load will be at the same low voltage. Often delivery will be at primary voltage, with the customer providing his own transformers and deciding on the voltage and number of phases on his premises. The primary system will probably supply the medium and large customers and thus absorb a large percentage of the increased load, and the secondary system will supply the smaller customers.

Reference has been made by two speakers to the two-phase system as being "inferior" or "inherently bad." Is a system inferior or inherently bad unless it is either extravagant or inadequate with regard to service? The two-phase, five-wire, secondary system is not a "proposed" system, but has been an actual reality for years. It has given adequate service since the inception of polyphase systems and still is giving economical service. It delivers standard voltages, and this cannot be said of some of the present and proposed three-phase systems. It employs standard apparatus. It affords maximum voltage and load balance in the system. It is flexible in growth and adequately serves the customers' conveniences.

Therefore, my conclusions still are:—The two-phase, five-wire secondary system is adequate and economical, and has a recognized place in distribution practise not inferior to any other system. The two-phase, five-wire system as well as any other adequate and economical system where once established should be continued unless another system presents greatly superior engineering and economic advantages.

The Oil Circuit Breaker Situation from an Operator's Viewpoint

BY E. C. STONE[1]

Member, A. I. E. E.

Synopsis.—This paper is an outline of the oil circuit breaker situation from the operator's standpoint, particularly with reference to interrupting duty, as it appears today to the author. It is not an original study, but rather an assembly of previously existing information, and is arranged by topics with a view to bringing out a large amount of discussion, in the hope that it may result in further clarifying the very complex problem of interrupting electric currents.

The topics taken up are as follows:

I Factors determining interrupting capacity, namely, intensity and duration of the arc.

II-III Essential features of breaker design and their functions.

IV Factors affecting interrupting duty, with especial emphasis on effect on same of system and fault grounding conditions.

V Relations between interrupting ratings and costs.

VI Status of interrupting ratings with reference to maximum nature of such ratings and facts upon which they are based; relative ratings on different operating duties and desirable modifications in method of rating.

VII Applications, particularly possibilities for improved practise in future, and necessity of adequate maintenance on all breakers in service.

At the 1918 Midwinter Convention of the American Institute of Electrical Engineers, a paper on "The Rating and Selection of Oil Circuit Breakers" was read by Messrs. Hewlett, Mahoney, and Burnham. In this paper the manufacturers presented their interpretation of the A. I. E. E. standards on oil circuit breakers as they existed at that time and a discussion of the features involved in the selection of oil circuit breakers for use on the various power systems. Since that time, much additional experience has been gained in the design and operation of oil circuit breakers and a definition of interrupting duty has been added to the standardization rules of the A. I. E. E.

In that which follows, no attempt at original research into the problem of oil circuit breaker interrupting duty has been made. Rather, the purpose is to present briefly a bird's-eye view of the circuit breaker situation from an operator's standpoint, as it appears to the author today. It is hoped that the outline which follows, of some of the more prominent phases of the subject, will call forth discussions which will bring out much important information.

The rating of an oil circuit breaker includes normal voltage, normal current, normal frequency, maximum momentary current which the breaker can withstand, and interrupting capacity. Of these items, all except the last are perfectly simple and not subject to argument. Hence, interrupting capacity is the only item of rating which is involved in the following discussion.

I—Factors Determining Interrupting Capacity of Oil Circuit Breakers

The interrupting duty imposed upon an oil circuit breaker when it opens a circuit depends on:

a. Intensity of arc between contacts, which is a function of magnitude of current interrupted.

b. Duration of arc, which is a function of the voltage tending to maintain the arc; that is, the "recovery voltage" which appears across the terminals of the switch at the moment the arc is interrupted.

The effect of the arc is to release an amount of energy in the tank which is determined by the intensity and duration of the arc, as stated above. This energy appears as heat which breaks down a portion of the oil in which the contacts are submerged. Gases are emitted, which develop high pressures, and carbon is deposited, causing loss of insulation strength of the oil. Also, the contacts are usually more or less burned. If, due either to too great intensity of arc (excessive current), or too great duration of arc (excessive voltage), or both, excessive amount of energy is released, the breaker will be unable to withstand the pressure developed and will give way, accompanied by more or less severe explosion, due to which the oil may ignite. The maximum amount of energy which the breaker safely can take care of marks the limit of its interrupting capacity.

After a breaker has opened the circuit, the gas pressure disappears in a comparatively short time, as the gas escapes through the vent, but the burning of contacts, carbonization of oil, and depositing of carbon on insulated surfaces inside the tank are accumulative. That is, every time a circuit breaker opens a circuit through which current is flowing, the arc produced causes burning of contacts, oil carbonization, and carbon deposit which effect a definite reduction in the interrupting capacity of the breaker. After a sufficient number of circuit openings, interrupting capacity of the breaker is exhausted and can only be restored by repairing contacts, cleaning inside insulating surfaces, and replacing old oil with new.

The loss of interrupting capacity of a breaker, as it operates, may be likened to loss of capacity in a storage battery as it discharges. After a certain duty has been performed, the breaker, like the storage battery, becomes exhausted. As the duty is intensified, the life

1. Planning Engineer, Duquesne Light Co., Pittsburgh, Pa.

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, June 22-26, 1925.

of the breaker is shortened, just as the life of the battery is shortened on heavy load duty. Again, just as the battery may be recharged after its life has been run, so a breaker can be brought back to its original rating by a little simple and inexpensive maintenance.

II—Essential Features of Oil Circuit Breaker Design which Determine Interrupting Capacity

The essential features of design which determine interrupting capacity are:

a. For interruption of arc—
- Contact break distance
- Speed of contact travel
- Contact pressure
- Magnetic blow-out effect

b. For absorption of energy of arc (gas pressure)—
- Volume of oil
- Oil head above contacts
- Air space above oil
- Venting

c. Mechanical Strength—Great mechanical strength is required throughout to withstand the strains due both to pressures developed by release of gas and to electromagnetic effects of the heavy currents handled.

d. Thermal capacity—All current-carrying parts must have sufficient thermal capacity to carry the maximum currents while they last.

Operating tendency is to require increased thermal capacity to take care of the longer duration of short-circuit current due to the higher relay settings used for obtaining selectivity of circuit-breaker operation and for taking advantage of the current decrement curve of the synchronous equipment.

e. Oil quality—

III—Design Features on which Difference of Opinion Exists

Opinion is divided as to the value of the following design features:

High Speed contacts

Explosion chamber

Multiple contacts in series

Resistance introduced into breaker circuit to reduce energy released by arc in breakers

Opinion is also divided as to the best means of absorbing the gas pressure and the different designs take care of this feature by various methods.

IV—Factors Determining the Interrupting Duty to which an Oil Circuit Breaker is to be Subjected

Since interrupting capacity depends on current interrupted and recovery voltage, the interrupting duty in any case varies with these two factors:

1. Factors affecting current to be interrupted—The maximum current which a circuit breaker may be required to interrupt is obviously a dead short circuit at its terminal.

The current at any point of a system, under short-circuit conditions, is affected by the following factors:[2]

a. The total kv-a. reactance, and transient characteristics of the synchronous machines connected to the system.

b. Number, reactance, resistance, capacitance, and arrangement of all circuits over which power can be supplied to the point of short circuit.

c. The kv-a. arrangement, resistance, reactance, and capacitance of all reactors and transformers, through which power can be supplied to the point of short circuit.

d. Contact resistance at the short circuit.

e. The nature of the short circuit, whether single-phase or multiphase.

f. The kv-a. and power factor of the load being carried at the time of short circuit.

g. The point of the pressure wave at which the short circuit was established.

h. The use of automatic voltage regulators.

i. Conditions as to grounding of system neutral and grounding of short circuit.

j. Elapsed time from first cycle of short circuit to interruption of arc on breaker contacts.

2. Factors affecting recovery voltage—Very little consideration, so far, has been given to these factors although they are fully as important as those affecting current. The most obvious are:

a. Phase angle between interrupted current and recovery voltage.

b. Conditions as to grounding of system neutral and grounding of short circuit.

c. The kv-a. and power factor of the load existing at the time of short circuit.

d. Arrangement and characteristics of circuits and apparatus.

The effect of item (a) has been discussed in a previous paper[3]. Under ordinary operating conditions item (c) should not vary sufficiently to affect radically the interrupting duty of the circuit breakers. The effect of Item (d) is to cause a high frequency transient voltage to be superimposed on the normal frequency recovery voltage, as a result of the discharge of stored energy in the system. Comparatively little data are available on the magnitudes of these transient voltages under varying system conditions—in most cases, however, it does not seem probable that they will increase the interrupting duties on breakers beyond the factors of safety intended to be in the breaker ratings.

Conditions as to grounding of system neutral and grounding of short circuit, item (b), however, have very marked effect on the recovery voltage and therefore

2. Items (a) to (h) listed herein are taken from the paper "Rating and Selection of Oil Circuit Breakers" by Hewlett, Mahoney, and Burnham, A. I. E. E., 1918.

Fig. 1—Relative Recovery Voltages for Various System Conditions

In Figs. 1A to 1C the numbers directly under the breaker contacts give the normal voltages, expressed in decimals of normal system line voltage, which will exist across the respective contacts under the conditions shown. Under usual operating conditions, these values may be assumed as the limiting normal frequency recovery voltages on which interrupting rating should be based.

The parts of the circuit in which short-circuit current flows are shown by heavy lines.

on the interrupting duties imposed on the breakers. The relative values of recovery voltage under the various possible grounding conditions are shown in Figs. 1a to 1c.

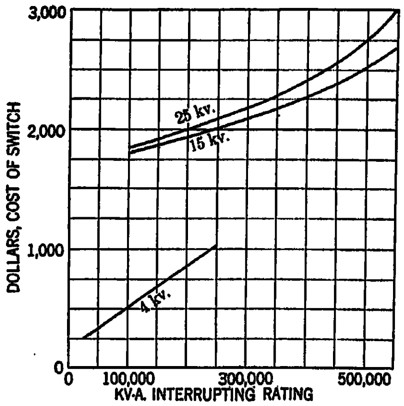

Fig. 2—Cost vs. Interrupting Rating for Oil Circuit Breakers. 25 Kv. and Below

V—Relation of Rated Voltage and Interrupting Capacity to Cost of Oil Circuit Breakers

For the study of problems in economics of system design a series of curves showing comparative costs

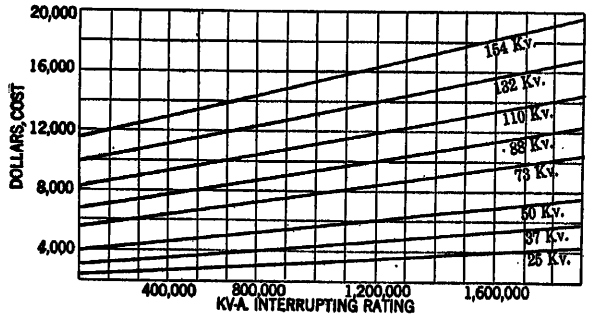

Fig. 3—Cost vs. Interrupting Rating for Oil Circuit Breakers, 25-Kv. and Above

of oil circuit breakers has been compiled. These curves are based on present day prices and are believed to present a fairly accurate picture of the relation of

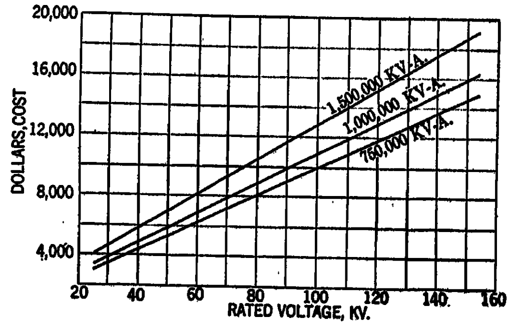

Fig. 4—Cost vs. Voltage Rating for Oil Circuit Breakers Interrupting Ratings 750,000-Kv-a. to 1,500,000-Kv-a.

costs to interrupting ratings as a whole, although in some individual cases the price of a given breaker may be considerably out of line. These curves are shown in Figs. 2, 3, and 4.

On low-voltage breakers interrupting capacity is the chief factor in determining price, while voltage has less effect. Thus, a 15-kv. breaker of 300,000-kv-a. interrupting capacity costs approximately 16 per cent more than a 15-kv. breaker of 130,000-kv-a. capacity, while a 25-kv. breaker of 500,000-kv-a. capacity costs approximately only 9 per cent more than a 15-kv-a. breaker of the same capacity. (Fig. 2.)

On high-voltage breakers, however, voltage is the chief factor in determining the price, while interrupting capacity has a lesser effect. Thus, a 37-kv. breaker of 1,500,000-kv-a. capacity costs approximately only 28 per cent more than a 37-kv. breaker of 750,000-kv. capacity, but a 73-kv. breaker of 750,000-kv-a. capacity costs approximately 60 per cent more than a 37-kv. breaker of the same capacity. (Fig. 2.)

VI—Status of Interrupting Ratings

Interrupting ratings of oil circuit breakers are admittedly maximum ratings so that breakers cannot be expected to function properly even slightly beyond their ratings. It is understood, however, that these ratings are based on interrupting an ungrounded short-circuit, under which condition the normal frequency recovery voltage is a maximum. (Fig. 1A.)

Interrupting ratings are based on a constantly increasing fund of knowledge resulting from tests in factory and field and from operating experience. Special attention is called to the exhaustive factory tests made by one manufacturing company. Some of the interrupting duties under which breakers have been tested in the field are shown in Table 1.

TABLE I
FIELD TESTS ON OIL CIRCUIT BREAKERS OF HIGH INTERRUPTING CAPACITY

Normal Line Voltage	Limiting Recovery Voltage	Maximum kv-a. three phase Interrupted	Amperes per Pole	Grounding Characteristic: System Neutral	Grounding Characteristic: Short Circuit
	(See Note)				
132 kv.	77 kv.	725,000	3150	Dead Grounded	Grounded
110 kv.	63 kv.	542,000	2850	" "	Grounded
44 kv.	44 kv.	280,000	3660	" "	Ungrounded
44 kv.	25 kv.	246,000	3220	" "	Grounded
24 kv.	14 kv.	580,000	14,000	" "	Grounded
23 kv.	23 kv.	450,000	11,400	Grounded through Resistance	Grounded
13 kv.	7.5 kv.	545,000	23,700	Dead Grounded	Grounded

Note: Limiting recovery voltage, as used in above table, is defined as the maximum or limiting normal frequency recovery voltage which can appear across the contacts of one switch pole after the arc is interrupted, under the grounding conditions existing in the test. For explanation of method of obtaining these values see Figs. 1A to 1D.

On the actual tests the recovery voltage did not in any case reach the full limiting value as given above, even taking into account such higher frequency harmonics as were developed.

So far as the writer has been able to ascertain, no field tests have been made where more than 725,000-kv-a. has been interrupted. Most of these field tests, as shown in the table, have been made on grounded short-circuits in systems with dead grounded neutral. In such cases the recovery voltage is approximately only 58 per cent of that on a system with neutral ungrounded or grounded through a high resistance. The interrupting duty under such tests was therefore only about 58 per cent of that which would have been imposed if the tests had been made on systems with high resistance instead of dead grounded neutral. In general, also, tests were made under conditions where the transient voltages resulting from the interruptions of the short circuit have been very small, but on the other hand, metallic short-circuits were used which would give more severe conditions than probably exist ordinarily in service.

Oil circuit breakers, with their designs based on the results of tests within the range of their interrupting rating, may be expected to perform satisfactorily up to these ratings, where they are installed under system conditions similar to those under which the field tests were made, particularly in regard to conditions as to grounding of system neutral and grounding of short circuits which the breaker must interrupt.

For ratings beyond the range of tests, it must be clearly borne in mind that very little direct data have been obtained and that designs are based on data deduced from tests made on lower interrupting duties. It remains to be seen how accurate the conclusions thus drawn will prove to be.

In oil circuit breakers for high voltages, the tank size is determined by the voltage rather than by interrupting duty. It is quite possible that the interrupting capacity of high-voltage breakers may prove to be larger than expected for this reason.

All published interrupting ratings are now based on the standard operating duty approved last year by the Protective Devices Committee and printed in the A. I. E. E. Journal for October, 1924.

Referring to the standard definition of interrupting rating on which the standard operating duty is based, it is probable that the term "Normal Voltage" will require further definition in view of the wide differences in the recovery voltage which may prevail with the same normal system voltage. Meanwhile it is assumed as stated above that this term is interpreted to mean that the switch will be able to perform its full operating duty under the conditions which will give a recovery voltage up to the magnitude which results when the short circuit is ungrounded. It is not clear, at the present time, whether this is always the case.

Further attention must also be given to the relative interrupting ratings of the same circuit breaker under different operating duties.

The following relative ratings have been proposed by the Power Club:

a. One-unit operating duty...... 100 per cent to 125 per cent
Rating varies between limits given with design of breaker

b. Two-unit operating duty, two-minute intervals (*standard duty*)........................... 100 per cent

c. Four-unit operating duty, two-minute intervals	70 per cent
d. Four-unit operating duty, one-half minute intervals	60 per cent
e. Four-unit operating duty, no time intervals	25 per cent
f. 300-unit operating duty, 15-minute intervals	30 per cent
g. Four-unit operating duty, successive intervals of 0, 30, 75 seconds	30 per cent
h. Four-unit operating duty, successive intervals of 15, 30, 75 seconds	40 per cent
i. Three-unit operating duty, one-minute intervals	70 per cent

It is recommended that operating duties (d), (e), (g), and (h) be confined to oil circuit breakers having interrupting ratings on standard operating duty not over 250,000 kv-a. and voltage ratings not over 37 kv.

Taking the above figures as a basis, it is probable that a breaker that will perform satisfactorily under operating duty (a) or (b), one or two interruptions, will also perform satisfactorily on any of the other operating duties at the percentage rating given. On the other hand, it does not seem at all certain that a breaker which will satisfactorily interrupt the lower values of kv-a. on multiple interrupting duty will also be able to interrupt the higher kv-a. of the one or two interruption operating duties on the percentage relation shown in the table.

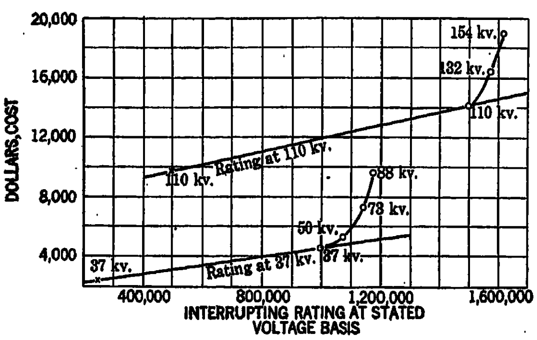

FIG. 5—COMPARATIVE COSTS OF INTERRUPTING RATINGS IN OIL CIRCUIT BREAKERS OPERATED AT VOLTAGES BELOW NORMAL

In Fig. 5 are shown the relative costs of obtaining interrupting capacity when using breakers at voltages below their normal rating. Thus, while a 37-kv. breaker of 1,150,000-kv-a. interrupting rating will cost $5000, a 73-kv-a. breaker, giving the same interrupting rating on 37-kv. operation, will cost $7300, an increase of 46 per cent. The effect of this relation of ratings is to make very much more expensive the use of breakers of higher-voltage ratings than the normal operating voltage of the system in which they are connected, although such practise becomes vitally necessary on some systems. Certain operating data which have come to the attention of the writer lead him to believe that in many cases the permissible increase in interrupting ratings at reduced voltage operation is too conservative and it is earnestly suggested that the manufacturers give careful consideration to revision of their present standards in this respect.

Tests are still urgently needed to prove performance at greater interrupting capacities and it is hoped that the operating companies will continue the practise of testing oil circuit breakers at progressively greater interrupting duties as the available short-circuit capacity on their systems increases. To assist in carrying out these tests and to provide for getting the greatest benefit from results obtained, a proposed uniform procedure for testing the interrupting rating of oil circuit breakers was approved by the Protective Devices Committee at its meeting last spring. This procedure now has the approval of the Electrical Apparatus Committee of the N. E. L. A. and is recommended as a basis of procedure for all future oil circuit breaker tests on power systems.

VII—APPLICATION OF OIL CIRCUIT BREAKERS

In considering the application of an oil circuit breaker to a specific situation, the maximum interrupting duty must be determined by calculation of maximum current to be interrupted and maximum recovery voltage. The interrupting rating of the breaker specified will depend upon the maximum interrupting duty as thus determined and the particular operating duty which will be demanded of the breaker in service. At the present time conservative practise requires that calculations be made on a basis that will give a maximum interrupting duty equal to or somewhat higher than that which can actually be imposed on the breaker.

Calculation of short-circuit current is thoroughly understood and can be made with almost any desired degree of accuracy.[4] Calculation of recovery voltage is not so well understood. The important factor to be taken account of in determining recovery voltage is the condition as to grounding of system neutral. (Refer to Figs. 1A to 1C). Up to the present time most of the heavy-duty oil circuit breaker experience has been derived from systems with dead, or nearly dead, grounded neutrals, on which the interrupting duty for a given current is of the order of only 58 per cent of that on a system with ungrounded or high-resistance grounded neutral. Hence on systems of the later type, which are becoming more numerous all the time, it becomes of prime importance to give careful consideration to the more severe conditions.

Up to the present time comparatively little attention has been given to refinement in the application of oil circuit breakers. As the interrupting ratings of breakers become more accurate it should be possible to fit breakers more closely to their individual duties. Many factors under operating conditions tend to make the current which must be interrupted on most faults of much less magnitude than the maximum current of a

4. "Application of Decrement Factors in Short Circuit Studies" by W. R. Woodward, *Electrical Journal*, May 1924.

dead short circuit at the breaker terminals. Some of the more obvious of these factors are:

Resistance in fault.

Faults resulting in grounds or three-phase shorts, whereas duty may be calculated on the more severe single-phase line to line short.

Neglect of system resistance in calculating fault currents.

In networks, the interruption of the fault in two or more steps.[5]

When these factors are known and circuit breaker ratings are also accurately determined, it may be found that the maximum conditions assumed in the selection of the breaker at the present time occur so seldom that they may be treated as a special case. This special treatment might involve allowing the breaker to function above its rating in these few instances, or by prescribing a less severe operating duty under especially heavy short circuits, or by installing breakers in group arrangement in such a manner that one breaker of sufficient interrupting capacity to meet maximum duty would be in series with a number of smaller breakers designed for average conditions and would only open

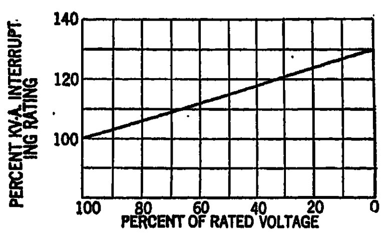

FIG. 6—INCREASE OF INTERRUPTING RATING OF AN OIL CIRCUIT BREAKER WHEN OPERATED AT A VOLTAGE BELOW ITS NORMAL VOLTAGE RATING

when the rating of the small breakers was exceeded by the short circuit. All of these methods are in use to a limited extent at the present time, but their effectiveness is uncertain, because of lack of exact knowledge as to conditions. Data on actual values of fault currents as experienced in every day operation are much needed, and it is believed that if such data could be obtained and analyzed, material savings in overall circuit-breaker investment might be effected without undue hazard to service.

A number of companies have found it necessary to use breakers designed for normal voltage higher than those of the systems on which they are to be used, in order to obtain adequate factors of safety against insulation failure. On the basis of ratings now standard, this factor of safety is obtained only at marked increase in cost. (Fig. 6.)

The standard definition of operating duty of a circuit breaker contemplates very clearly that after the rated interrupting duty of the breaker is performed, the breaker is no longer good for its rating until suitable maintenance has been performed. The reasonableness of this condition is found in the explanation in Section I above of what happens within the breakers when a current is interrupted. It is of the utmost importance that this limitation be recognized. An adequate system of inspection and maintenance must be set up if satisfactory service is to be obtained. In this connection it is obvious that the cost of maintenance will be less where the rated interrupting capacity of the breaker is in excess of the maximum duty it is called upon to perform. In circuit-breaker installations, therefore, some consideration should be given to striking a balance between first cost and maintenance cost. Due consideration of both of these factors will sometimes call for a larger breaker than would otherwise be specified.

Discussion

W. S. Edsall: We feel that there is not a great deal in this paper that can be discussed by the manufacturers, because it is a paper primarily presenting the operators' viewpoint.

This showing of the various conditions of the grounding of the system and generator is going to help the general situation. The effect of grounding upon recovery voltage and the effect of recovery voltage upon the duty of an oil circuit breaker have not been given the attention the subject merits by either the manufacturer or the operator. The manufacturer has known that very severe duties are imposed upon the breaker under high recovery-voltage conditions. The operators in many cases have not known that the systems contained certain combinations of reactance and capacitance which would, under certain conditions, give high recovery voltages.

We feel it important that the recommendation of the Protective Devices Committee regarding definitions for normal voltage, recovery voltage, normal current, etc., should be followed out. The publication of such definitions will tend to call attention to the conditions that exist, and will lead to more accurate application of breakers to the system.

Some European engineering associations have already made definitions that would distinguish between normal voltage and recovery voltage.

O. K. Marti: Mr. Stone brings out in his paper that it would be highly essential, in the future designs of breakers, to have more data regarding four distinguished designs (see his paper under III) since the opinion is greatly divided as to their value. I shall refer below to two designs which European engineers, at present, believe to be the right steps in the right direction, namely, to the application of multiple contacts in series and to the introduction of a resistance into the breaker circuit.

Very little information has been actually published regarding the operation of breakers embodying the above designs. To my knowledge, there are only two references on the foregoing information, the first in a report to the Swiss Commission by Dr. B. Bauer[1], and the second in an article by Mr. G. Bruehlmann[2] in the *Brown Boveri Review*. Both articles are based upon elaborate tests which led to facts not suspected at the time of starting the investigations.

In Fig. 1 herewith is shown an arrangement whereby a protective resistance may be introduced by means of multiple contacts in series, and its effect realized from Fig. 2. An a-c. arc is extinguished at the moment the current passes through zero if the recovery voltage does not increase high enough so that an arc can be struck anew. Thus it may be noted from the oscillograms taken at Section I of Fig. 1 and shown in Fig. 2 that the increase of the voltage immediately after the arc in Section I extinguished, in case of introducing a protective resistance (see curve denoted by 4) was much more favorable than when no

1. *Bulletin*, Ass. Suisse des Electriciens, 1915.
2. *Brown Boveri Review*, March, 1923, page 43.

resistance was introduced (see dotted curve denoted by 7). The advantage of the new design lies in the slow increase of the voltage due to the fact that it retards its recovery speed and thus gives the produced arc gases time to cool. Furthermore, there may be noted the very favorable influence of the recovery voltage immediately before the arc extinguishes, having then the value of the ignition voltage. Tests with breakers having various sizes of protective resistances, in addition to many unexpected facts, gave the following results:

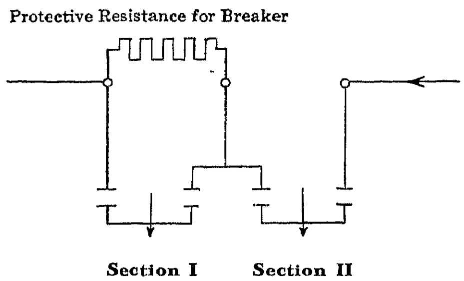

FIG. 1—DIAGRAM OF CONNECTION OF A BREAKER WITH PROTECTIVE RESISTANCE

The best interrupting conditions in any breaker circuit are obtained when a protective resistance eight or ten times the short-circuit impedance is introduced during the short circuit.

The duration of the arc decreased considerably, while the breaker duty, volume of arc gases, and the pressure of the oil decreased accordingly. It was actually found in several tests that the released energy in the arc was less than 1/10th.

Other tests which were conducted by the Swiss Federal Railroads on single-pole breakers rated 15,000 volts, 350 amperes, revealed the fact that, in a single tank of less than 5.5 cu. ft.

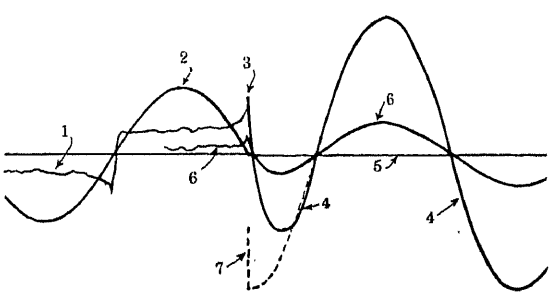

FIG. 2—VOLTAGE AND CURRENT WHEN A CIRCUIT BREAKER HAVING PROTECTIVE RESISTANCE IS TRIPPED BY A SHORT-CIRCUIT AS SHOWN IN SECTION 1

volume over 100,000 kv-a. interrupting capacity could easily be handled by introducing in the breaker circuit a protective resistance with multiple-break arrangement. The protective resistance in the above breaker is an integral of the breaker and is inserted in the tank. The result of this test was the adoption of such breakers as standard designs by two state railways in Europe.

The addition of a resistance to a breaker or to the system of a power station should not be considered as a step in the wrong direction in breaker design, since similar steps are being made at the present time along this line in protecting electric equipment, as, for instance, by the addition of reactors, a limitation of the short-circuit current is obtained.

A schematic arrangement of a multiple-contact breaker is shown in Fig. 3. The purpose of this design is mainly for the reduction of the produced arc gases and the deposit of carbon, the latter causing loss of insulating strength of the oil during interruption. By dividing up the arcing distance, less energy is released, and since the gas is produced at several places throughout the oil volume, the latter is therefore much more quickly cooled. Moreover the arc can be much more easily controlled, and, therefore, several dielectric problems overcome without a complicated design. Realizing that 100,000 volts require an arcing distance of over 70 in., the foregoing fact would be greatly appreciated in the design of high-voltage breakers.

It might also be of interest to know that there have been investigations by a European company concerning a new contact device using two series coils so arranged as to form a compact piece of apparatus, which produces a powerful action with a minimum of space. The field produced by these coils closes the breaker against the forces which are especially severe at a short circuit just as easily as at normal load. The forces tending to part the contacts are due to the electrodynamic action and the gases produced between the contacts resulting from the current and the arc. The magnitude of such forces and their influence

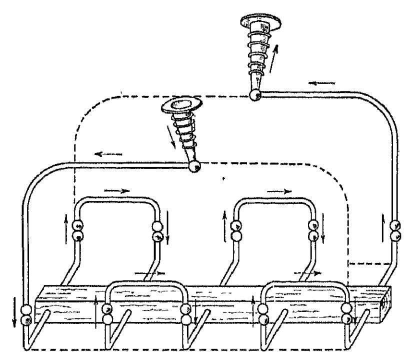

FIG. 3—ARRANGEMENT OF BREAKS AND PATH OF CURRENT IN CASE OF TEN-SERIES BREAKS

upon the operation of the breaker and its control mechanism may be better realized after considering the following figures; by breaking a current of about 25,000 amperes and assuming that its maximum value including the asymmetrical component is about 50,000 amperes, the foregoing forces would be approximately 400 lb. which have to be given due consideration in the design of breakers.

The factors determining the duty of a breaker are tabulated under Table IV of Mr. Stone's paper. It follows that the duty depends upon a great number of factors which require a very tedious and rather drawn-out procedure when given due consideration by selecting a breaker. It may be of interest, therefore, to know that a table for ratings of circuit breakers has been published by the Swiss Commission of Oil Circuit Breakers[3] which may be considered as a first step to simplify the foregoing mentioned procedure. This table is shown as Table I herewith and has already been adopted in various parts of Europe.

A. H. Kehoe: Many of the large capacity circuit breakers require extrapolation of published test data to establish their rating. This applies particularly to the restoring voltage after final rupture takes place. Future tests of circuit breakers should be with restoring voltage at least equal to the system voltage on which the circuit breaker is to be used, and for some situations double normal voltage should be used on the test circuit in order to obtain correct performance data of the breaker.

In several places the paper mentions contact resistance at the short-circuit as being one factor to be considered in selecting

3. *Bulletin No.* 2 Ass. Suisse des Electriciens, 1925.

the size of breaker required. While it may be possible to arrange a circuit so that faults will be in the form of arcs, yet short-length arcs have voltage drops in the order of 100 to 200 volts for currents from 1000 to 15,000 amperes so that on high-voltage systems contact resistance is negligible. This fact is of importance in considering the destructive forces at a fault, particularly on high-voltage cable systems. Instead of in-

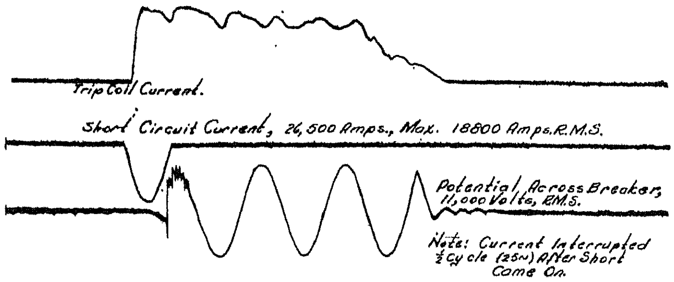

FIG. 4—HIGH-SPEED, OIL CIRCUIT BREAKER TEST, ALL POSSIBLE LOAD

creasing with the voltage, the destructive effect is quite the reverse, as high-voltage lines generally have a considerably lower value of short-circuit current than do the circuits now commonly used.

J. B. MacNeill: On the second page of his paper Mr. Stone gives certain features of design which affect rupturing capacity, and states that there exist differences of opinion regarding the most effective principle for a particular range of circuit breaker sizes and capacity is limited in its use to such sizes.

It is generally known that the magnetic blowout effect of the current passing through the loop formed by the contacts and

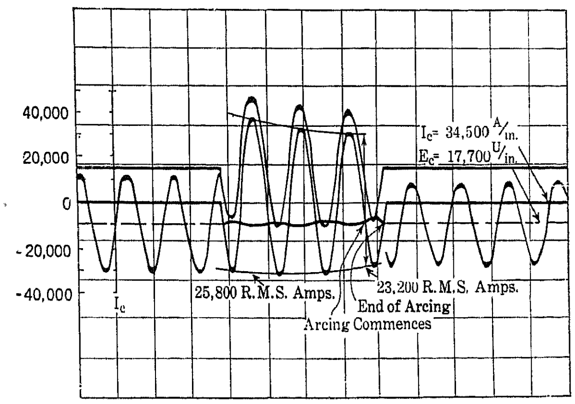

FIG. 5—OSCILLOGRAM OF OIL CIRCUIT BREAKER TEST OPENING APPROXIMATELY 25,000 R. M. S. AMPERES AT 13,200 VOLTS, 25 CYCLES

terminals of an ordinary moderate-voltage breaker has a tremendous effect in accelerating the arc formed between the contacts. The length of the arc thus formed may be pretty much independent of the mechanical speed of the breaker al-

TABLE I

DUTY IMPOSED ON ONE BREAKER POLE ON TWO- AND SINGLE-PHASE SHORT CIRCUITS COMPARED WITH DUTY ON THREE-PHASE SHORTS

		Short Circuit via transmission lines and transformers	Short Circuit at generator terminals (without appreciable line impedance)	
Quantity	Nature of Short Circuit	Initial Short equals sustained Short	Initial Short	Sustained Short
	Three-phase	100%	100%	100%
Current interrupted..........	Two-phase	$\frac{\sqrt{3}}{2} \times 100 = 87\%$	abt. 100%	abt. 115-150%
	Single-phase	100%	abt. 115%	abt. 150-200%
	Three-phase	100%	100%	100%
Voltage.....................	Two-phase	$\frac{1}{\sqrt{3}} \times 100 = 58\%$	$\frac{1}{\sqrt{3}} \times 100 = 58\%$	abt. 65- 85%
	Single-phase	$\frac{100}{1.5} = 67\%$	$\frac{100}{1.5} = 67\%$	abt. 85-115%
	Three-phase	100%	100%	100%
Interrupting capacity........	Two-phase	50%	$\frac{1}{\sqrt{3}} \times 100 = 58\%$	abt. 75-125%
	Single-phase	$\frac{100}{1.5} = 67\%$	c.a. $\frac{115}{1.5}$ 77%	abt. 125-230%

The table is based on the assumption that the impedance of the generators in each phase is smaller by about 15% on two-phase and single-phase shorts when compared with three-phase shorts, due to the magnetic interlinkage of the phases.

In the last column the first figure refers to low-speed generators, the second figure to turbo generators.

merits of some of these features. The general use of certain of these features over a large range of voltage classes and interrupting capacities necessarily results in the application in places where a given principle may not be used to its full advantage as well as in places where the principle may be particularly useful. For instance, the magnetic blowout effect referred to by Mr. Stone is of negligible importance on high-voltage breakers where the current to be interrupted is only a few thousand amperes. On the other hand the use of high-speed breaks on low-voltage breakers where the interrupting current is large, would be entirely superfluous. The best results are obtained when the though sluggish breaker action is not to be advocated. As an illustration of what can be accomplished with magnetic blowout effects, Fig. 4 herewith shows an oscillogram of a special circuit breaker opening a current of 18,000 r. m. s. amperes on a single-phase grounded circuit at 11,000 volts. The total time of operation of the circuit breaker including the tripping time, movement of the contacts, and blowing out of the arc, is only one-half cycle on 25 cycles. Fig. 5 shows an oscillogram of a standard circuit breaker of the dead-tank variety opening a current of approximately 20,000 amperes and in which the total period of arcing is approximately one-half cycle on 25 cycles.

inasmuch as the time of arcing cannot be reduced below one-half cycle provided the arc starts at the beginning of the voltage wave, it can readily be seen that the addition of high-speed breaks or other features of design in an attempt to reduce arcing further would simply be adding complication to the breaker structure.

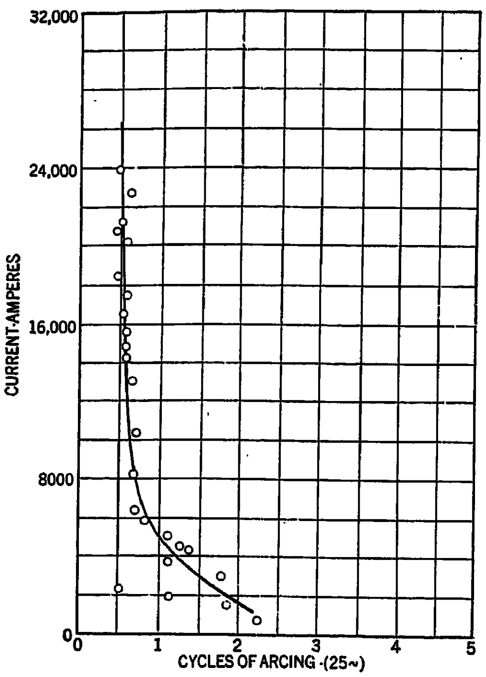

Fig. 6—Duration of Arcing as Obtained from Average of More than 200 Oil Circuit Breaker Test Oscillograms

The increased efficiency of the magnetic blowout with increasing currents is shown in Fig. 6 in which ordinates are r. m. s. currents and abscissas are cycles of arcing on a 13,200-volt, 25-cycle circuit. It is evident that the curve becomes asymptotic at one-half cycle. This curve represents the data from a large number of tests on several sizes of breakers and

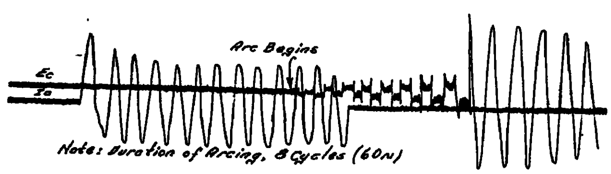

Fig. 7—Oscillogram of Oil Circuit Breaker Test, Opening Approximately 3000 Amperes at 44 Kv., 60 Cycles

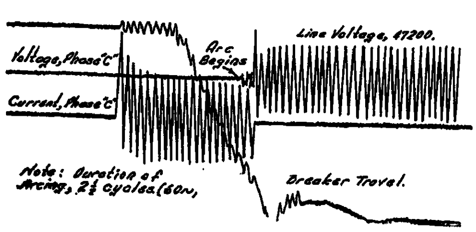

Fig. 8—Circuit Breaker Test

various oil conditions and illustrates the dependability and regularity of operation under these conditions of breakers using this principle.

On the other hand, for high-voltage breakers in which the magnetic blowout effect is inherently small, some device must be resorted to to prevent the building up between the contacts of a pillar of arc gas which may result in an unnecessary long period of arcing. For this purpose high-speed breaks are particularly useful. Anyone who has had the experience of opening an ordinary knife switch will realize the difference that high-speed contacts make on arc duration and the amount of burning on the contact parts. Fig. 7 shows the operation of an ordinary speed breaker at 44,000 volts on opening approximately 3000 amperes at 60 cycles. The arc extends over several cycles which, of course, represents a certain amount of burning of contact parts and oil and the generation of gas pressure in the breaker structure. In Fig. 8 is shown an oscillogram of a breaker with high-speed contacts opening approximately 4500 amperes at 44,000 volts, 60 cycles and, therefore, the amount of arcing can be compared directly to that in Fig. 7. The total duration of arcing with the high-speed contact is 2½ cycles on a 60-cycle circuit and consequently the amount of burning on the breaker contacts, the pressure generated in the tank, and the amount of oil burned up are reduced to a minimum.

Fig. 9 shows curves of the relative speed of the arcing members of a breaker with ordinary breaks and of the same breaker

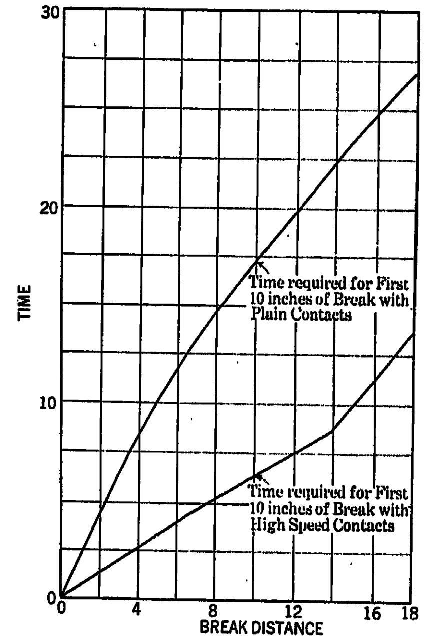

Fig. 9—Relative Speeds of Plain and High-Speed Contacts

equipped with high-speed contacts. These data were taken with oscillographs but represent mechanical action of the parts only. The time for a given break with high-speed contacts is approximately one-third that required for the same displacement with ordinary break and this ratio holds closely over a large range of voltage classes. Reference to Figs. 7 and 8 indicates that the ratio of arcing period for the two constructions favors the high speed contacts more than does the comparison of mechanical speeds.

M. I. Pupin: In listening to the discussion on circuit breakers, I observed that there was one fundamental principle which I think is never taken account of in the design of circuit breakers. We always take note of the principle of conservation of energy. The energy,—that is, the electrical energy,—must be transformed into some other form of energy. That, of course, is correct. But when you do that, you go only half-way. There is another principle in the science of electricity which must be taken into account, and that is the principle of conservation of momentum. You must provide something which will take up the electromagnetic momentum accompanying, say, 50,000 or 100,000 amperes, and this so far as I can see, is not so easy to do.

Arnold Roth: Perhaps I may take up the question of the voltage. As I am acquainted with the work of the European

committee mentioned in Mr. Stone's report, I might tell you how we came to the conclusion to introduce the "recovery voltage" in the duty cycle and in the duty imposed on a circuit breaker.

For the time lag of our relays, we use one second and two seconds, and there are generating stations using four and five seconds. As generally known, there is a very big difference for generating stations between the value of the initial rush of short-circuit current and the sustained value. This difference is due to the decreasing of the field. But there is a second effect of this weakening of the field, that is, the decreasing of the induced voltage. It takes place in quite the same relation as the decrease of current and I wonder that more attention has not been given to this fact. As a consequence of this effect, if you have a ratio of 4 to 1 between momentary and sustained short circuit, you might have almost the same relation between the induced voltage at the beginning and at the end of the short circuit. The induced voltage during short circuit is identical with the recovery voltage after rupturing the circuit. That is to say, in a 15-kv. network, you would have at the end of a short circuit a voltage of only 3700. You have a relation between the sustained and the momentary short-circuit kv-a. imposed on your breaker, not of 1 to 4, as we used to calculate, but of 1 to 16. That is to say, if you cut the short circuit in four, or to 0.1 sec. for this special case, you would have a difference from 1 to 16 that might be in one case 500,000 kv-a. for momentary tripping and in the other 30,000 kv-a. with time delay. You see a big difference, and it is absolutely necessary to introduce this relation in order to have a clear comparison between different tests and different kinds of breakers.

I would not uphold our European practise to delay tripping as long as we do. I think we shall have to build breakers able to break the initial short circuit. But even for "momentary" breaking, if you analyze the short-circuit tests made, you will find it very difficult to have the whole voltage of your station as recovery voltage in the moment you are breaking your short circuit. That is to say, take a 100,000-volt network, and you will always find that if, in the moment of the establishment of the short circuit, the voltage has been 100,000 volts, you will have to break only about 85,000 volts if you don't employ special apparatus to trip the breaker before the short circuit occurs, as is the practise in artificial tests.

One of the reasons of European operating companies for introducing long relay setting might be of some interest. These companies installed breakers for the calculated short-circuit capacity when they built the generating stations; afterwards the short-circuit capacity grew and the breakers were no longer sufficient to break the short circuits. Then the operators gave a very long time-setting to the relays in order to reduce the duty. They had really had some reserve for their breakers in the time setting of the relays.

I shall not say that it is good practise, but it is a practise with which we have to calculate in Europe, and to make possible the calculation, we recently introduced the definition of the recovery voltage into our regulation. I would not dare to say that this manner of calculation has become general practise, but we hope it may.

I should like to ask you some questions. I have had opportunity to see many of the leading engineers of this country and have been astonished to find how different are their opinions on the actual situation of the short-circuit-breaker question. I have been in companies where they told me it was quite all right and that they had no difficulties at all. Then there were other networks where it was quite the opposite. Now if you calculate in a general way the short-circuit capacity of the different networks and see the general conditions you would think they are the same. Of course, there must be some reason for this different behaviour. I think it would be a very interesting subject to investigate.

Another question is that of secondary explosions. I have heard many times that one of the most important reasons for the blowing up of breakers is the secondary explosion. We used to make some tests on secondary explosions by exploding gas mixtures, and we found that it takes a relatively big spark to cause an explosion. If we only had on insulators those small sparks which we have as "static" or something like that, it would be quite impossible to ignite the gas. I understand that after a breaker has operated, there is a mixture of explosive gas in the tank of this breaker, but I can't understand how you get the ignition. I should be very much interested if it could be explained.

Perhaps it would be interesting to do some work on the voltage drop in the arcs of short circuits. We made a test with two parallel iron tubes as electrodes and a copper wire acting as fuse with some 90,000-kv-a., short-circuit capacity behind 8000 volts induced voltage. We found about the same values of drop in the arc you had here of 2 to 3 per cent, but this was true only for the first ten or twenty cycles, and afterwards the length of the arc grew and the voltage drop became quite considerable compared to the induced voltage of the circuit, so an influence of the arc resistance on the value of the short-circuit current and consequently on the duty imposed on the breaker is possible if the tripping of the breaker occurs in the moment the arc has a great length. The influence was so great that in some cases the arc was extinguished without operation of the breaker. It took the form of a horseshoe growing bigger and bigger, up to a diameter of 15 to 20 ft. and then extinguishing.

O. R. Schurig (by letter): The following discussion refers particularly to the subject of secondary gas explosions. According to Dr. Roth's discussion, data obtained in Europe appear to show that secondary explosions are less likely to occur than American experience has indicated. It is, therefore, the object of this discussion to present some data obtained in this country on the subject of secondary gas explosions.

Secondary explosions in oil-circuit breakers take place when properly proportioned mixtures of air and gases of decomposition from the oil are ignited. Hence the necessary requirements for secondary explosions are:

1. A combustible gas (or vapor),
2. The presence of oxygen (as, for instance, in air),
3. The proportions of gas and air must be within the explosions limits, and
4. A source of high temperature, such as a flame, an arc, or high-temperature gases.

Tests have shown that the conditions for secondary explosions are likely to be met in oil-circuit breakers unless preventives are applied.

It is well known that the *gases evolved during circuit* interruption in oil are combustible and capable of explosion when suitably mixed with air. The analysis of the gases discharged by an arc between brass electrodes under oil (a commonly used mineral switch oil) showed a hydrogen content of the order of 60 per cent by volume at room temperature. Other explosive gases such as methane and ethylene are also present.

An investigation conducted at Schenectady in 1920 and 1921 to determine the *proportions of gas and air required for explosive mixtures* showed that mixtures containing 5 per cent gas or more up to 50 per cent are explosive, while mixtures not within this range of proportions are not explosive.[4]

The *maximum pressures of explosion* were eight times as high as the initial pressures, all pressures being measured in absolute

4. For the present purpose, the term explosive is defined as capable of rapid combustion in a manner creating a material pressure rise. The maximum velocity of flame propagation was found to be of the order of 30 ft. per sec. as indicated by the experimentally observed time interval between the beginning of the ignition arc and the occurrence of the maximum pressure.

units, in tests made with initial pressures ranging from atmospheric to 40 lb. per sq. in. absolute (*i. e.*, from 0 to 25 lb. per sq. in. gage). In other words, the maximum pressures of explosion for mixtures of circuit-breaker gases and air are, roughly, 100 lb. per sq. in. gage for a mixture initially at atmospheric pressure, and 300 lb. per sq. in. gage for a mixture initially at 25 lb. per sq. in. gage pressure. Mixtures containing, roughly, 20 per cent oil-circuit-breaker gases and 80 per cent air (by volume) gave the highest pressures above indicated.

In regard to the *ignition of the gases*, investigations have shown that high-pressure secondary explosions are brought about not only by an igniting arc, (either the main circuit breaker arc or some other arc reaching the explosive gas mixture), but also by hot gases rising out of the oil and mixing with the air in the air space, *i. e.*, in the absence of an igniting arc. Thus secondary gas explosions are within common possibility unless suitable preventives are applied (to effect cooling of the rising gases, proper confinement of the arc, or elimination of sparks or arcs in the air space).

In addition to special investigations on this subject, the occurrence of secondary gas explosions from each of the causes stated above has been observed on numerous occasions during oil circuit breaker tests when the breakers were over-loaded beyond their rupturing capacity or when means for preventing secondary explosions were omitted.

E. C. Stone: I shall refer the question of secondary explosion to the circuit breaker designers.

With reference to the circuit breaker situation in transmission net works, present operating conditions probably depend on whether the circuit breakers at the present time are subjected to less or more than the duties which they can stand. In some cases over-capacity breakers may have been originally installed, or the growth may have been slow, while in other cases the breakers, when installed, may have had little factor of safety and systems may have grown very materially since.

I was very much interested in Doctor Roth's statement as to how the consideration of recovery voltage came about in Europe. In this country, two seconds is about the highest relay setting used. This limit has probably been set by the possible physical damage to equipment and disturbances to motor service. It seems to me that if we allowed five seconds duration of short circuit on our systems as they are operated in this country, we would get into all kinds of trouble, both with our executives and with our customers.

The recovery-voltage proposition came to my attention through a comparison of tests made on circuit breakers of the order of 500,000 kv-a. interrupting capacity on systems with dead-grounded neutral with those tested on systems where the neutral was grounded through fairly high resistance. A study of the oscillograms from the two systems brought out very clearly the difference in the recovery voltage under the two different conditions as to neutral grounding.

It seems to me very important, at the present time, that we should give very serious consideration to "recovery voltage." The fact that along the "decrement" curve the recovery voltage decreases as well as the current is another reason why recovery voltage should be given more serious consideration.

In this discussion the question of rebuilding existing systems has come up. In such a matter economics plays a very important part. We cannot afford to spend a very large amount of money for a benefit from which dividends will not be derived for a good many years in the future. On the contrary, we must see an almost immediate dividend on all money that is to be spent. The "fixed charges" saved in a step-by-step development will often be many times more than the increased cost of such step development.

There was an expression of difference of opinion between Mr. Kehoe and Doctor Roth with reference to the voltage at the arc in a fault. I am inclined to think that both were right. Mr. Kehoe referred particularly to underground systems where the arc is confined within close limits, while Doctor Roth referred to overhead systems where there is ample opportunity, particularly with a slight wind, for the arc to spread. Our experience on the system with which I am connected indicates quite clearly that the duty on oil circuit breakers on overhead systems is less than the duty on underground systems, where the theoretical maximum short-circuit current is the same in both cases. Perhaps the behavior of the arc as the breaker opens is one of the factors. Short circuits may occur on pole lines, as well as in cables, by failure of two insulators simultaneously, but in this case, if a wooden crossarm is used, there is considerable resistance in the short circuit.

One of our men recently reported a failure from lightning on a 66,000-volt line which was rather interesting. He saw the flash start at the insulator on a tower, spread to an arc between wires, which were about 7 ft. apart, and travel down the span for probably 15 ft. or more, after which the arc broke. It was, however, immediately reestablished at the insulator and the same action occurred again. This was repeated several times until the opening of circuit breakers cleared the line. If the circuit breaker had opened at the moment the arc was broken its duty would have been, of course, light. This illustrates the possibilities that are to be found on overhead systems where an unstable arc is involved.

The Quadrant Electrometer

BY W. B. KOUWENHOVEN*

Member, A. I. E. E.

Synopsis.—*The quadrant electrometer has long been recognized as a valuable instrument for measuring power in a-c. circuits, especially at low values of the power factor. Nevertheless, it has been used but little. This has been caused to some extent by the fact that Maxwell's treatment does not hold for all electrometers, and by the difficulty of determining its constant with alternating current.*

In this paper, the author has discussed the theory of the instrument from the viewpoint of power measurements and has reduced its general equation to a simple form. He has shown how its constants may be determined with continuous current, and that these constants also apply in a-c. power measurement. He has checked the theoretical calculations by experiments. Data of the determination of the constants of a given instrument with continuous current are given in the paper, as well as examples of the use of the instrument in the measurement of power in a number of alternating circuits having different characteristics.

THE quadrant electrometer has had long recognition as an instrument possessing excellent characteristics for the purpose of measurement. Nevertheless, it has been used but little. To a great extent, this has been due to the fact that its theory is not available in any one place, but one must search in foreign publications[1] to find it. With this instrument, it is possible to measure small alternating voltages and currents; also small amounts of power at very low values of power factor.

I. Theoretical

The instrument depends upon electrostatic repulsions and attractions for its torque. It consists of a needle,

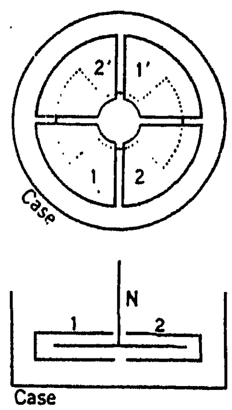

Fig. 1—Quadrant Electrometer

or disk, cut in the shape of a figure eight and suspended by means of a conducting fiber in a cylindrical metal box, cut into four equal quadrants. The needle and the quadrants are all mounted inside of a metal case, which protects them from external fields.

The case is fitted with a window through which the motion of the needle may be observed. The needle and the quadrants are insulated from each other and the case, and the latter is provided with leveling screws.

*Associate Professor of Electrical Engineering, The Johns Hopkins University.

1. For list of references see end of paper.

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, June 22-26, 1925.

The theory of this instrument was developed by Maxwell[2] as follows:

Let N = Needle potential
Let P_1 = Potential of quadrant pair No. 1
Let P_2 = Potential of quadrant pair No. 2
Let Q_0 = Charge on needle
Let Q_1 = Charge on quadrant pair No. 1
Let Q_2 = Charge on quadrant pair No. 2
Let Q_c = Charge on case

The case is grounded in practise and its potential is therefore zero.

The charges will be

$$\left.\begin{aligned} Q_0 &= K_{00}\,N + K_{01}\,P_1 + K_{02}\,P_2 \\ Q_1 &= K_{10}\,N + K_{11}\,P_1 + K_{12}\,P_2 \\ Q_2 &= K_{20}\,N + K_{21}\,P_1 + K_{22}\,P_2 \\ Q_c &= K_{c0}\,N + K_{c1}\,P_1 + K_{c2}\,P_2 \end{aligned}\right\} \quad (1)$$

Here, K_{00}, K_{01}, K_{02}, etc., are coefficients of induction of the conductors for electrostatic charges.

Since the needle and the quadrant pairs are completely enclosed by the case, the algebraic sum of the charges must equal zero and therefore,

$$Q_0 + Q_1 + Q_2 + Q_c = 0 \quad (2)$$

From equations (1) and (2), it follows that

$$(K_{00}+K_{10}+K_{20}+K_{c0})\,N + (K_{01}+K_{11}+K_{21}+K_{c1})\,P_1 + (K_{02}+K_{12}+K_{22}+K_{c2})\,P_2 = 0$$

and, since this relation must hold for all values of the potentials N, P_1 and P_2, we have:

$$K_{00} + K_{10} + K_{20} + K_{c0} = 0 \quad (3)$$

$$K_{01} + K_{11} + K_{21} + K_{c1} = 0 \quad (4)$$

$$K_{02} + K_{12} + K_{22} + K_{c2} = 0 \quad (5)$$

Now, assume that the needle is connected to quadrant pair No. 1, and at the same time grounded on the case; and that a positive potential P_2 is placed on quadrant pair No. 2. Then the needle will swing from quadrant pair No. 1 into quadrant pair No. 2. As the needle moves, some of the coefficients of electrostatic induction will change while others will remain constant.

If we let K' designate the new values of these coefficients we will have, for example, instead of (4),

$$K_{01}' + K_{11}' + K_{21}' + K_{c1}' = 0 \quad (6)$$

Now, $K_{21} = K_{21}'$ and $K_{c1} = K_{c1}'$ because there is no change in the relative positions between the two quadrant pairs or between the case and quadrants No. 1.

Therefore

$$K_{01}' + K_{11}' = K_{01} + K_{11}$$

As the needle swings from quadrant pair No. 1 into quadrant pair No. 2, K_{01} must decrease, and Maxwell assumed that

$$K_{01}' = K_{01} - X\,\theta \qquad (7)$$

where X is a constant and θ the angle through which the needle swings.

It follows from (7) that:

$$K_{11}' = K_{11} + X\,\theta \qquad (8)$$

In like manner, Maxwell showed that

$$K_{02}' = K_{02} + X\,\theta$$
$$K_{22}' = K_{22} - X\,\theta$$

and

$$K_{c0} = K_{c0}'$$
$$K_{c2} = K_{c2}'$$
$$K_{00} = K_{00}'$$

It is evident that the increase in the value of one coefficient of electrostatic induction, as the needle swings, must be balanced by an equal decrea sein the corresponding coefficient if equations (3), (4) and (5) are to hold.

The energy that the system possesses after the deflection, θ, is given by the relation:

$$W' = \tfrac{1}{2} K_{00}' N_0^2 + \tfrac{1}{2} K_{11}' P_1^2 + \tfrac{1}{2} K_{22}' P_2^2 + K_{01}' N P_1 + K_{02}' N P_2 + K_{12}' P_1 P_2 \qquad (9)$$

The change in energy produced by the deflection is given by the first differential of (9) with respect to the deflection, and keeping in mind the values of the coefficients of electrostatic induction we find:

$$\frac{dW'}{d\theta} = \tfrac{1}{2} X P_1^2 - \tfrac{1}{2} X P_2^2 - X N P_1 + X N P_2 \qquad (10)$$

The change in energy caused by the deflection is equal to the work done in twisting the suspension. If one assumes that k is the constant of the suspension per unit angle of deflection, one has,

$$k\,\theta = X(P_1 - P_2)\left(N - \frac{P_1 + P_2}{2}\right)$$

This is usually written

$$D\,\theta = (P_1 - P_2)\left(N - \frac{P_1 + P_2}{2}\right) \qquad (11)$$

This is Maxwell's equation for the quadrant electrometer and according to him, D is a constant.

The deflection of the electrometer depends upon the forces of attraction and repulsion between the charges on the needle and quadrants and the counter torque produced by twisting the suspension. Orlich and Schultz[3] showed that the D in Maxwell's equation is not a constant except for very small deflections and for some special electrometers. In most electrometers, D varies with the needle potential and the potential difference between the quadrants, and when the electrometer is used as a deflection instrument, this variation must be taken into account.

There are at least two reasons for the variation in D. The first is that the directing force changes as the needle deflects and, under these circumstances,

$$K_{01}' \neq K_{01} - X\,\theta$$

but the function is more complicated and is better expressed by

$$K_{01}' = K_{01} \pm x\,\theta \pm y\,\theta^2$$

The same is true of the electrostatic coefficients of induction, K_{02}', K_{11}', K_{22}' and K_{00}'. That the coefficient for the needle, K_{00}, should vary as the needle deflects is to be expected when you consider that it is practically impossible to get the needle exactly central.

The second reason for the variation in D is caused by the fact that the quadrant electrometer is very sensitive to small differences of potential when used in quadrant or power connection. Contact differences of potential exist between the needle, the case and the quadrants. If we let

p_0 = contact potential difference between needle and case

p_1 = contact potential difference between quadrant No. 1 and case

p_2 = contact potential difference between quadrant No. 2 and case

Then

$$N = V_0 + p_0$$
$$P_1 = V_1 + p_1$$
$$P_2 = V_2 + p_2$$

where V_0, V_1 and V_2 equal the outside potentials applied to the needle, quadrant pair No. 1 and quadrant pair No. 2, respectively.

We shall rewrite the equation (9) for the energy in the system and substitute the new values of N, P_1 and P_2, at the same time substituting

$$A_0 = \tfrac{1}{2} K_{00}' \qquad B_0 = K_{12}'$$
$$A_1 = \tfrac{1}{2} K_{11}' \qquad B_1 = K_{01}'$$
$$A_2 = \tfrac{1}{2} K_{22}' \qquad B_2 = K_{02}'$$

$$W' = A_0 (V_0 + p_0)^2 + A_1 (V_1 + p_1)^2 + A_2 (V_2 + p_2)^2 + B_0 (V_1 + p_1)(V_2 + p_2) + B_1 (V_0 + p_0)(V_1 + p_1) + B_2 (V_0 + p_0)(V_2 + p_2) \qquad (12)$$

Expanding the equation (12) for the energy in the system and grouping terms, we have

$$W' = A_0 V_0^2 + A_1 V_1^2 + A_2 V_2^2 + B_0 V_1 V_2 + B_0 V_0 V_1 + B_2 V_0 V_2 + B_1 V_0 V_1 + B_2 V_0 V_2 + (2 p_0 A_0 + p_1 B_1 + p_2 B_2) V_0 + (2 p_1 A_1 + p_2 B_0 + p_0 B_1) V_1 + (2 p_0 A_2 + p_1 B_0 + p_0 B_2) V_2 + A_0 p_0^2 + A_1 p_1^2 + A_2 p_2^2 + B_0 p_1 p_2 + B_1 p_0 p_1 + B_2 p_0 p_2 \qquad (13)$$

Let

$$C_0 = 2 p_0 A_0 + p_1 B_1 + p_2 B_2$$

Let

$$C_1 = 2 p_1 A_1 + p_2 B_0 + p_0 B_1$$

Let

$$C_2 = 2 p_2 A_2 + p_1 B_0 + p_0 B_2$$

Let

$$H = A_0 p_0^2 + A_1 p_1^2 + A_2 p_2^2 + B_0 p_1 p_2 + B_1 p_0 p_1 + B_2 p_0 p_2$$

Substitute these values in equation (**13**) and rewrite

$$W' = A_0 V_0^2 + A_1 V_1^2 + A_2 V_2^2 + B_0 V_1 V_2 + B_1 V_0 V_1 + B_2 V_0 V_2 + C_0 V_0 + C_1 V_1 + C_2 V_2 + H \quad (14)$$

The first six terms of equation (**14**) correspond to those in equation (**12**) and they are independent of the contact potentials. The C_0, C_1 and C_2 terms depend upon both the applied and contact potentials and terms containing contact potentials only are covered by the H term.

The new torque equation, whose derivation will be found in Part III of this paper, is derived from equation (**14**) and is given below:

$$\theta\,[1 + R\,(V_0 - V_1)\,(V_0 - V_2) + S\,(V_1^2 - V_2^2)] = a_0 V_0^2 + a_1 V_1^2 + a_2 V_2^2 + b_1 V_0 V_1 + b_2 V_0 V_2 + c_0 V_0 + c_1 V_1 + c_2 V_2 \quad (18)$$

The D of Maxwell's equation (**11**) equals the terms embraced in the brackets of equation (**18**) and it is no longer a constant, but varies with the potentials applied to the needle and quadrants. The right-hand side of equation (**18**) contains four terms corresponding to the four terms of Maxwell's equation (**11**) and in addition to these, it contains an $a_0 V_0^2$ term and three terms, $c_0 V_0$, $c_1 V_1$ and $c_2 V_2$, which depend upon the contact potentials and are not included in equation (**11**.) Equation (**18**) is the general equation of the quadrant electrometer. This equation will be further simplified in the experimental work that follows.

A study of equation (**18**) shows that there are two controling forces present in the quadrant electrometer. These are the mechanical control produced by the torsion of the suspension and the electrostatic control caused mainly by lack of symmetry in the instrument. The presence of the electrostatic control is indicated by the terms embraced in the brackets of equation (**18**). The algebraic sum of these two controling forces opposes the deflecting torque set up by the applied potentials. By proper adjustment and construction the electrostatic control may be made to add to the restoring torque of the suspension, to vanish entirely, or to neutralize the suspension torque. This last condition is used in the Crompton electrometer[1] to increase its sensitivity. In power measurements it is usual to reduce the effect of electrostatic control to as low a value as possible.

Setting Up of the Electrometer

The setting up of the electrometer may be divided into four parts:

1: *Leveling*. Remove the case and sighting through the quadrant slits, level in one direction. Turn through ninety degrees and level again. Continue turning and leveling until the instrument is perfectly level in all directions.

2. *Setting horizontal position of needle.* Bring the needle in position so that it is bisected by the quadrant slits and adjust its height until as nearly as can be determined by the eye, it is midway between the quadrants. Replace the case and make the final adjustment for the horizontal position. To accomplish this, connect both quadrants to the case and to ground and apply a high continuous positive potential to the needle. Note the deflection. Then reverse the continuous potential, making the needle negative, and note the deflection. Adjust the horizontal position of the needle with respect to the quadrant slits until the two deflections are equal. The needle is then accurately centered horizontally.

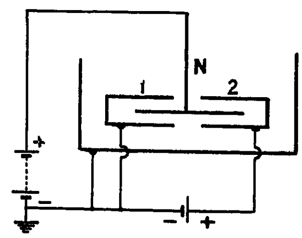

Fig. 2—Connections for Adjusting the Height of the Electrometer Needle

3. *Adjust for height.* Apply a high continuous potential to the needle and a small continuous potential between the quadrants as shown in Fig. 2. Adjust the height of the needle until the deflection is a minimum. The needle is then midway between the quadrant faces.

4. *Adjust so that the mechanical and electrical zeros*

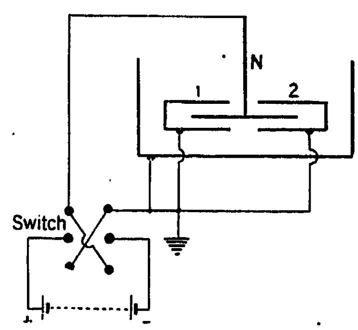

Fig. 3—Connections for Bringing the Mechanical and Electrical Zeros into Coincidence

coincide. Connect both quadrants to the case and to ground and apply a high continuous or alternating potential to the needle. Tilt the instrument by means of the leveling screws until the zero position remains the same with the voltage either on or off the needle. When this adjustment has been properly made, the position of maximum electrostatic capacity coincides with the natural zero of the instrument, and the mechanical and electrical zeros coincide. This adjustment is very important and should be checked when ever the instrument is used.

The connections used for bringing the mechanical and electrical zeros into coincidence is shown in Fig. 3. When this adjustment has been made, the $a_0\,V_0^2$ term of equation (**18**) is eliminated. This may be seen from a study of the values of the terms of the right hand side of equation (**18**)

Value of terms of equation (18)

Position of Switch	$a_0\,V_0^2$	$+a_1\,V_1^2$	$+a_2\,V_2^2$	$+b_1\,V_0\,V_1$	$+b_2\,V_0\,V_2$	$+c_0\,V_0$	$+c_1\,V_1$	$+c_2\,V_2$	Deflection
Up	+	0	0	0	0	+	0	0	$=\alpha$
Down	+	0	0	0	0	−	0	0	$=\beta$

When this adjustment has been properly made, $\alpha = \beta = 0$. Then if we take the sum of the two deflections we shall have

$$\alpha + \beta = 2\,a_0\,V_0^2 = 0$$

Therefore

$$a_0 = 0$$

It does not follow, however, that the $c_0\,V_0$ term also equals zero when the mechanical and electrical zeros coincide. The constant, c_0, includes contact potentials, and when the quadrants are not connected and grounded, as in Fig. 3, these may become of importance. The constant, a_0, however, does not depend upon the contact potentials, and it may safely be taken as zero when the electrometer is adjusted.

Neglecting the $a_0\,V_0^2$ term, equation (**18**) reduces to

$$\theta\,[1 + R\,(V_0 - V_1)\,(V_0 - V_2) + S\,(V_1 - V_2)^2] = a_1\,V_1^2 + a_2\,V_2^2 + b_1\,V_0\,V_1 + b_2\,V_0\,V_2 + c_0\,V_0 + c_1\,V_1 + c_2\,V_2 \qquad (19)$$

DETERMINATION OF THE CONSTANTS

In determining the constants, the quadrant connection is employed. In this connection, the needle is

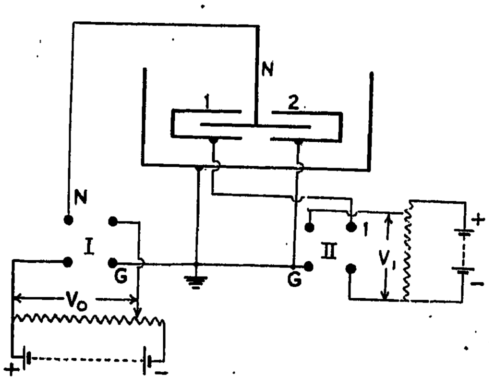

FIG. 4—QUADRANT CONNECTION FOR DETERMINING THE ELECTROMETER CONSTANTS

at a high potential, one quadrant pair is connected to the case and grounded and the other is at a low potential. The constants may be determined by using alternating current[4] and measuring the power consumed in a load of known characteristics, but they are most readily determined with continuous current. The connections are shown in Fig. 4.

In the diagram of connections, V_2 is zero, V_1 is a relatively low potential and is very small compared to V_0, the needle voltage. Under these conditions, it is possible to neglect certain of the terms which form the left hand side of equation (**19**) and we may write

$$\theta\,[1+R\,V_0^2] = a_1\,V_1^2 + a_2\,V_2^2 + b_1\,V_0\,V_1 + b_2\,V_0\,V_2 + c_0\,V_0 + c_1\,V_1 + c_2\,V_2 \qquad (20)$$

In Fig. 4 there are two reversing switches or commutators marked with the Roman numerals, I and II respectively. There are four possible positions of the two commutators and the terms forming the right hand side of equation (**20**) have different signs depending upon the positions of the commutators. We obtain a deflection for each of the four positions of the commutators. The deflections and the signs or values of the corresponding terms are given below:

Position of Commutator I	II	Value of Terms $a_1 V_1^2$	$+a_2 V_2^2$	$+b_1 V_0 V_1$	$+b_2 V_0 V_2$	$+c_0 V_0$	$+c_1 V_1$	$+c_2 V_2$	$=[1+R V_0^2]$	Deflection θ
‖	‖	+	0	−	0	+	−	0	=["]	α
=	‖	+	0	+	0	−	−	0	=["]	β
=	=	+	0	−	0	−	+	0	=["]	γ
‖	=	+	0	+	0	+	+	0	=["]	δ

The constants are determined from the above deflections as follows:

$$[1 + R\,V_0^2]\,(\alpha - \beta + \gamma - \delta) = -4\,b_1\,V_0\,V_1 \qquad (21)$$

$$[1 + R\,V_0^2]\,(\alpha - \beta - \gamma + \delta) = +4\,c_0\,V_0 \qquad (22)$$

$$[1 + R\,V_0^2]\,(\alpha + \beta - \gamma - \delta) = -4\,c_1\,V_1 \qquad (23)$$

$$[1 + R\,V_0^2]\,(\alpha + \beta + \gamma + \delta) = +4\,a_1\,V_1^2 \qquad (24)$$

If we take readings of the deflections for two or more values of the voltages V_0 and V_1 we shall obtain sufficient data to solve the above equations for the constants. For example, let α', β', γ' and δ' equal the deflections obtained when V_0' and V_1' are the voltages applied to the needle and quadrant 1 respectively. Then from equation (**21**) we obtain

$$\frac{[1+R\,V_0'^2]}{b_1} = -\frac{4\,V_0'\,V_1'}{\alpha' - \beta' + \gamma' - \delta'} = X_1 \qquad (25)$$

For applied voltages V_0'' and V_1'' we get the deflections $\alpha'', \beta'', \gamma''$ and δ'' for the four positions of the commutations respectively, and equation (**26**) follows:

$$\frac{[1+R\,V_0''^2]}{b_1} = -\frac{4\,V_0'\,V_1''}{\alpha'' - \beta'' + \gamma'' - \delta''} = X_2 \qquad (26)$$

Here X_1 and X_2 are the numerical values of the right hand sides of equations (**25**) and (**26**) respectively.

Solving these two simultaneous equations for b_1 we find that,

$$b_1 = \frac{V_0'^2 - V_0''^2}{X_2\,V_0'^2 - X_1\,V_0''^2} \qquad (27)$$

and substituting the value of b_1 in equation (25) we obtain,

$$R = \frac{b_1 X_1 - 1}{V_0^{\prime 2}} \tag{28}$$

In a similar manner, we can obtain the other constants from equations (22), (23) and (24).

It is evident from the symmetrical construction of the electrometer that

$$\begin{aligned} a_2 &= -a_1 \\ b_1 &= -b_2 \\ c_1 &= -c_2 \end{aligned}$$

We may also prove that:

$$\begin{aligned} a_2 &= \tfrac{1}{2} b_1 \\ a_1 &= -\tfrac{1}{2} b_1 \end{aligned} \tag{33}$$

The mathematical proof of equation (33) is given in the mathematical part of this paper and the confirming experimental data will be found in the experimental part.

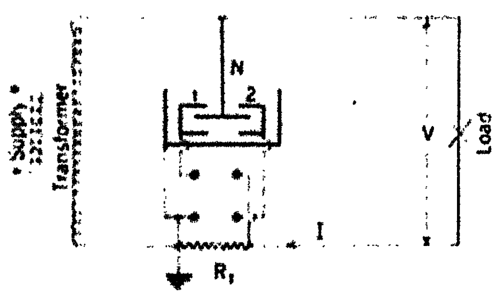

FIG. 5 CONNECTIONS FOR MEASURING POWER WITH FULL VOLTAGE ON NEEDLE

If we substitute these values of the constants in equation (19) it becomes,

$$[1 + R(V_0 - V_1)(V_0 - V_2) + S(V_1^2 - V_2^2)]\,\theta$$

$$= -\frac{b_1}{2} V_1^2 + \frac{b_1}{2} V_2^2 + b_1 V_0 V_1 - b_1 V_0 V_2 + c_0 V_0$$

$$+ c_1 V_1 + c_2 V_2 \tag{34}$$

If the quadrant electrometer is to be used in measuring power in a-c. circuits, it is only necessary to know the constants R and b_1. The other constants may either be reduced to zero or made negligible.

POWER MEASUREMENT

The quadrant connection is the one employed in measuring power in a-c. circuits. The quadrant electrometer may be connected so that there is either full voltage on the needle or only a fraction of the full voltage. A diagram of the connections for full voltage on the needle is shown in Fig. 5. The effective voltage across the load is V and the effective value of the load current is I. R_1 is a non-inductive capacity free resistance. Only one commutator is used.

We shall assume that the instantaneous value of the voltage and current are designated by v and i respectively and that Φ is the phase angle between them. Then

$$\begin{aligned} v &= \sqrt{2}\, V \sin \omega t \\ i &= \sqrt{2}\, I \sin (\omega t \pm \Phi) \end{aligned}$$

When a quadrant electrometer is supplied with alternating current, the needle potential V_0, and the quadrant potentials, V_1 and V_2, are the instantaneous values of the applied voltages. The electrometer reads the integral of these voltages over a complete period T.

For example:

$$a_1 V_1^2 = \frac{1}{T} \int_0^T 2 I^2 R_1^2 \sin^2 (\omega t \pm \Phi) = I^2 R_1^2$$

$$c_0 V_0 = \frac{1}{T} \int_0^T \sqrt{2}\, V_0 \sin \omega t = 0$$

It follows, from the above, that the c_0, c_1 and c_2 terms will all equal zero when the electrometer is used to measure power in a-c. circuits.

On alternating power measurements, V_1 and V_2, the quadrant potentials, are small compared to V_0, the needle potential and we may therefore neglect the S term, and as the c_0, c_1 and c_2 terms are equal to zero, we can write equation (19)

$$[1 + R V_0^2]\,\theta = -\frac{b_1}{2} V_1^2 + \frac{b_1}{2} V_2^2$$

$$+ b_1 V_0 V_1 - b_1 V_0 V_2 \tag{35}$$

We shall apply this equation to the measurement of the power consumed by the load of Fig. 5, bearing in mind the fact that V_0 is the instantaneous value of the potential from the needle to ground, and that V_1 and V_2 are the values of the instantaneous potentials from quadrant pairs No. 1 and No. 2 to ground respectively.

In Fig. 5, we see that,

$$\begin{aligned} V_0 &= v + i R_1 \\ V_2 &= i R_1 \text{ or } 0 \\ V_1 &= 0 \text{ or } i R_1 \end{aligned}$$

The values of V_1 and V_2 depend upon the position of the commutator.

The integral of the $b_1 V_0 V_1$ term over a complete period is as follows:

$$\frac{b_1}{T} \int_0^T V_0 V_1 = \frac{b_1}{T} \int_0^T (v + i R_1)\,(i R_1)$$

$$= b_1 (R_1 I V \cos \Phi + I^2 R_1^2)$$

There are two positions of the commutator and the value and signs of terms of equation (35) are given below. The circuit conditions and the applied voltage must remain constant while the deflections are measured.

VALUE OF TERMS

Position of Commutator	$-\frac{b_1}{2} V_1^2$	$+\frac{b_1}{2} V_2^2$	$+b_1 V_0 V_1$	$-b_1 V_0 V_2$	Deflection
‖	0	$+\frac{b_1}{2} I^2 R_1^2$	0	$-b_1(R_1 I V \cos \Phi + I^2 R_1^2)$	$= [1 + R V_0^2]\ \alpha$
=	$-\frac{b_1}{2} I^2 R_1^2$	0	$+b_1(R_1 I V \cos \Phi + I^2 R_1^2)$		$= [1 + R V_0^2]\ \beta$

Taking the algebraic sum of these deflections, we get

$$[1 + R V_0^2] (\beta - \alpha)$$
$$= - b_1 I^2 R_1^2 + 2 b_1 (R_1 I V \cos \Phi + I^2 R_1^2) \quad (36)$$

The needle voltage, V_0, is equal to the vector sum of the load voltage, V, plus the drop across the non-inductive resistance R_1. Since the drop is very small compared to the load voltage we may assume that V_0 on the left hand side of equation (36) is equal to V.

Rewriting equation (36) and combining like terms we obtain

$$\frac{[1 + R V^2] (\beta - \alpha)}{2 b_1 R_1} = I V \cos \Phi + \frac{I^2 R_1}{2} \quad (37)$$

It is evident from equation (37) that the quadrant electrometer, with full voltage on the needle, measures

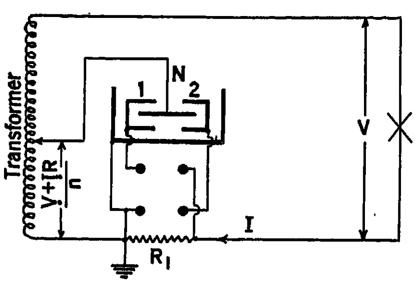

Fig. 6—Measurement of Power with Less than Full Line Voltage on Needle

the power consumed by the load, plus one-half the power lost in the resistance, R_1.

The power consumed by the load is

$$I V \cos \Phi = \frac{[1 + R V^2]}{2 b_1} \cdot \frac{1}{R_1} (\beta - \alpha) - \frac{I^2 R_1}{2} \quad (38)$$

Equation (37) holds for all values of power factor, both leading and lagging. The only constants involved are b_1 and R which may be determined as already outlined.

If R has a negligible value or if readings are taken on a number of loads at a constant voltage V, then the expression

$$\frac{1 + R V^2}{2 b_1} = K$$

where K is a constant.

The deflections α and β for the two positions of the commutators are right and left deflections respectively and the resulting deflection $(\beta - \alpha)$ is usually written equal to θ. Equation (37) may then be written as follows:

$$\frac{K \theta}{R_1} = I V \cos \Phi + \frac{I^2 R_1}{2} \quad (39)$$

If the quadrant electrometer is used to measure power with less than full voltage on the needle, the diagram of connections are given in Fig. 6 is applicable. Here V, I and R_1 have the same meanings as in Fig. 5. In

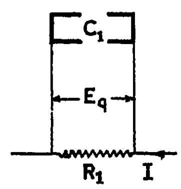

Fig. 7—Condenser C_1 Formed by the Electrometer Quadrants

this case the needle voltage equals the vector sum of the load voltage, V, plus the $I R_1$ drop divided by n, where n is the factor by which the voltage across the

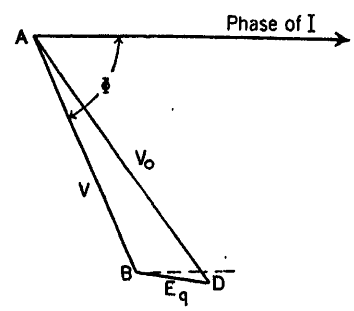

Fig. 8—Vector Diagram of the Circuit Shown in Fig. 5 for a Condenser Load

needle must be multiplied to give the total voltage of the circuit.

The instantaneous value of the voltage across the needle is

$$\frac{v + i R_1}{n}$$

There are two positions of the commutator and the value and signs of the terms of equation (35) for reduced voltage on the needle are given as follows:

VALUE OF TERMS

Position of Commutator	$-\frac{b_1}{2} V_1^2$	$+\frac{b_1}{2} V_2^2$	$+b_1 V_0 V_1$	$-b_1 V_0 V_2$	Deflection
||	0	$+\frac{b_1}{2} I^2 R_1^2$	0	$-b_1\left(\frac{R_1 I V \cos\Phi + I^2 R_1^2}{n}\right)$	$= [I + R V_0^2]\ \alpha$
=	$-\frac{B_1}{2} I^2 R_1^2$	0	$+b_1\left(\frac{R_1 I V \cos\Phi + I^2 R_1^2}{n}\right)$	0	$= [\ + R V_0^2]\ \beta$

Taking the algebraic sum of these two deflections, we obtain,

$$[1 + R V_0^2]\ \theta$$

$$= -b_1 I^2 R_1^2 + 2 b_1 \frac{R_1 I V \cos\Phi}{n} + 2 b_1 \frac{I^2 R_1^2}{n} \tag{40}$$

$$[1 + R V_0^2]\ \theta$$

$$= \frac{2 b_1}{n} R_1 \left(I V \cos\Phi + \frac{2 - n}{2} I^2 R_1 \right) \tag{41}$$

as stated above, the needle voltage is equal to

$$V_0 = \frac{\dot{V} + \dot{I} R_1}{n}$$

In practise, $\dot{I} R_1$ is very small compared with V. It is usually less than one per cent of the load voltage and for practical purposes we may write

$$V_0 = \frac{V}{n}$$

We obtain, when we make this substitution in equation (41),

$$\frac{\left[1 + R\left(\frac{V}{n}\right)^2\right]}{2 b_1} \cdot \frac{n}{R_1} \cdot \theta$$

$$= I V \cos\Phi + \frac{2 - n}{2} I^2 R_1 \tag{42}$$

If n equals one, equation (42) reduces to equation (37), which is the power equation for full voltage on the needle of the quadrant electrometer. A further study of equation (42) shows that if n is equal to two, the last term of the equation vanishes; if n is greater, the last term becomes negative. This is true at all values of power factor. These deductions are verified by experiments reported in the experimental part of the paper.

In special cases, equation (42) may be written

$$\frac{K n \theta}{R_1} = I V \cos\Phi + \frac{2 - n}{2} I^2 R_1 \tag{43}$$

Equation (43), however, holds only for the conditions where R is negligible or where readings are taken with a constant voltage applied to the needle.

Equation (35) gives the simplified form of the quadrant electrometer power relations. In this equation θ equals the algebraic sum of the two deflections α and β for the two positions of the commutator. The circuit conditions and the applied voltage are assumed to remain constant while these readings are being taken. Under these conditions we noted that

$$V_1 = I R_1 \text{ or } 0$$

and

$$V_2 = 0 \text{ or } I R_1$$

Therefore, if we determine the signs and the values of the terms of equation (35) for the two commutator positions and take their algebraic sum, we may write

$$[1 + R V_0^2]\ \theta = 2 b_1 V_0 V_1 - b_1 V_1^2 \tag{44}$$

This equation is a simplified form of equation (35). If we substitute in equation (44), the values of the needle voltage to ground, V_0, and the drop across the resistances, V_1, expressed in the form of their vector relations, we obtain exactly the same result as was found by the method used in determining equations (37) and (41). An example of this method is given in the paragraphs devoted to the question of errors.

Errors

The sources of error in the measurement of power with the quadrant electrometer have already been ably discussed in an Institute paper[5]. Therefore only a single case, illustrating the applications of equation (44), will be considered in this paper.

If we study the diagrams of connections in Fig. 5 and 6, we see that the electrostatic capacity between the quadrants pairs, No. 1 and No. 2, and their leads is in parallel with the non-inductive resistance R_1. The drop across R_1 and this condenser in parallel with it will not be in phase with I as assumed. Let C_1 equal the capacity of this condenser in farads. Then if E_q equals the voltage across the quadrants we find that

$$E_q = \frac{I R_1 (1 - j \omega C_1 R_1)}{1 + \omega^2 C_1^2 R_1^2} \tag{45}$$

The vector diagram of the electrometer, with full voltage across the needle and a capacity load in the circuit, is shown in Fig. 8. In Fig. 8 $A B = V$, the voltage across the load; $B D = E q$, the voltage drop across R_1 and C_1 in parallel, and $A D = V_0$, the voltage across the needle. $A D$ is also the vector sum of V and $E q$.

With I as the reference vector, the vector equations are as follows:

$$\dot{V} = V \cos\Phi - j \sin\Phi$$

$$\dot{V}_1 = \frac{I R_1}{1 + \omega^2 C_1^2 R_1^2} - j \frac{I \omega C_1 R_1^2}{1 + \omega^2 C_1^2 R_1^2}$$

$$V_0 = V\cos\Phi - j\,V\sin\Phi + \frac{I\,R_1}{1+\omega^2 C_1^2 R_1^2} - j\,\frac{I\,\omega\,C_1 R_1^2}{1+\omega^2 C_1^2 R_1^2}$$

Substitute the vector relations of V_0 and V_1 in equation (44) and take the power product and simplify

$$\frac{(1+R\,V^2)\,(1+\omega^2 C_1^2 R_1^2)}{2\,b_1 R_1}\,\theta = I\,V\cos\Phi + \tfrac{1}{2}\,\frac{I^2 R_1}{(1+\omega^2 C_1^2 R_1^2)} + I\,(\omega\,C_1 R_1)\,V\sin\Phi + \tfrac{1}{2}\,\frac{I^2 R_1\,(\omega\,C_1 R_1)^2}{1+\omega^2 C_1^2 R_1^2} \quad (46)$$

The capacity C_1 is, however, very small and at commercial frequencies $\omega^2\delta C_1^2 R_1^2$ is negligible. Therefore, we may write

$$\frac{(1+R\,V^2)}{2\,b_1 R_1}\,\theta = I\,V\cos\Phi + \frac{I^2 R_1}{2} + I\,(\omega\,C_1 R_1)\,V\sin\Phi \quad (47)$$

Equation (47) is the same as that derived by Messrs. Simons and Brown[5] using a different method.

Other sources of error are the charging current flowing from the needle to the high quadrant and through the shunt resistance R_1, the phase shift of the needle voltage introduced by the use of a potential divider, the phase shift due to the resistance of the needle suspension, and any energy loss that may be present in the electrometer itself.

II—Experimental

Determination of the Constants b_1 and R. The constants, b_1 and R, are best determined with continuous potentials, although they may be determined with alternating potentials.

The diagram of connections is given in Fig. 4. The voltage applied to the needle could be varied through a range of from about 50 to 600 volts. It was measured with a Weston laboratory standard voltmeter. The voltage applied to the quadrants was varied from 2 to 15 volts and was measured with a Siemens and Halske instrument.

The quadrant electrometer was set up, leveled, and carefully adjusted, with about 600 volts on its needle, until its electrical and mechanical zeros coincided. Then readings of the deflections for the different positions of the two commutators were taken for various values of V_0 and V_1. Four readings were taken for each set of voltages, which were maintained constant while the deflections were noted. In taking a set of readings it is best to commutate in a regular manner and read at regular intervals after commutating.

The electrometer used was one constructed in the electrical laboratories of the Johns Hopkins University. The quadrants were of aluminum. The inside diameter of the cylindrical box from which they were cut was 15.24 cm. and its height was 3.81 cm. The needle was also of aluminum, and the length of its phosphor bronze suspension was approximately 20 cm. The quadrant pairs and the needle were insulated by special bakelite supports.

The readings upon which the calculations of the constant b_1 and R are based are given in Table I.

TABLE I

V_0 Volts	V_1 Volts	Position of Commutator No. I	No. II	cm.	cm. $\theta = \alpha-\beta+\gamma-\delta$	$\frac{4V_0V_1}{\theta}$
100	5	‖	‖	$-3.6 = \alpha$		
		=	‖	$+3.35 = \beta$		
		=	=	$-3.6 = \gamma$		
		‖	=	$+3.35 = \delta$	−13.9	+143.9
100	10	‖	‖	−7.35		
		=	‖	+6.52		
		=	=	−7.32		
		‖	=	+6.55	−27.74	+144.1
100	15	‖	‖	−11.3		
		=	‖	+9.65		
		=	=	−11.3		
		‖	=	+9.65	−41.9	+143.2
270	5	‖	‖	−9.6		
		=	‖	+9.3		
		=	=	−9.6		
		‖	=	+9.3	−37.8	+142.5
270	10	‖	‖	−19.6		
		=	‖	+18.35		
		=	=	−19.6		
		‖	=	+18.35	−75.9	+143.5
500	2	‖	‖	−7.12		
		=	‖	+7.55		
		=	=	−7.1		
		‖	=	+7.5	−29.27	+136.6
500	5	‖	‖	−18.3		
		=	‖	+18.15		
		=	=	−18.25		
		‖	=	+18.15	−72.85	+137.4

The first three sets of readings were taken with V_0 equal to 100 volts and they give an average X_1 of 143.73. The next two sets of readings are for V_0 equal to 270 volts, and X_2 equals 143.0. The last two sets of readings were at 500 volts and X_3 average equals 137.0.

Calculating b_1 from these results in accordance with equation (27) we get an average b_1 of

$$b_1 = +\,0.00695$$

calculating R from equation (28) gives

$$R = -\,1.95 \times 10^{-7}$$

Determination of the Constant a_1. In order to check equation (24)

$$[1 + R\,V_0^2]\,(\alpha+\beta+\gamma+\delta) = +\,4a_1\,V_1^2 \quad (24)$$

an attempt was made to determine a_1 by this connec-

tion. Since a_1 depends upon the value of the quadrant voltage, V_1 was made equal to V_0 in this test. The results are given in Table II.

TABLE II

Position of Commutator No. I	Position of Commutator No. II	V_0 Volts	V_1 Volts	cm.	$\theta = \alpha + \beta + \gamma + \delta$ cm.
‖	‖	25	25	$-6.6 = \alpha$	
=	‖			$+2.35 = \beta$	
=	=			$-6.6 = \gamma$	
‖	=			$+2.35 = \delta$	-8.5
‖	‖	40	40	-17.25	
=	‖			$+5.65$	
=	=			-17.3	
‖	=			$+5.65$	-23.25

The calculation of a_1 from the results in Table II and in accordance to equation (24) gave

$$a_1 = +0.00351$$

According to the theory a_1 has half the value and a sign opposite to that of b_1 and it is clear that this test gives a fair check of the theoretical calculation. This method is, however, not suited for the determination of a_1, because in order to get readings of sufficient difference to make it possible to calculate a_1 with any degree of accuracy we must make the quadrant voltage large compared to the needle voltage. This is not in accordance with the theory of the quadrant connection which presupposes a high needle voltage and a low quadrant voltage.

A better way to prove that a_1 has half the value of b_1 is to use the two idiostatic connections A and B of the electrometer which are shown in Fig. 12.

The readings for connections A and B are given in Table III for an applied voltage of 44.5 volts in each case.

TABLE III

Position of Commutators III	Position of Commutators II	Connection A Deflections cm.	Connection α Deflections cm.
‖	‖	+6.6	+6.6
=	‖	+6.6	+6.6
=	=	−6.1	−6.1
‖	=	−6.1	−6.1

Exactly the same deflections were found for both connections A and B and they were in the same directions. Therefore equation (33), whose proof is given in the mathematical part of the paper is true.

$$a_2 = \tfrac{1}{2} b_1 \qquad (33)$$
$$a_1 = -\tfrac{1}{2} b_1$$

Proof of the Power Equation with Full Voltage on Needle. Equation (37) states that the deflection of a quadrant electrometer is proportional to the power consumed in the load plus one-half the power loss in the shunt resistance R_1 at any value of the power factor.

In order to check this relation the quadrant electrometer was connected up as in Fig. 9, and three loads were used in turn. The first load was a non-inductive resistance R_0. The second load consisted of an inductance, L, and the third, of a mica condenser, C.

The test at unity power-factor load will be considered first. In this test, the secondary voltage of the trans-

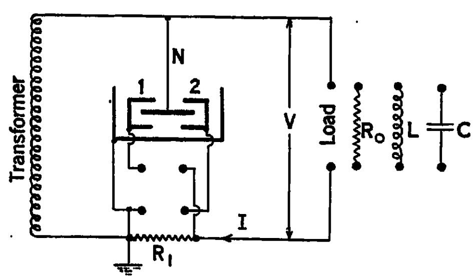

FIG. 9—QUADRANT ELECTROMETER WITH FULL VOLTAGE ON NEEDLE AND DIFFERENT LOADS

former was maintained constant at 100 volts and 60 cycles. Readings of the deflections were taken with three values of R_1, namely, 100, 2000, and 7000 ohms respectively. The value of the load resistance, R_0, was adjusted for each value of R_1 so that the power loss in R_0 was maintained constant at 0.32 watts.

The constant of the electrometer with 100 volts applied to the needle is

$$K = \frac{1 + R V^2}{2 b_1} = \frac{(1 - 1.95 \times 10^{-7} \times 100^2)}{2 \times 0.00695} = 71.8$$

The results of the unity power factor test are given in Table IV.

TABLE IV

R_0 Ohms	R_1 Ohms	I Milli-Ampere	$I^2 R_0$ Load Watts	$\frac{I^2 R_1}{2}$ Watts	Electrometer θ cm.	Electrometer $\frac{K\theta}{R_1}$ Watts	$I^2 R_0 + \frac{I^2 R_1}{2}$ Watts calculated
29250	1000	3.31	0.32	0.006	4.5	0.324	0.326
27125	2000	3.44	0.32	0.013	9.45	0.339	0.333
13650	7000	4.83	0.32	0.082	39.6	0.406	0.402

In Table IV, the current, I, is calculated from the known constants of the circuit. The watts consumed in the load, I^2R_0, and one-half the loss in the shunt resistance R_1 are also calculated, as are the values given in the last column.

A comparison of the watts registered by the electrometer for the different values of R_1 and the watts calculated, as given in the last column of Table IV, shows a fairly close agreement. A comparison of the last two columns of Table IV shows conclusively that at unity power factor equation (37) holds and the instruments read the watts lost in the load plus one-half the loss in the resistance shunting the quadrants.

The inductive load, lagging power factor test followed the resistance test. The inductance used as the load consisted of an air cored copper coil with a resistance of

1650 ohms and a coefficient of self-induction of 7.73 Henrys. At a frequency of 60 cycles the reactance was 2915 ohms. Readings were taken at two values of R_1 and the applied voltage was adjusted so as to maintain the current constant and thus keep the load at a uniform amount.

The voltages used were 55 and 46.5 volts respectively, and at this value of the voltage the constant of the electrometer = 72.

The results are given in Table V. In this test the power factor was 56.6 per cent lagging.

TABLE V

Voltage	R_1 Ohms	Circuit Impedance Ohms	I Milli-amp.	Load Watts	$\frac{I^2 R_1}{2}$ Watts	Electrometer θ cm.	Electrometer $\frac{K\theta}{R_1}$ Watts	Load $+\frac{I^2 R_1}{2}$ Watts Calculated
46.5	1000	4664	1.178	0.23	0.069	4.1	0.296	0.299
55.0	2000	3940	1.178	0.23	0.138	10.2	0.367	0.368

A comparison of the watts as measured by the quadrant electrometer with the calculated watts shows a good agreement. A study of the last two columns of Table V shows conclusively that, at a lagging power factor of 56.6 per cent, the electrometer reads the power consumed by the load plus one-half the power lost in the shunt resistance.

The capacity load test was made with a standard mica condenser whose capacity was 1/10 of a microfarad. The frequency used was 60 cycles. Readings were taken at three values of the shunt resistance R_1 and the applied voltage was varied between the limits of 396 and 400 volts so as to maintain the current through the circuit and the load constant. At 400 volts the constant of the electrometer is 69.7. The results are given in Table VI.

TABLE VI

Voltage	R_1 Ohms	Circuit Impedance Ohms	I Milli-amp.	Load Watts	$\frac{I^2 R_1}{2}$ Watts	Electrometer θ cm.	Electrometer $\frac{K\theta}{R_1}$ Watts	Load $+\frac{I^2 R_1}{2}$ Watts
396	1000	26520	14.9	0.027	0.111	1.95	0.136	0.138
398	2000	26570	14.9	0.027	0.222	7.15	0.249	0.249
400	4000	26800	14.9	0.027	0.444	27.10	0.472	0.471

The watts consumed by the load are determined by subtracting from the watts measured by the electrometer one half of the loss in the shunt resistance R_1. Another method of determining the watts load is to plot the watts measured by the electrometer as ordinates against the values of the shunt resistance R_1 as abcissas. These points should lie on a straight line, as shown in Fig. 10. If this line is extended to the ordinate axis it will cut that axis at a value equal to watts lost in the load. From Fig. 10 we see that the load loss is equal to 0.027 watts. The power factor of the condenser load used in this test is 0.47 per cent.

A comparison of the results given in the last two columns of Table VI show clearly that the quadrant electrometer with full voltage on the needle reads the loss in the load plus one-half the loss in the shunt resistance R_1. The curve plotted from the results in Fig. 10 also confirms this conclusion.

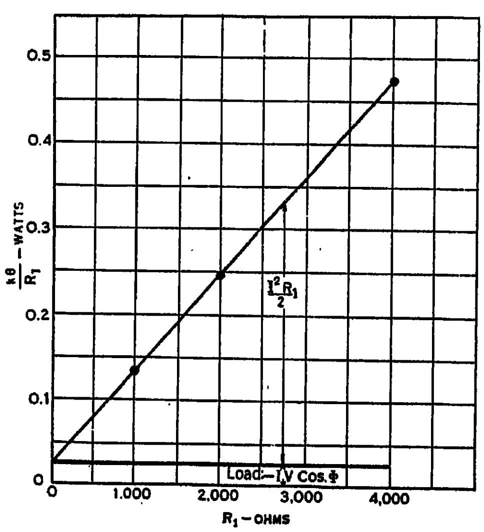

Fig. 10—Curve Showing the Relation Between Watts Measured by the Electrometer and the Shunt Resistance R_1 with Full Voltage on the Needle. Plotted from the Results of Table VI

The results of these three tests prove conclusively the correctness of equation (37), namely, that the quadrant electrometer with full voltage on the needle reads the power consumed by the load plus one-half the loss in the shunt resistance, irrespective of the value of the power factor.

Proof of the Power Equation with Reduced Voltage on the Needle. Equation (42) applies to this type of measurement.

$$\frac{\left[1 + R\left(\frac{V}{n}\right)^2\right]}{2\, b_1} \cdot \frac{n}{R_1} \cdot \theta = I\, V \cos \Phi + \frac{2-n}{2} I^2 R_1 \tag{42}$$

The sign of the last term, or correction term, depends upon the value of n. If n is equal to two, the term vanishes. If n is greater than two, the term becomes negative. In order to check this relation, readings were taken at unity power factor load for n equal to three different values. The connections used are those given in Fig. 6.

The first test was run with n equal to two and the voltage of the transformer was 160 volts at 60 cycles. The voltage applied to the electrometer needle was one-half of the transformer voltage and equaled 80 volts.

The constant of the electrometer for this needle voltage was 71.9.

Readings were taken at three values of the shunt resistance, and the load which consisted of a non-inductive resistance was maintained constant. The results are given in Table VII.

TABLE VII

R_0 Ohms	R_1 Ohms	I Milli-amp.	$I^2 R_0$ Load Watts	Electrometer θ cm.	$\frac{n\,K\,\theta}{R_1}$ Watts
29250	1000	5.29	0.825	5.75	0.826
27125	2000	5.49	0.825	11.5	0.826
20000	5000	6.4	0.82	28.7	0.825

It is apparent from the results given in Table VII that when n equals two, the quadrant electrometer reads directly the power consumed in the load, and the correction term vanishes.

The second unity power-factor test was made with one-third of the transformer voltage applied to the needle, that is, n equaled three. The transformer voltage in this test was 240 volts at 60 cycles and this gave a needle voltage of 80, the same as used in the run with n equal to two. The electrometer constant equaled 71.9 in this test also.

For the value of n equal to three, the correction of equation (42) becomes negative and equals

$$-\frac{I^2 R_1}{2}$$

The results of this test are given in Table VIII. Readings were taken for three different values of shunt resistance R_1.

TABLE VIII

R_0 Ohms	R_1 Ohms	I Milli-amp.	$I^2 R_0$ Load Watts	$\frac{I^2 R_1}{2}$ Watts	Electrometer θ cm.	$\frac{n\,K\,\theta}{R_1}$ Watts	$I^2 R_0 - \frac{I^2 R_1}{2}$ Watts Calculated
29250	1000	7.93	1.84	0.032	8.45	1.82	1.81
27125	2000	8.24	1.84	0.068	16.2	1.75	1.77
13650	7000	11.62	1.84	0.473	44.2	1.36	1.37

It is evident from the results given in Table VIII that when n is equal to three the correction term becomes negative. The check between the calculated watts and the watts as measured by the electrometer is good.

The third unity power-factor test was made with n equal to four. Under this condition equation (42) becomes

$$\frac{\left[1 + R\left(\frac{V}{n}\right)^2\right]}{2\,b_1}\,\frac{n}{R_1}\,\theta = I\,V\cos\Phi - I^2 R_1$$

Readings were taken for three conditions. In the first, the loss in the shunt resistance was less than the load. In the second, the loss in the load and the loss in the shunt resistance were equal, and in the third, the loss in the shunt resistance was greater than the loss in the load. This last condition should give a negative deflection of the electrometer.

The voltage of the transformer was 400 volts at 60 cycles. This gives, with n equal to four, a needle voltage of 50 volts and an electrometer constant of 72. The results are given in Table IX, which is divided into two parts. Part I gives the calculated watts and Part 2 gives the electrometer readings.

TABLE IX

Part I

R_0 Ohms	R_1 Ohms	I Milli-Amp.	$I^2 R_0$ Load Watts	$I^2 R_1$ Watts	$I^2 R_0 - I^2 R_1$ Watts Calculated
15000	10000	8.	0.96	0.64	+0.32
10000	10000	10.	1.0	1.0	0
10000	15000	8.	0.64	0.96	−0.32

Part II

R_0 Ohms	R_1 Ohms	Electrometer: Position of Commutator	Readings cm.	Deflection cm.	$\frac{n\,K\,\theta}{R_1}$ Watts
15000	10000	‖ =	+6.2 −5.3	+11.5	+0.33
10000	10000	‖ =	−0.7 −0.7	0	0
10000	15000	‖ =	−7.15 +9.1	−16.25	−0.312

A study of Table IX shows that the electrometer reading reversed and became negative when the loss in the shunt resistance was greater than the load loss as predicted. A comparison of Parts I and II shows clearly that the experimental results check the theory.

The experimental results of Tables VII, VIII, and IX definitely prove that the sign of the correction term of equation (42) depends upon the value of n and not upon the value of the power factor.

In order to prove that equation (42) holds at low power factor, a set of results is given in Table X that were taken on another electrometer which was convenient. The load consisted of a high-voltage condenser of about 0.02 microfarads capacity. The voltage applied was 7500 volts at 60 cycles. The value of n was six and the electrometer constant was 83.5. The current was measured by another electrometer which was used as a voltmeter.

For n equal to six, the correction term becomes $-2\,I^2 R_1$.

TABLE X

R_1 Ohms	I Milli-ampere	Load Watts	$2\,I^2 R_1$ Watts	Electrometer θ cm.	$\frac{n\,K\,\theta}{R_1}$ Watts	Load $-2\,I^2 R_1$ Watts Calculated
2000	4.7	0.264	0.085	+0.7	+0.175	+0.179
4000	4.7	0.264	0.177	+0.7	+0.0875	+0.087
5000	4.7	0.264	0.221	+0.4	+0.040	+0.043
8000	4.7	0.264	0.354	−1.45	−0.09	−0.09
10000	4.7	0.264	0.442	−3.55	−0.178	−0.178

The watts measured by the electrometer are plotted against R_1 in Fig. 11. The readings lie on a straight line and the intercept of this line on the Y axis gives a loss in the condenser under test of 0.264 watts. A comparison of the last two columns of Table X shows an excellent agreement between the watts as measured by the electrometer and the calculated watts. The power factor of the load used in this test was 0.75 per cent. The results in Table X also show that the electrometer deflection changed to negative when the loss $2\,I_2\,R_1$ became greater than the load.

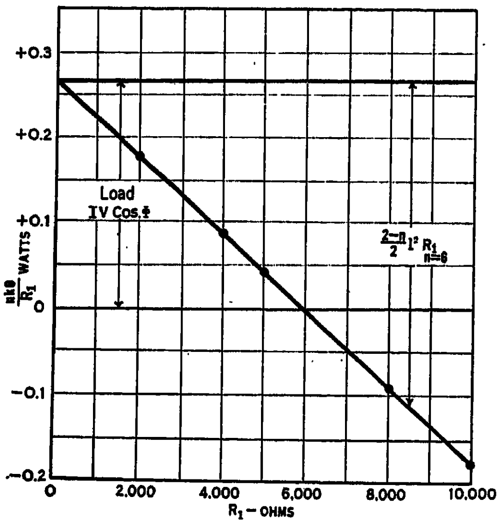

Fig. 11—Curve Showing the Relation Between Watts Measured by the Electrometer and the Shunt Resistance R_1 with $n = 6$. Plotted from the Results of Table X

The results of this test prove that equation (**42**) holds at low power factor.

The experimental results prove conclusively that equations (**37**) and (**42**) are derived correctly and that they are applicable at all values of power factor.

III. Mathematical

Derivation of the torque equation:

We assume that

$$A_0 = a_0'' + a_0\,\theta + a_0'\,\theta^2$$
$$A_1 = a_1'' + a_1\,\theta + a_1'\,\theta^2$$
$$A_2 = a_2'' + a_2\,\theta + a_2'\,\theta^2$$
$$B_1 = b_1'' + b_1\,\theta + b_1'\,\theta^2$$
$$B_2 = b_2'' + b_2\,\theta + b_2'\,\theta^2$$
$$C_0 = c_0'' + c_0\,\theta + c_0'\,\theta^2$$
$$C_1 = c_1'' + c_1\,\theta + c_1'\,\theta^2$$
$$C_2 = c_2'' + c_2\,\theta + c_2''\,\theta^2$$

If we study the electrometer, we see that B_0, the coefficient of electrostatic induction between quadrant pairs 1 and 2 will not change with the deflection because the quadrants are fixed in position and the motion of the needle does not intercept lines of force passing between them. The terms covered by H are also independent of the deflection if the instrument is properly set up as explained in the body of the paper.

In order to determine the torque, differentiate equation (**14**) with respect to the deflection, and we get

$$\frac{d\,w'}{d\theta} = a_0\,V_0^2 + a_1\,V_1^2 + a_2\,V_2^2 + b_1\,V_0\,V_1 + b_2\,V_0\,V_2 + c_0\,V_0 + c_1\,V_1 + c_2\,V_2 + \theta\,(2\,a_0'\,V_0^2 + 2\,a_1'\,V_1^2 + 2\,a_2'\,V_2^2 + 2\,b_1'\,V_0\,V_1 + 2\,b_2'\,V_0\,V_2 + 2\,c_0'\,V_0 + 2\,c_1'\,V_1 + 2\,c_2'\,V_2) \qquad (\mathbf{15})$$

Substituting the value of $\frac{d\,w'}{d\,\theta} = C\,\theta$; we find

$$\theta\,(c - 2\,a_0'\,V_0^2 - 2\,a_1'\,V_1^2 - 2\,a_2'\,V_2^2 - 2\,b_1'\,V_0\,V_1 - 2\,b_2'V_0\,V_2 - 2\,c_0'\,V_0 - 2\,c_1'\,V_1 - 2\,c_2'\,V_2) = a_0\,V_0^2 + a_1\,V_1^2 + a_2\,V_2^2 + b_1\,V_0\,V_1 + b_2\,V_0\,V_2 + c_0\,V_0 + c_1\,V_1 + c_2\,V_2 \qquad (\mathbf{16})$$

A study of the symmetry shows that $a_1' = -\,a_2'$ and that $b_1' = -\,b_2'$. We also see that the c_0', c_1' and c_2' terms, which include the small contact potentials, depend upon only the first power of the applied voltages and therefore they may be neglected.

Rewriting equation (**16**) we get

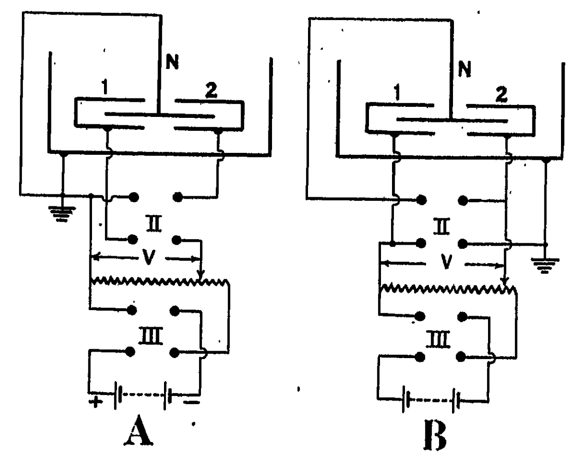

Fig. 12—Idiostatic Connections

$$\theta\,[c - \{2\,a_0'\,V_0^2 + 2\,a_1'\,(V_1^2 - V_2^2) + 2\,b_1'\,V_0\,(V_1 - V_2)\}] = a_0\,V_0^2 + a_1\,V_1^2 + a_2\,V_2^2 + b_1\,V_0\,V_1 + b_2\,V_0\,V_2 + c_0\,V_0 + c_1\,V_1 + c_2\,V_2. \qquad (\mathbf{17})$$

Experimental results show that the torque equation (**17**) may be written in a more useful form; namely

$$\theta\,[1 + R\,(V_0 - V_1)\,(V_0 - V_2) + S\,(V_1^2 - V_2^2)] = a_0\,V_0 + a_1\,V_1^2 + a_2\,V_2 + b_1\,V_0\,V_1 + b_2\,V_0\,V_2 + c_0\,V_0 + c_1\,V_1 + c_2\,V_2 \qquad (\mathbf{18})$$

Proof that $a_2 - a_1 = b_1$:

In order to prove this relation the connections shown in Fig. 12 are used. These connections are known as the idiostatic connections and are also used where the electrometer is used as a voltmeter.

There are two possible arrangements of the connections which are shown in Figs. 12 A and B. In connection A the needle and either quadrant, 1 or 2, are grounded and in connection B the needle is not grounded but quadrants 1 or 2 are grounded depending upon the position of the commutators.

For connection A, V_0, the needle potential is zero and equation (**19**) reduces to

$$\theta \{1 + R\, V_1\, V_2 + S\,(V_1 - V_2)^2\} = a_1\, V_1^2 + a_2\, V_2^2 + c_1\, V_1 + c_2\, V_2 \qquad (29)$$

because all of the terms containing V_0 will be zero.

We get a deflection for each of the four positions of the commutators and the signs of the terms of equation (**29**) are given below

Position of Commutator III	II	Values of the Terms $a_1 V_1^2$	$+ a_2 V_2^2$	$+ c_1 V_1$	$+ c_2 V_2$	Deflection
||	||	0	+	0	−	= { } α
=	||	0	+	0	+	= { } β
=	=	+	0	+	0	= { } γ
||	=	+	0	−	0	= { } δ

Taking the algebraic sum of these deflections as follows, we get

$$\{1 + R\, V_1\, V_2 + S\,(V_1 - V_2)^2\} = M$$

$$\{M\}\,(\alpha + \beta - \gamma - \delta) = 2\,(a_2 - a_1)\, V^2 \qquad (30)$$

In connection B, Fig. 12, equation (**19**) holds and contains all of its terms. Here we see that, depending upon the positions of the commutators,

$$V_0 = V_1 = V \text{ or } V_0 = V_2 = V$$

$$V_1 = V \text{ or zero and } V_2 = V \text{ or zero}$$

The deflections for each of the four commutator positions and the signs of the terms are as follows:

Position of Commutator III	II	Values of the Terms $a_1 V_1^2$	$+ a_2 V_2^2$	$+ b_1 V_0 V_1$	$+ b_2 V_0 V_2$	$+ c_0 V_0$	$+ c_1 V_1$	$+ c_2 V_2$	Deflection
||	||	+	0	+	0	+	+	0	= [M] α
=	||	+	0	+	0	−	−	0	= [M] β
=	=	0	+	0	+	+	0	+	= [M] γ
||	=	0	+	0	+	−	0	−	= [M] δ

Taking the algebraic sum of these deflections as follows, we obtain

$$[M]\,(\alpha + \beta - \gamma - \delta) = 2\,(a_1 - a_2)\, V^2 + 2\,(b_1 - b_2)\, V^2 \qquad (31)$$

If the same voltage is used in connections A and B of Fig. 12, then both will give equal deflections in the same directions. That the deflections will be in the same directions may be seen from a study of the connections. Consider connection A with both commutators vertical; then the needle and quadrant pair No. 1 will be grounded and therefore at same potential and quadrant pair No. 2 will be negative and the needle will swing into quadrant pair No. 2. In connection B, with both commutators vertical, the needle and quadrant pair No. 1 are again connected together, and therefore at the same potential which in this case is positive. Quadrant pair No. 2 will be grounded, and the needle will again swing into quadrant pair No. 2. Since the same voltage is used in both A and B connections, the deflections will be equal.

Experiments show that the two connections give equal deflections and also that they are in the same direction. Therefore it follows that the right hand sides of equations (**30**) and (**31**) must be equal, and we have

$$2\,(a_2 - a_1)\, V^2 = 2\,(a_1 - a_2)\, V^2 + 2\,(b_1 - b_2)\, V^2 \qquad (32)$$

Solving, we find that

$$2\,(a_2 - a_1) = b_1 - b_2.$$

or

$$a_2 - a_1 = \tfrac{1}{2}\,(b_1 - b_2)$$

Owing to the symmetrical construction of the electrometer

$$b_1 = -\, b_2 \text{ and } a_1 = -\, a_2$$

Therefore

$$a_2 = \tfrac{1}{2}\, b_1 \qquad (33)$$
$$a_1 = -\, \tfrac{1}{2}\, b_1$$

Conclusion

In order to use the quadrant electrometer for the measurement of power, it is necessary only to determine two constants, namely b_1 and R. This may be done with continuous current. In some instruments, R has a negligible or zero value.

The quadrant electrometer may be used in measuring a-c. power with either full or a fraction of the full voltage applied to its needle. In the case where full voltage is used on the needle, equation (**37**) holds.

$$\frac{[1 + R\, V^2]}{2\, b_1} \times \frac{\theta}{R_1} = I\, V \cos \Phi + \frac{I^2\, R_1}{2} \qquad (37)$$

In cases where a fractional part of the full voltage is applied to the needle, equation (**42**) holds

$$\frac{\left[1 + R\left(\frac{V}{n}\right)^2\right]}{2\, b_1} \times \frac{n\, \theta}{R_1} = I\, V \cos \Phi + \frac{2 - n}{2}\, I^2\, R_1 \qquad (42)$$

These equations hold for all values of the power factor both lagging and leading.

The general power equation of the quadrant electrometer for a-c. circuits is given by equation (**44**).

$$\frac{[1 + R\, \dot{V}_0^2]}{2\, b_1}\, \theta = \dot{V}_0\, \dot{V}_1 - \frac{\dot{V}_1^2}{2} \qquad (44)$$

Here $\dot{V}_0$ is the voltage applied to the needle and $\dot{V}_1$ is the voltage applied to the quadrant pairs. In using this equation both are to be expressed in their vector form. By means of equation (**44**) it is a simple matter to determine what the instrument will read under any conditions in an a-c. circuit.

The experimental data presented amply proves the theory given in this paper.

The author wishes to thank Mr. W. W. Hill and

Mr. G. A. Irland for their assistance in the experimental work.

Discussion

J. B. Whitehead: Those of us who have had occasion to measure small values of dielectric loss with the quadrant electrometer instrument, know of the apparent facility and convenience of that instrument. I say "apparent" because we also know that we soon run into many entirely unexpected and apparently inexplicable phenomena in connection with the instrument. In the literature we find a great deal on the instrument and think we will be able to clear up our difficulties. As we go on, however, we find that the points of view of the several people who have written on the quadrant electrometer often differ. The several authors introduce different constants and we are left with a large number of constants, whose relative importance we are unable to determine easily.

I think that Dr. Kouwenhoven has rendered a very important service, in that he has considered the quadrant electrometer from its simplest stage as represented by Maxwell's equations, in which we find every coefficient of induction which is required by a system involving three elements. Some of the constants will change with the deflection of the instrument. The service he has rendered is to show that used as a power instrument, many of these constants disappear, either through mutual neutralization or because they happen to be so small as to be negligible. He has thus brought the instrument to a point where it is shown to be reliable through the determination of only two constants, and these two constants can be determined by d-c. measurement.

D. M. Simons: Anyone who has had much practical experience with the quadrant electrometer has found that the so-called constant of the instrument is usually by no means what its name implies; we usually found that the constant would have different values at different voltages, and until certain adjustments were made, it would vary with the magnitude of deflection. It gave one rather a lack of confidence in the fundamentals of the theory of the instrument, because Maxwell's equation was based on the constancy of the proportion between the deflection and the total load. There have been some indications in print that the relationship did not hold good, such as Orlich's article in the *Zeitschrift fur Instrumentenkunde* about ten years ago and the article by Cantutti in *l'Elettricista* in 1923, and the matter has been in the minds of a great many people, without any definite solution. I think, therefore, that Dr. Kouwenhoven is all the more to be congratulated on having solved the question so thoroughly in a quantitative manner.

Personally, I find it rather difficult to mention the quadrant electrometer without discussing the zero method, and the subject is not entirely inappropriate, because one of the main advantages of the zero method is that no knowledge of the constant is required. We described a zero method last year before the Institute,[1] which I believe is very practical, the deflection being brought back to zero merely by the insertion of a resistance in the needle circuit, the value of power factor of the load being calculated in terms of the resistance required. Using any zero method with the electrometer, there are certain great advantages; a straight-line constant is not necessary, and thus there is much greater freedom in the design of the instrument. The setting is practically independent of voltage fluctuations, and thus the measurements may be made much more accurately and quickly than with a deflecting instrument where the needle will swing with every fluctuation of voltage. The reading with the zero method is proportional to power factor, while in the deflection method it is proportional to watts, and thus the zero method is more suitable for the measurement of ionization.

S. L. Gokhale: 1. To begin with, I suggest that the title of the paper be changed to "Electrostatic Wattmeter;" in the past, all the valuable literature on this subject has been indexed under the head "quadrant electrometer," and it is generally overlooked by those who are searching for information on methods for measurement of power.

2. Tables IV, V, and VI constitute a very convincing demonstration of the reliability of this type of wattmeter, for loads of low power factor, but all the cases treated by the author are loads of no distortion. The particular case I am interested in, is the case of core loss in iron for flux density near saturation, involving not only a very low power factor but also a serious distortion of the current wave, with a possibility of distortion of the voltage wave also. It seems to me that the instrument would prove very satisfactory for this purpose also, but I would prefer to have the fact demonstrated, if possible.

3. The question of instrument error, that is, error characteristic of the instrument, irrespective of the nature of the load, is also quite important. On this point, I suggest, by way of experiment, the measurement of core loss in an air-core transformer (*i. e.*, mutual inductor); as there is no real loss to be measured, any apparent loss would obviously be the instrument error. Another experiment directed towards the same end would be the measurement of core loss in iron-core transformers at low flux density by the electrostatic wattmeter, and also by the electro-dynamometer wattmeter.
